  - 50 to 75 mg of doxorubicin is loaded into each vial of microspheres with a maximum of two vials being used per procedure. 100 to 300 micron LC beads™ and 50 to 100 micron QuadraSpheres™ are commonly used. The particles are then injected (FIG 10) until there is significant slowing of flow within the target vessels.
  - Irinotecan has been used, instead of doxorubicin, in treating patients with colorectal cancer that has metastasized to the liver.
- Transarterial embolization (TAE), also known as bland embolization, has also been performed. TAE uses Ethiodol embolization, particulate embolization, or a combination of both without the addition of any chemotherapeutic agent.

Removal of the Catheters and Sheath

- The puncture site is closed using manual pressure or an arterial closure device.

Follow-up

- Labs in about 4 weeks to evaluate liver function
- Repeat imaging if needed.
- Repeat embolization, if needed, in about 4 to 6 weeks.

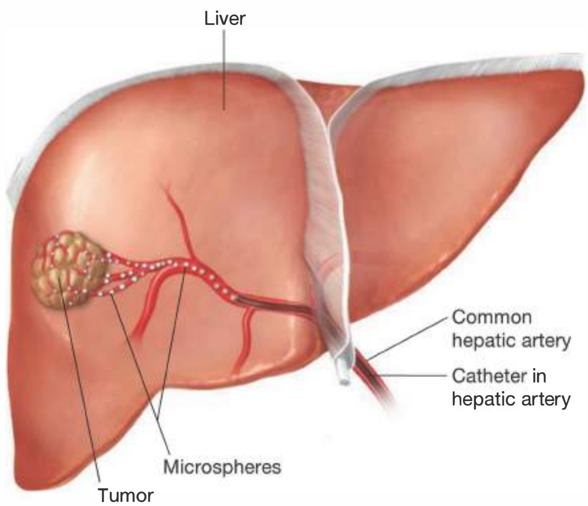

FIG 10 ● Drug-eluting microspheres block the arterial supply to the tumor and then the chemotherapy drug is slowly released directly to the tumor.

RADIOEMBOLIZATION

Sir-Spheres™ or TheraSphere™

- ^{90}Y binds to particles that are less than 35 microns in size. Sir-Spheres**™** are resin-based particles, whereas the TheraSphere™ particles are nonbiodegradable glass microspheres.

Superior Mesenteric, Celiac, and Common Hepatic Arteriograms

- The initial steps are similar to TACE. The arteriograms are evaluated for vessel patency and anatomic variants.

Arteriograms of the Gastroduodenal, Right, and Left Hepatic Arteries

- Evaluation of anatomy is performed with special attention paid to branches that lead to the GI tract such as the right gastric and supraduodenal arteries (**FIG 11**).
- Branches connecting to the GI tract, such as the gastroduodenal artery (GDA), are embolized (**FIG 12**). These branches must be embolized as ^{90}Y particles in the GI tract can cause severe, slow-healing ulcers.

Lobar Injection of Technetium-99m (Tc 99m) Macroaggregated Albumin

- The Tc 99m macroaggregated albumin (MAA) particles are used to simulate the ^{90}Y particles. Nuclear imaging is then performed to evaluate for activity in the GI tract and the amount of shunting to the lungs (**FIG 13**).
- If there is activity in the GI tract following MAA injection, with no obvious feeding vessel that can be embolized, ^{90}Y therapy should not be administered.

Return for Injection of Yttrium 90 Particles

- This is performed subsequent to the initial assessment of anatomy, appropriate embolization of vessels feeding the GI tract, and MAA evaluation. The catheter is placed in the same position as during the Tc-99m MAA injection. The catheter position is similar to **FIG 8** when performing right lobar embolization.
- The ^{90}Y particles are injected with extreme care to prevent spillage of radioactive particles (**FIG 14**).
- If there is 10% to 15% hepatopulmonary shunting on the MAA study, then the Sir-Spheres™ dose is decreased by 20%. If the shunting is 15% to 20%, then the dose is decreased by 40%.
- If hepatopulmonary shunting is greater than 20%, then Sir-Spheres™ are not administered.
- When using TheraSphere™, the limitation of what can be administered to the lungs is based on the cumulative dose, irrespective of the lung shunt.

Removal of the Catheters and Sheath

- The puncture site is closed using manual pressure or an arterial closure device.

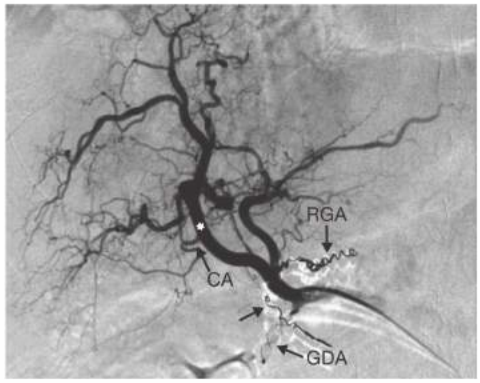

FIG 12 ● An Amplatzer plug has been used to embolize the GDA with microcoils within the right gastric artery (RGA) and supraduodenal arteries (SDA). The microcatheter would then be placed distal to the cystic artery origin for right lobar Tc-99m MAA and ^{90}Y injections *(asterisk)*.

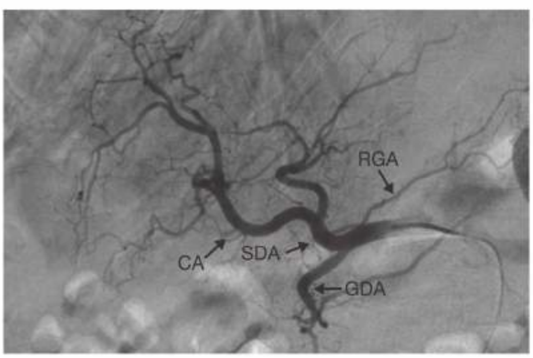

FIG 11 ● Common hepatic arteriogram demonstrates the anatomy prior to Tc-99m MAA particle injection. Branches leading to the GI tract will need to be embolized to prevent ^{90}Y particle reflux to these branches with subsequent injury. GDA, gastroduodenal artery; SDA, supraduodenal artery; RGA, right gastric artery; CA, cystic artery.

FIG 13 ● Nuclear imaging following Tc-99m MAA administration demonstrates no activity within the GI tract and 13.4% shunting to the lungs. The dose of Sir-Spheres™ to be given would be reduced by 20% due to the degree of shunting.

Follow-up

- Labs in about 4 weeks to evaluate liver function
- Repeat imaging if necessary.
- Workup for the second lobar injection is begun about 4 to 6 weeks after the initial side if labs and imaging are adequate. The patient will need an arteriogram and repeat Tc-99m MAA injection as well, prior to radioembolization of the second lobe, if needed.

FIG 14 ● The Sir-Spheres™ particles are connected to the catheter via a special delivery system to prevent spillage of radioactive material.

PEARLS AND PITFALLS

Patient history and physical findings.	■ Patients without an intact sphincter of Oddi are at much higher risk of abscess formation and need extended antibiotic prophylaxis. ■ Do not overtreat in patients with borderline hepatic function. The procedure can always be repeated at a later time.
Imaging and other diagnostic studies	■ C-arm CT scan may be helpful to verify that the catheter is in the correct arterial branch as it may be difficult to tell with lesions that are not well visualized. (**FIG 15**). ■ Hepatic tumors may be supplied by nonhepatic vessels, especially subcapsular lesions. Parasitized flow from the inferior phrenic, internal mammary, and intercostals arteries may need to be embolized (**FIG 16**). ■ It may be difficult to tell if there is arterial tumor enhancement on a contrasted CT scan with Ethiodol in place. A noncontrast scan (**FIG 17**) is needed for comparison or an MRI can be obtained.
Surgical technique (TACE)	■ Arterial-portal shunts can be embolized with large particles or coils prior to TACE. ■ There are more postembolization syndrome symptoms with oily chemoembolization than with drug-eluting microspheres. ■ Embolization of dome lesions may cause right shoulder pain or hiccups. Steroids (Medrol Dosepak) may be helpful.
Surgical technique (^{90}Y)	■ Even though the GDA and right gastric arteries are embolized, do not inject ^{90}Y via the common or proper hepatic arteries.

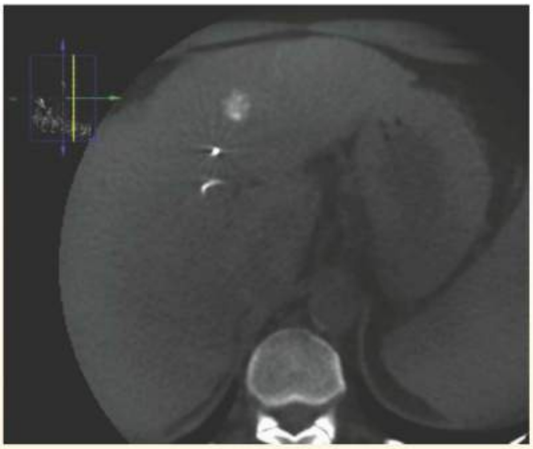

FIG 15 ● C-arm CT shows tumoral enhancement demonstrating that the microcatheter is within the correct arterial branch prior to chemoembolization. The tumoral enhancement was not appreciated by conventional arteriography.

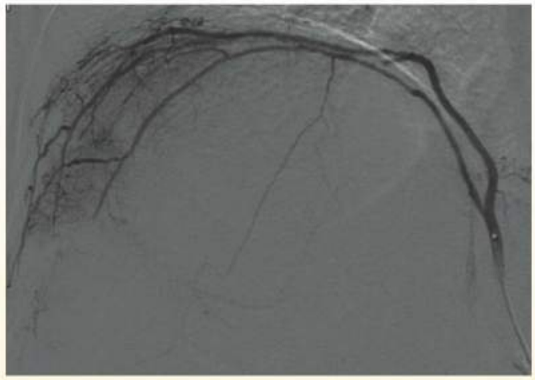

FIG 16 ● Right inferior phrenic arteriogram demonstrates tumor enhancement in the dome of the liver supplied by the distal phrenic branches. These branches were then embolized.

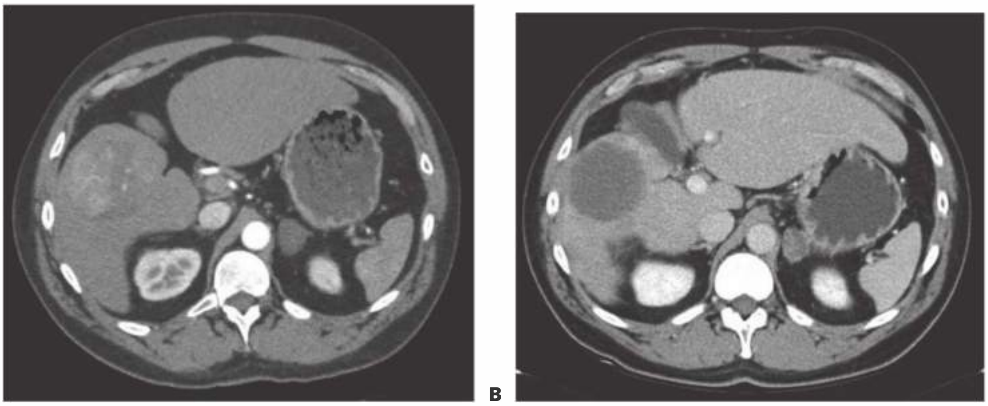
FIG 17 ● CT scan demonstrates residual Ethiodol within a tumor on a noncontrast examination. A noncontrast exam must be obtained prior to the contrast-enhanced exam to demonstrate the difference between contrast enhancement and residual Ethiodol.

POSTOPERATIVE CARE

- Pain medications
- Antiemetics
- Proton pump inhibitor (radioembolization)
- Steroids (Medrol Dosepak)
- Antibiotics (as indicated)
- Hospitalization for TACE is typically overnight for microsphere embolization and up to several days for oily chemoembolization. Patients that receive radioembolization can typically be discharged the same day.
- Repeat labs and imaging are typically obtained. Protocols are institution-specific and not typically driven by data.
- Further embolization procedures as needed. Imaging after TACE is about 4 to 6 weeks after the completion of embolization. If there is tumor identified on repeat imaging, then embolization is again performed. If no further tumor is identified, then imaging is performed every 3 months (**FIG 18**).
- Imaging after radioembolization is performed 2 to 3 months after the last lobe is embolized as it can take longer to see the effects.

OUTCOMES

- In 2002, two separate studies demonstrated that TACE for HCC had a statistically significant survival advantage over the best supportive care that was available.[4,5] Since then, other studies have confirmed these findings in patients with well-compensated cirrhosis.
- In patients with limited hepatic reserve or decreased performance status, there have been better outcomes with drug-eluting microspheres as compared to oily chemoembolization.[6] In addition, the treatment was better tolerated by the patients.
- Treatment using drug-eluting microspheres loaded with doxorubicin demonstrated a statistically longer time to progression and fewer recurrences when compared to bland embolization.[7]



A B

FIG 18 ● **A.** Initial CT scan demonstrates a large, contrast-enhancing HCC in the right lobe of the liver prior to treatment. **B.** A follow-up CT 5 weeks after treatment using doxorubicin-loaded LC beads shows that the tumor is slightly smaller and there is no further contrast enhancement. Repeat imaging would then be performed about 3 months later.

- Patients with HCC and Child-Pugh A disease survive significantly longer following ^{90}Y radioembolization than do those patients with Child-Pugh B disease, 17.7 versus 7.7 months, respectively.[8]
- In a study of patients with unresectable, chemoresistant liver metastases treated with ^{90}Y radioembolization, the median survival for patients was 15.2 months for those with colorectal tumors, 25.9 months for those with neuroendocrine tumors, and 6.9 months for those with noncolorectal, non-neuroendocrine tumors.[9]

COMPLICATIONS

- Groin hematoma/pseudoaneurysm
- Liver insufficiency
- Severe postembolization syndrome
- Routine postembolization syndrome is not an unexpected event. Postembolization syndrome includes pain, fever, and nausea/vomiting. Severe postembolization syndrome would necessitate an extended hospital stay or readmission.
- Hepatic abscess
- Cholecystitis
- Nontarget embolization with GI tract ulceration

Chapter 21 Segmental Hepatectomy

Neil H. Bhayani   Eric T. Kimchi   Niraj J. Gusani

DEFINITION

- A segmental hepatectomy consists of surgical resection of one or more functional anatomic segments of the liver, as originally classified by Couinaud (**FIG 1**). Nomenclature for liver resections was standardized in the Brisbane conference.[1]
- The most common anatomic segmental resections are (1) right posterior sectionectomy (segments 6 and 7), (2) left lateral sectionectomy (segments 2 and 3), and (3) caudate lobe resection (segment 1).
- Smaller resections of a single segment or nonanatomic subsegmental resections will not be covered in this chapter. Usually, these involve simple excisions without formal inflow or outflow occlusion or delineation of the segmental vascular or biliary anatomy.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients should be good medical candidates for major surgery.
- Preoperative planning requires a thorough history of previous abdominal surgeries.
- If performing a metastasectomy, there should be a thorough evaluation of extrahepatic disease. The presence of extrahepatic disease should be considered in conjunction with the tumor type and extent of resection to determine if the patient will benefit from surgical intervention involving the liver or extrahepatic sites.
- Episodes of jaundice, hepatitis exposure, alcohol, illicit drug abuse, and treatment with chemotherapy should be elicited to ascertain the health of the liver parenchyma.
- A complete viral hepatitis panel should be obtained as part of screening surgical candidates.
- Liver function can be assessed by the Child-Pugh classification and/or the Model for End-Stage Liver Disease (MELD). Neither metric has been definitively shown to be superior in determining a patient's ability to tolerate surgery.[2]

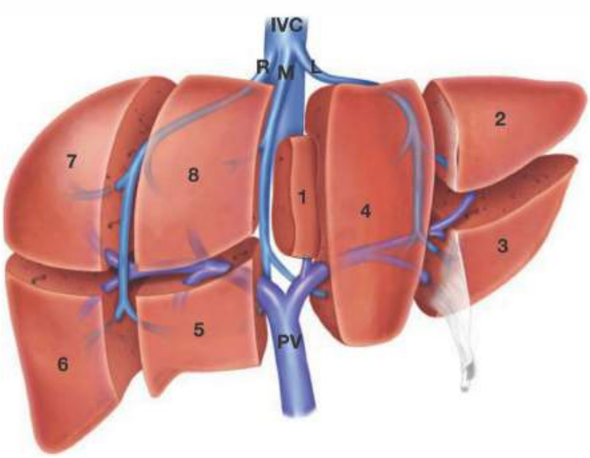

FIG 1 ● Couinaud segments with vascular anatomy.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Multiphase, contrast-enhanced cross-sectional imaging with either computed tomography (CT) or magnetic resonance imaging (MRI) is necessary for planning surgery. Both imaging modalities are of similar sensitivity and may often be used interchangeably or in combination to better define certain pathologic processes.
- In a normal, healthy liver, a future (postresection) hepatic remnant composed of at least two contiguous segments with adequate inflow and outflow and measuring 25% of the complete liver volume is sufficient functional liver to allow for full hepatic recovery. However, in a damaged or cirrhotic liver, a remnant of greater than 40% is often recommended, although the percentage of viable remnant liver may need to be greater, depending on the amount of damage/dysfunction of the liver. Segmental hepatic resections rarely induce hepatic insufficiency unless the remnant liver is severely diseased.
- Concern for significant hepatic dysfunction should be investigated by objective testing of the liver. Transjugular measurement of the portal pressure gradient (normal <5 to 8 mmHg), routine serum liver function tests, and biopsy (to evaluate steatosis or cirrhosis) are the most common modalities to evaluate the extent of hepatic disease.
- In Asia, indocyanine green clearance testing is often performed to quantify liver health. This is rarely performed in the United States.
- In patients with evidence of decompensated cirrhosis (Child's B and C) and pathologic conditions that have demonstrated benefit from transplantation (hepatocellular cancer, neuroendocrine malignancies, and some hilar cholangiocarcinomas), surgeons should consider a referral for transplantation.

SURGICAL MANAGEMENT

- The indications for hepatectomy include diagnostic uncertainty, symptomatic benign lesions, and malignancy (Table 1).
- The strongest evidence for hepatic metastasectomy shows that R0 resection prolongs survival and is potentially curative for colorectal carcinomas and neuroendocrine tumors.

Table 1: Indications for Hepatectomy

Diagnosis	Premalignant disease
Focal nodular hyperplasia vs. hepatocellular adenoma	Hepatocellular adenoma
	Biliary cystadenoma
Symptoms	Malignancy
Hemangioma	Metastasis
Simple cysts	Hepatocellular carcinoma
Benign disease	Cholangiocarcinoma
Refractory abscesses/cholangitis	
Severe hepatolithiasis	

Preoperative Planning

- Ideally, preoperative cross-sectional imaging should be discussed with skilled radiologists before surgery and be available throughout the procedure.
- Vascular, particularly hilar, arterial anomalies are common. Inadvertent injury at surgery may be prevented by thorough multiplanar analysis of preoperative imaging.
- 3-D reconstruction is not mandatory, but understanding of all the lesions and their relation to hepatic and portal venous structures is imperative. This should be combined with intraoperative ultrasound.
- For postoperative pain control, we employ epidural catheters, administered by a dedicated pain service, placed preoperatively.
- Low central venous pressure (CVP) anesthesia is a cornerstone in reducing blood loss in hepatic surgeries. To maintain low CVP (5 to 8 mmHg), good communication with the preoperative nursing and anesthesia teams is critical.
- Patients receive appropriate prophylactic antibiotics due to transection of the biliary tree (clean-contaminated surgery). We consider cases with an indwelling biliary device as contaminated procedures secondary to colonization of the biliary tract.
- Most patients undergoing hepatectomy are at high risk for venous thromboembolic (VTE) disease due to age, presence of malignancy, and complex and long major abdominal surgery. Unfractionated heparin is given subcutaneously prior to induction and redosed every 8 hours as needed. Patients undergoing hepatectomy for malignant diagnoses are usually sent home on a 30-day course of low-molecular-weight heparin for VTE prophylaxis.

Positioning

- Supine with arms abducted. Laparoscopic resections may be facilitated by use of the modified lithotomy position or of a split-leg table. For extreme lateral right liver lesions, full lateral positioning may be used.

TECHNIQUES

RIGHT POSTERIOR SECTIONECTOMY (SEGMENTS 6 AND 7)

Exposure

- A subcostal, chevron, or midline incision can be used. It is our preference to operate through a midline incision.
- A fixed traction system is employed. Retraction of the costal margin is critical.

Mobilization

- The round ligament is ligated but kept long to allow its use for countertraction and exposure. The falciform ligament is divided close to the liver, thus minimizing interference from this structure during intraoperative ultrasonography (IOUS).
- Dissection of the apex of the right triangular ligament proceeds from medial to lateral. The peritoneum and areolar tissue surrounding the anterior and lateral aspects of the right hepatic vein (RHV) is cleared. To continue laterally and inferiorly, the liver can be retracted medially and compressed posteriorly.
- If caval compression induces hypotension, temporary release of retraction may be all that is required. Alternatively, raising the inferolateral edge of the right liver will expose the final attachments of the right triangular ligament.
- Complete mobilization of the right liver requires extensive exposure of the lateral and anterior surface of the inferior vena cava (IVC). Medial retraction and cephalad rotation of the inferolateral edge raises the liver off the IVC.
- A variable number of short hepatic vein branches drain the right hepatic lobe directly into the IVC. These should be carefully ligated using 4-0 ties and clips. We avoid use of clips on the hepatic side of these small vessels as they may interfere with parenchymal transection and reserve their use for the branches on the caval side.
- At the proximal and lateral aspect of the IVC, there is a ligamentous band/parenchymal bridge, which extends from segment 7 to the retroperitoneal tissue behind the IVC. Release of this band is critical in the exposure and safe dissection of the RHV. This band can be vascular and transection should be performed by ligation, stapling, or use of bipolar transection of this tissue.

Hilar Dissection and Vascular Control

- Anterior and cranial fixation of the falciform ligament exposes the hilum.
- Antegrade cholecystectomy is performed to expose the right lateral hilar plate.
- IOUS should be used routinely to examine the hepatic parenchyma for known and occult lesions. IOUS confirms vascular anatomy, identifies major vascular branches, and maps the proximity of hepatic and portal vein branches near the lesions.
- After creating an aperture through the gastrohepatic ligament, an umbilical tape is placed around the porta hepatis. Creation of a loose Rummel tourniquet permits a rapid Pringle maneuver in the event of bleeding.
- Dissection begins at the right lateral edge of the hepatic plate. Dissection on the contralateral side should be avoided to prevent inadvertent injury and to minimize scarring in case subsequent hepatectomy is required.
- In the right hilum, the right hepatic artery (RHA) is superficial and is accordingly dissected first. The RHA typically bifurcates as it enters the right liver. Both the anterior and posterior branches should be identified. A vascular loop facilitates gentle traction, and a bulldog clamp is then placed on the right posterior artery (FIG 2).
- Perfusion in the right anterior and proper hepatic artery (in the porta hepatis) as well as the left hepatic artery (LHA) should now be confirmed. Manual palpation or Doppler exams are sufficient. IOUS in the hilum or of the parenchyma can be used for confirmation.

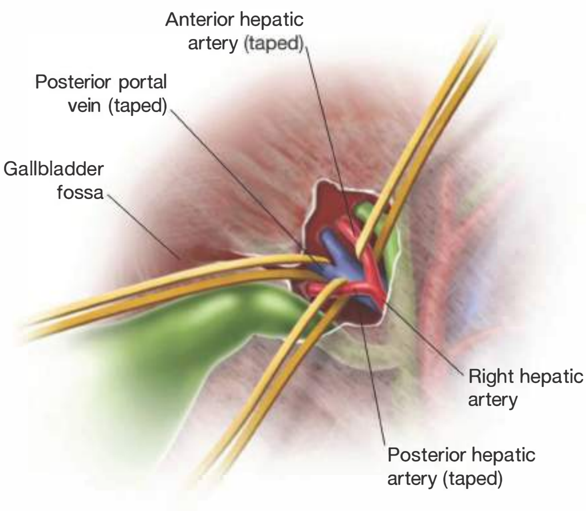

FIG 2 ● The right portal pedicle is exposed, and the anterior and posterior branches are visualized prior to ligation of the right posterior hepatic artery or portal vein.

- If no deficit is noted, then the clamp may be removed and the posterior branch of the RHA can be divided between 2-0 silk ligatures and 3-0 suture ligatures. Division should expose the right portal vein (RPV) posteriorly and cephalad to the RHA.
- The RPV dissection should identify anterior and posterior branches and also the RPV or left portal vein (LPV) bifurcation. Correct identification of the bifurcation of the RPV and LPV is imperative to avoid ligating or narrowing the main portal trunk or the takeoff of the LPV. During this exposure, posterior branches of the RPV to the caudate (segment 1) can easily be avulsed. These should be preemptively ligated or avoided as the dissection proceeds to avoid unnecessary bleeding. Further dissection along the circumference of the RPV should allow identification and isolation of the right anterior and right posterior branches. In some circumstances, a short segment hepatotomy of segment 6 may be used to access the posterior portal vein. Isolation of the posterior branch may be confirmed by IOUS. The posterior branch of the RPV is encircled with a vessel loop or a ¼-in Penrose drain to allow gentle traction.
- We routinely transect the posterior portal vein with a vascular stapler. An articulating stapler is useful in obtaining the optimal angle for transection. Extreme care is taken during passage of the jaws of the stapler to avoid disruption of nearby vascular branches. If difficulty is encountered, often, the narrow jaw can be inserted into the opening of the Penrose drain and gentle withdrawal of the Penrose guides the stapler in the appropriate plane.
- We do not routinely perform extrahepatic division of the right posterior hepatic duct. Rather, we prefer to ligate and divide it intraparenchymally during the parenchymal transection with the stapler. This technique allows us to safely ligate the duct distal to the bifurcation and avoids unnecessary hilar dissection, which can devascularize or injure the biliary system.
- The posterior section should begin to demarcate. Inflow occlusion is now complete.
- The RHV is not routinely isolated for posterior sectionectomy, but branches are ligated intrahepatically during parenchymal transection.

Parenchymal Transection

- To begin transection, we use cautery to disrupt Glisson's capsule and mark the line of transection. This process is continued circumferentially. IOUS may be helpful to identify the extent of the lesion and to mark an appropriate medial margin.
- This circumferential groove will serve as a guide for the completion of the hepatic transection with staplers. The importance of creating a fully circumferential groove (especially posteriorly) in order to provide tactile and visual guide for stapling cannot be overstated.
- The next 1 to 2 cm of liver parenchyma can be transected with an energy source. Bipolar, radiofrequency, or ultrasonic-generated heat energy can be used at the surgeons' preference. We find superior hemostasis with saline-radiofrequency devices, which seal vasculature and bile ducts alike.
- A Pringle maneuver may be applied at this point to occlude collateral flow through the liver remnant. This prevents unexpected bleeding during parenchymal transection.
- Stapling of the remaining hepatic parenchyma is our preferred means of completing the transection. Having two staplers permits the use of one while the other is being reloaded, allowing for rapid transection. The thin (metal) end of the stapler is tunneled bluntly into the hepatic parenchyma. Alternatively, a groove for insertion of this end can be created by gentle passage of a closed curved clamp. Closure of the stapler is analogous to crushing the hepatic parenchyma with a metal clamp during the classical crush-clamp hepatic transection.
- The stapler should be passed through the parenchyma without resistance. Resistance may indicate that the stapler is encountering the sidewall of a vessel. Forcing the stapler through these branches may cause significant bleeding.
- Smaller bites with the stapler results in slow, sequential parenchymal compression and avoids tearing of vessels. Pushing out excess tissue allows superior staple formation, minimizing the chance of bleeding or bile leak.
- Difficulty in closing or firing the stapler may be encountered when (1) too much tissue is between the jaws or (2) the right hepatic duct (RHD) is ligated and divided.
- With the left hand holding the right liver, the line of transection can be controlled. With the fingers in the posterior groove, the IVC is protected and the endpoint of the transection is known at all times. The entire transection continues with repeated firings of the stapler.
- For a complete or formal right posterior sectionectomy, the plane of transection should parallel the lateral aspect of the RHV (**FIG 3**).

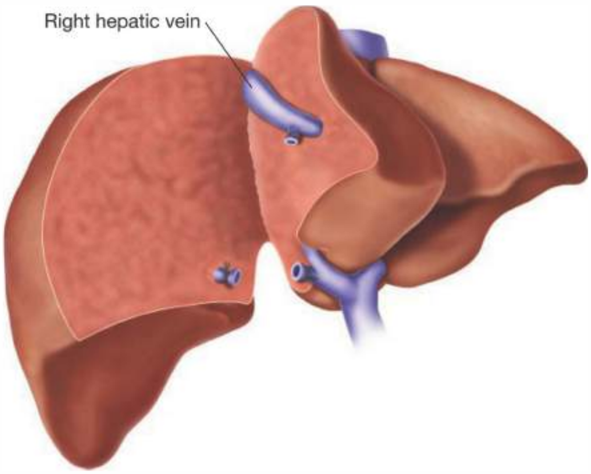

FIG 3 ● For a complete or formal right posterior sectionectomy, the plane of transection should parallel the lateral aspect of the RHV.

Completion

- After the parenchyma is divided, the specimen is removed from the field. We routinely work with the pathologists to orient the specimen, ink the appropriate margins, and assess gross margins intraoperatively.
- Hemostasis is achieved at the cut edge of the liver. We prefer the bipolar, saline-perfused radiofrequency ablation (RFA) device, which is effective in sealing small vessels and bile ducts.
- Care should be taken to avoid coagulating major biliary branches, as this may lead to subsequent stricture. Any area of bile leak, which might be near a larger bile duct, can also be ligated with absorbable monofilament suture.
- For areas of bleeding near the hilum, where energy devices may risk damage to crucial structures, we employ manual pressure and/or topical hemostatic agents and precise suturing when necessary.
- A large, closed suction drain may be placed adjacent to the transected parenchyma at the surgeon's preference.
- We reapproximate the falciform ligament to prevent lateral rotation of the remnant that may result in kinking and possible occlusion or thrombosis of the hepatic veins.

LEFT LATERAL SECTIONECTOMY (SEGMENTS 2 AND 3)

Mobilization

- Dissection of the apex of the left triangular ligament proceeds from lateral to medial. It may be helpful to place a laparotomy pad posterior to the left triangular ligament to help protect the gastric cardia and gastroesophageal junction.
- The peritoneum and areolar tissue surrounding the lateral aspect of the left hepatic vein (LHV) is cleared. Anterior retraction may aid in doing this safely.

Hilar Dissection and Vascular Control

- IOUS is used to locate and mark the capsule where the LHV will be encountered during transection. This visual reminder can be useful during parenchymal division.
- The gastrohepatic ligament is divided, including any aberrant LHA. An umbilical tape can now be placed around the porta hepatis in preparation for a rapid Pringle maneuver in the event of bleeding.
- Dissection begins at the left lateral edge of the round ligament, passing into the umbilical fissure. Dissection on the main porta hepatis or the contralateral side should be avoided to prevent inadvertent injury and to minimize scarring in case subsequent hepatectomy is required.
- The branches of the LHA and LPV supplying the left lateral section can be individually isolated and ligated on the left side of the round ligament. More proximal dissection on the main LHA and LPV is not necessary. Vascular control can be obtained by Pringle, if needed (**FIG 4**).

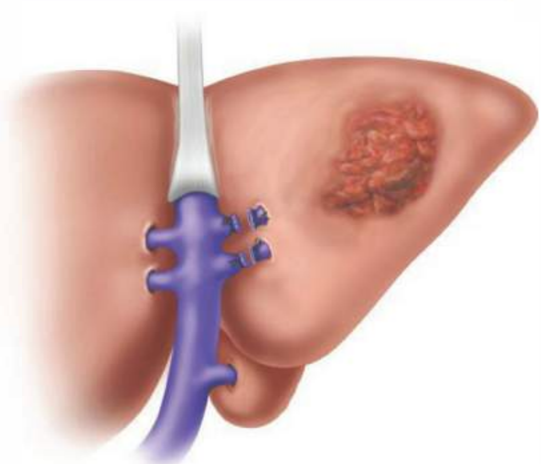

FIG 4 ● The LPV is shown in the umbilical fissure. The left-sided branches to segments 2 and 3 require ligation.

- The LHV is not isolated extrahepatically for a left lateral sectionectomy but is ligated intrahepatically during transection. Tumor location may require extrahepatic ligation of the LHV.

Parenchymal Transection and Completion

- As described above
- At the most cranial part of the parenchymal transection, the LHV will be encountered. This is best ligated with a vascular stapler; it is usually larger than recommended for energy-sealing device (**FIG 5**).

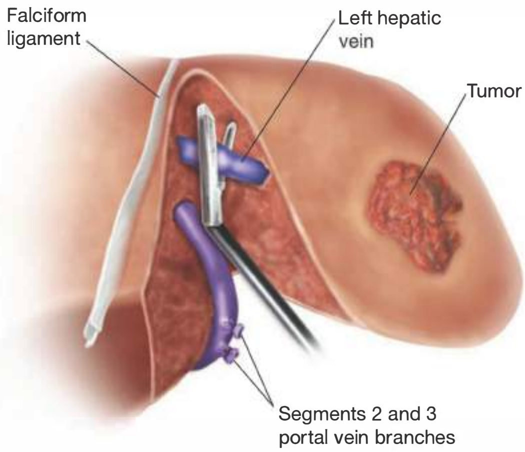

FIG 5 ● The LHV is ligated intraparenchymally with a stapler.

CAUDATE LOBE RESECTION (SEGMENT 1)

Mobilization

- Dissection of the apex of the left triangular ligament proceeds from medial to lateral. The left triangular ligament should be divided as described earlier.
- For larger tumors or tumors that are close or involve the caudate isthmus, complete mobilization of the right liver is also necessary. This requires ligation of the short hepatic branches between the posterior liver and the IVC.
- The peritoneum and areolar tissue surrounding the lateral aspect of the LHV is cleared. Anterior retraction may aid in doing this safely.
- The gastrohepatic ligament is divided. If an aberrant LHA is present, there should be an attempt to preserve it. However, division of the LHA may be necessary for adequate exposure. After this mobilization is complete, the left liver can be rotated anteromedially to visualize the caudate lobe (**FIG 6**).
- IOUS examines the liver for known and occult lesions.
- The arterial and portal venous inflow arises as smaller posterior branches off the main or left hilar structures.
- The caudate branches to the hilar vessels and bile duct are identified on the anterior surface of the caudate. These can be ligated using energy devices, ligatures, or clips.
- Dissection begins by dividing the parenchyma, sometimes called the "caudate isthmus." This bridge of tissue crosses anterior to the IVC and fuses with segment 6 at the left lateral edge of the ligamentum teres passing into the umbilical fissure. Sequential sealing of this bridge can be performed with monopolar, radiofrequency, bipolar, or staplers. Alternatively, a right-angled clamp can be used to isolate small packets of parenchyma, which are then ligated between 3-0 ties.
- Caudate outflow is via small veins directly into the IVC and the RPV. These should be ligated individually, as described above.

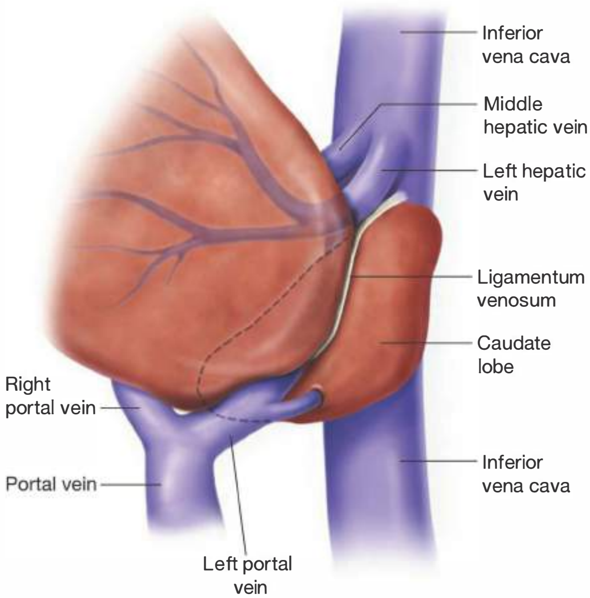

FIG 6 ● With rotation of the left liver, the caudate lobe is seen in relation to the LHV, ligamentum venosum, the IVC, and a major branch from the LPV.

- The posterior surface of confluence of the hepatic veins, particularly the middle and LHVs, overlies the cephalad most aspect of the caudate lobe (**FIG 7**). Safe dissection here requires good mobility of the right and left lobes of the liver.

Parenchymal Transection and Completion

- As described above

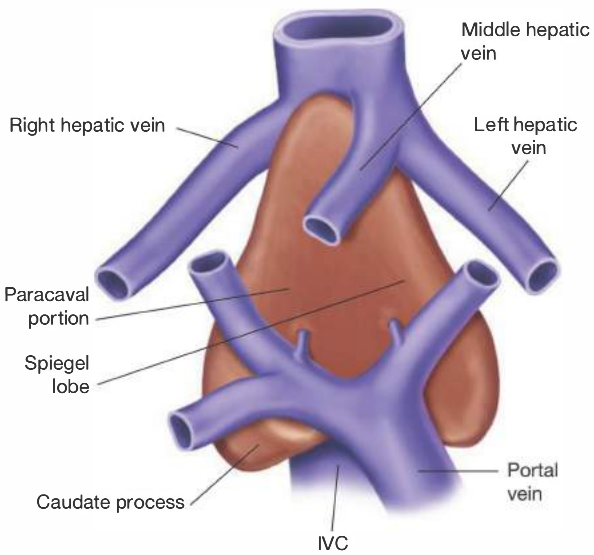

FIG 7 ● The upper pole of the caudate lobe lies between the IVC and the confluence of the middle and left hepatic veins.

PEARLS AND PITFALLS

Patient history	■ Suggestion of hepatic insufficiency or damage should be aggressively evaluated to reduce postresection hepatic failure.
Imaging and testing	■ High-quality imaging and a thorough understanding of hepatic anatomy is essential for proper surgical planning. ■ Liberal use of volumetry is warranted. ■ Vascular abnormalities should be detailed on preoperative imaging.
Vascular isolation	■ Avoid unnecessary dissection in order to minimize the risk of contralateral injury.
Parenchymal transection	■ Low CVP anesthesia is essential to minimize intraoperative blood loss during hepatic transection. ■ Stapling quickly divides the hepatic parenchyma, vasculature, and bile ducts, minimizing blood loss and bile leaks. ■ Small venous bleeders encountered during dissection can be simply tamponaded, sealed with an electrosurgical device, or on occasion, sutured or clipped.
Hemostasis	■ Use of energy near major biliary or hilar structures should be avoided.

POSTOPERATIVE CARE

- VTE prophylaxis is continued, including doses on the day of surgery as appropriate to the dosing schedule.
- Antibiotics are only continued to complete less than 24 hours of prophylaxis.
- All patients are given supplemental magnesium (6 g/IV once), phosphate (sodium phosphate, 30 mmol/IV TID), and vitamin K (phytonadione, 5 mg/SC q8h) to aid in liver regeneration and production of normal levels of vitamin K–dependent factors. This is given regardless of serum levels.
- Drains are checked for bilirubin on postoperative day 3. If the level is less than or equal to serum levels and the output is less than 100 mL per day, the drain is removed.

OUTCOMES

- In experienced centers, mortality is now less than 3% and morbidity is approximately 20%.[3]
- Overall and disease-specific survival at 5 years can reach 69% and 72%, respectively, varying with the underlying pathology.[4]
- Neoadjuvant or adjuvant systemic treatment, a total of 6 months of perioperative therapy, is recommended.[5]

COMPLICATIONS

- Volume-outcomes relationships are prominent in hepatic resection.
- Outcomes specific to hepatectomy include bile leaks (5.9%), perihepatic abscesses (3.7%), hemorrhage (0.9%), and hepatic insufficiency (3.1%).[6]

- Bile leaks can be managed by percutaneous drainage or endoscopic retrograde cholangiopancreatography (ERCP) with sphincterotomy to facilitate internal drainage.

Chapter 22

Minimally Invasive Sectional and Segmental Hepatic Resection

Kevin T. Nguyen

DEFINITION

- The International Hepato-Pancreato-Biliary Association (IHPBA) Brisbane 2000 terminology of liver anatomy and resections[1] defines a segmental hepatic resection as a liver resection of one of nine anatomic Couinaud's segments and a sectional hepatic resection as a liver resection of anatomic sections or sectors (right posterior section [Couinaud's segments 6 and 7], right anterior section [Couinaud's segments 5 and 8], left anterior section [Couinaud's segment 4], or left lateral section [Couinaud's segments 2 and 3]).

PATIENT HISTORY AND PHYSICAL FINDINGS

- The indications for liver resection include primary or metastatic malignant liver lesions or symptomatic benign liver lesions in patients who are surgical candidates. Patients who are candidates for an open liver resection should be considered for a possible minimally invasive approach.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Eovist™-enhanced liver magnetic resonance imaging (MRI) or triphasic, contrast-enhanced computed tomography (CT) scan of the abdomen are virtually equivalent for assessment of disease. They can be complementary in characterizing lesions and determining the probable pathology.
- Localize the tumor(s) with respect to the portal structures and hepatic veins to evaluate for resectability. Can an R0 liver resection be performed with curative intent, namely obtaining adequate margins, while leaving a sufficient functional liver remnant with preserved vascular inflow and outflow?
- Pay attention to anatomic variants (i.e., replaced/accessory left hepatic artery, replaced/accessory right hepatic artery, trifurcation of the main portal vein, takeoff of the right anterior or right posterior portal vein from the left portal vein, the presence of large inferior hepatic veins, etc.).

SURGICAL MANAGEMENT

Preoperative planning

- Where is the transection plane to achieve a negative margin and preserve adequate functional liver reserve?
- Where should the port positions be to provide optimal triangulation?

Positioning

- Supine with arms abducted. Split-leg positioning is an option preferred by some liver surgeons.

TECHNIQUES

LAPAROSCOPIC LEFT LATERAL SECTIONECTOMY

- A purely laparoscopic left lateral sectionectomy can be attempted for hepatic lesions located within segments 2 and/or 3 of the liver (**FIG 1**).

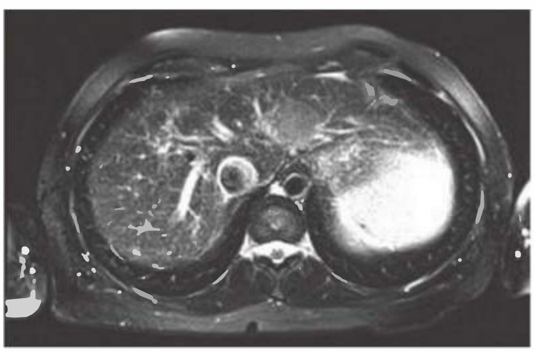

FIG 1 ● Left lateral sector hepatocellular carcinoma.

Port Placement

- Initial trochar placement: open Hasson approach at a periumbilical position, Veress needle approach in left upper quadrant, or optical separator approach in the left upper quadrant
- **FIG 2** shows the suggested port positions for a purely laparoscopic left lateral sectionectomy. A 12-mm port at the periumbilical incision, a 12-mm port in left upper quadrant midclavicular line for laparoscopic ultrasound and Endo GIA stapler, a 5-mm port in left upper quadrant midclavicular line, and a 5-mm left subcostal/left flank port.

Mobilization of the Left Lateral Segment

- Using a thermal energy device of choice through the right upper quadrant 12-mm port, divide the round ligament at the abdominal wall. The assistant provides countertension through the left-sided 5-mm ports.
- Using hook cautery through the right upper quadrant 12-mm port, divide the falciform ligament toward the insertion of hepatic veins into the inferior vena cava (IVC). The assistant provides countertension through the

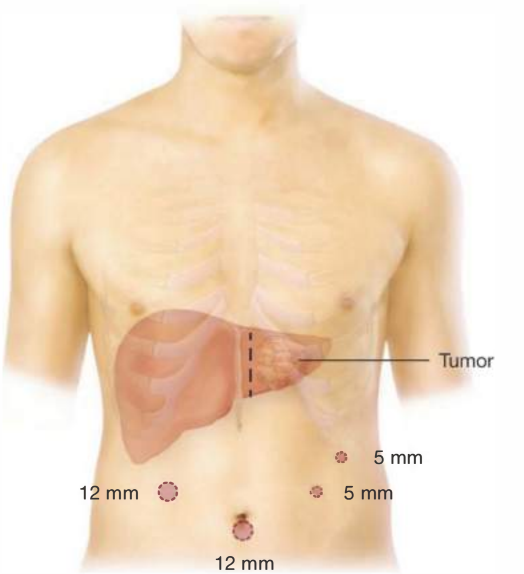

FIG 2 ● Port positions for purely laparoscopic left lateral sectionectomy.

left-sided 5-mm ports by compressing the liver posteriorly and inferiorly. The avascular adventitia protecting the hepatic veins should be divided to fully expose the anterior aspect of the common trunk of the middle and left hepatic vein.

- Using the hook cautery through the left upper quadrant 5-mm port, divide the left triangular ligament. Optional: Protect the stomach and spleen with a 4 × 4 gauze between the left triangular ligament and stomach.
- Using the hook cautery through the left-sided ports, divide the hepatogastric ligament, and identify any replaced or accessory left hepatic artery. The assistant lifts the left lateral section through the right upper quadrant 12-mm port. Clip and ligate any replaced/accessory left hepatic artery.
- Rarely, obtaining an adequate margin will dictate extraparenchymal dissection of the portal structures supplying segments 2 and 3. The author's favored approach is to identify the left hepatic artery near the porta hepatis and dissect it distally to identify and divide the segmental branches of all of the portal structures.

Parenchymal Transection of the Liver

- Ultrasound the liver and ensure that the liver mass(es) is/are localized only in the left lateral sector of the liver and that the transection plane achieves an adequate oncologic margin (≥1 cm).
- Mark the transection plane just to the left of falciform ligament with the hook cautery.
- The first 2 cm of parenchymal depth can be divided safely with an energy device of choice (**FIG 3**). The optimal trajectory for the liver parenchymal transection is through the right upper quadrant 12-mm port heading toward the insertion of the left hepatic vein. The camera is at the periumbilical port and the assistant uses an atraumatic grasper and suction/irrigator from the left-sided 5-mm ports.
- As the dissection progresses deeper into the parenchyma, expect to encounter the crossing segments 2 and 3 portal veins, biliary branches, and hepatic vein branches. Using a flat, blunt instrument (e.g., laparoscopic bowel grasper), create a tunnel in the liver parenchyma below these crossing branches (**FIG 4**). The tunnels creates an easy path for the Endo GIA stapler (2.5-mm vascular loads are preferred) (**FIG 5**). The blunt instrument and lower blade of the stapler should easily slide through liver parenchyma. If the instrument meets resistance, it suggests a crossing vascular or biliary branch along that path and the instrument needs to be redirected. The last division to free the liver section is the division of the left hepatic vein approximately 2 cm from the insertion into the IVC with Endo GIA vascular load.
- A 4 × 4 gauze can be used to dry the cut surface of the liver to identify any areas of bleeding or bile leak.

FIG 3 ● Superficial parenchymal transection with Harmonic scalpel.

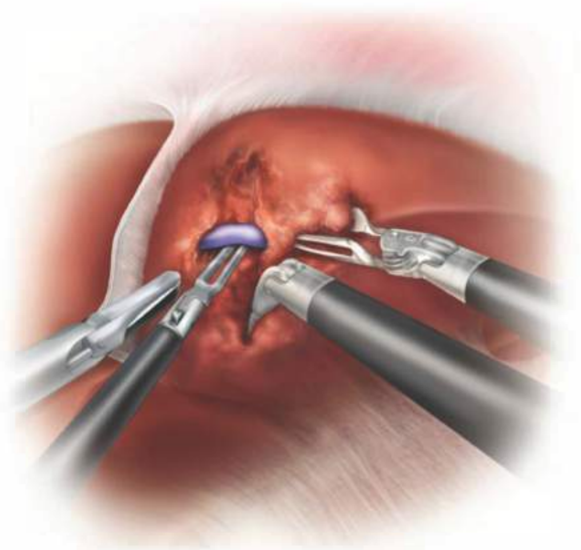

FIG 4 ● Creating a tunnel through the liver parenchyma using a flat laparoscopic blunt grasper.

The laparoscopic energy source is then used to control any small bleeders or oozing. (The author advises against using the laparoscopic argon beam due to the risk of argon embolism.) Any large vessels or bile leaks should be controlled with sutures.

- Place a specimen retrieval bag through a Pfannenstiel or an enlarged periumbilical incision to extract the specimen.
- Incisions larger than 12 mm are closed with the 0 Vicryl using the Carter-Thompson device or with a standard open closing technique.

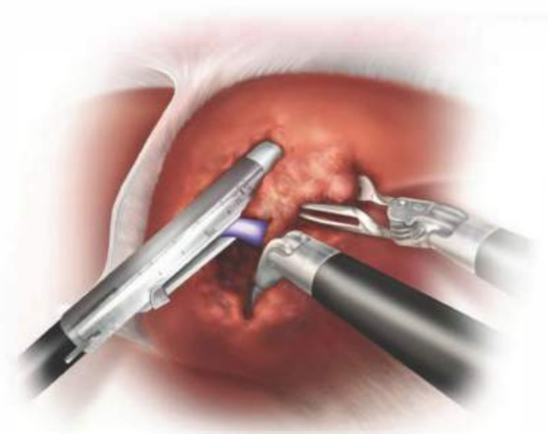

FIG 5 ● Stapling and crossing large vascular branches with the Endo GIA vascular load stapler.

LAPAROSCOPIC RIGHT POSTERIOR SECTIONECTOMY

- A purely laparoscopic right posterior sectionectomy can be attempted for hepatic lesions located within segments 6 and/or 7 of the liver (**FIG 6**).

Port Placement

- **FIG 7** shows the suggested port portions for a purely laparoscopic right posterior sectionectomy: a 12-mm port at the periumbilical incision, a 12-mm port in right upper quadrant midclavicular line and 2 cm above the level of the umbilicus for laparoscopic ultrasound and Endo GIA stapler, a 5-mm port in right flank, a 5-mm port in the left upper quadrant/midclavicular line, and a 5-mm port in the subxiphoid/epigastric region.

Mobilization of the Right Lobe of the Liver

- Using a thermal energy device of choice, through the right upper quadrant 12-mm port, divide round ligament from the abdominal wall.

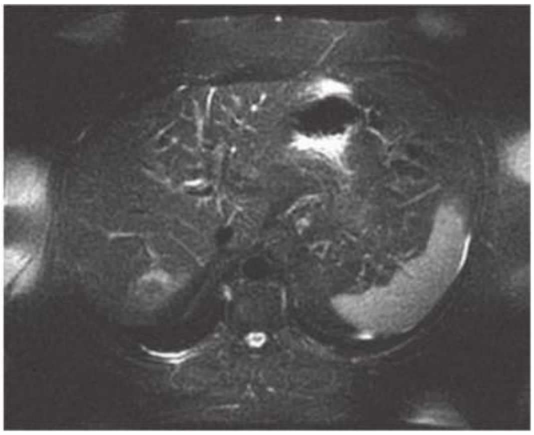

FIG 6 ● Colorectal metastasis to the right posterior sector of the liver.

- Using the hook cautery, divide the falciform ligament toward the insertion of hepatic veins into the IVC. The avascular adventitia protecting the hepatic veins should be divided to fully expose the anterior aspect of the right hepatic vein. This can be more easily reached through the epigastric 5-mm port.
- Mobilize the right lobe of the liver off the retroperitoneum. The assistant on the left uses a nontraumatic, expanding retractor through the left upper quadrant 5-mm port to lift the right lobe of the liver. This will expose the plane by placing tension on the posterior peritoneum attachments to the liver. The surgeon is on the right side with the suction/irrigator on the left hand through the right flank 5-mm port and hook cautery in the right hand through the right upper quadrant 12-mm port. Divide the peritoneum close to but not on the liver and enter the avascular plane. The assistant continually lifts the right lobe of the liver anteriorly and toward the left to further expose the dissection plane. The right kidney and adrenal gland should be swept posterior by the surgeon using the suction/irrigator in the left hand. Dissect superiorly toward the diaphragm and right triangular ligament and toward the IVC.

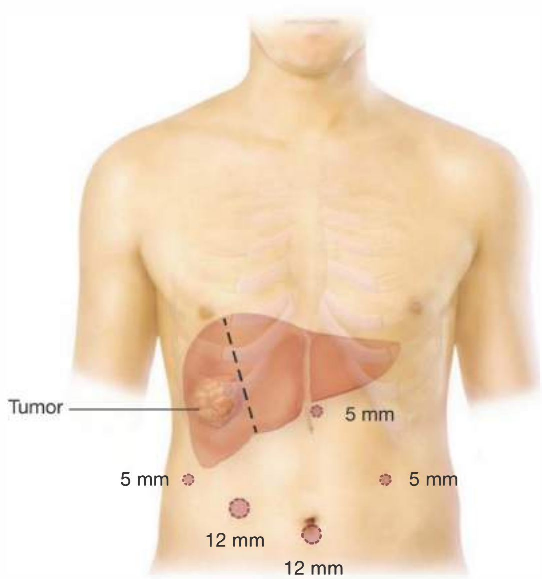

FIG 7 ● Port positions for purely laparoscopic right posterior sectionectomy.

- Using the hook cautery through the right flank 5-mm port, divide the right triangular ligament and the diaphragmatic attachment of the right lobe toward the right hepatic vein.
- Additional mobilization can be achieved when necessary by isolating and dividing the short veins from the caudate lobe entering the vena cava. Most can be safely controlled with bipolar electrocautery or ultrasonic shears. Some will require clipping. An accessory right hepatic vein should be expected. This vessel is best controlled and divided with a vascular staple load (2.5 mm).
- Perform a laparoscopic cholecystectomy in standard fashion.
- Ultrasound the liver and confirm the lesion(s) are in the right posterior section (Couinaud's segments 6 and 7). If a right posterior sectionectomy is planned, then mark liver using the hook cautery along an imaginary line from the right of the gallbladder fossa to 2 to 3 cm to the right of the right hepatic vein. This imaginary line of transection should be parallel but lateral to Cantlie's line of transition for an anatomic right or left hepatectomy.

Parenchymal Transection of the Liver

- The first 2 cm of parenchymal depth can be divided with an energy device of choice. This can also be performed along the posterior surface of the liver along the planned transection plane. The laparoscopic energy device can be used to dry the cut surface of the liver periodically.
- As the dissection proceeds, repeat performance of ultrasound evaluation can assist in the intraparenchymal identification of the segments 6 and 7 portal veins, biliary branches, and hepatic vein branches. Use a flat, blunt instrument (e.g., laparoscopic bowel grasper) to create a tunnel below these crossing branches to apply the Endo GIA stapler (vascular loads [2.5 mm] are preferred). The instrument should easily slide through the liver parenchyma. If the instrument meets resistance, it suggests a crossing vascular or biliary branch and the instrument should be redirected. The last division to free the liver section is the division of the right hepatic vein approximately 2 to 3 cm from the insertion into the IVC with Endo GIA vascular load.
- A 4 × 4 gauze can be used to dry the cut surface of the liver to identify any areas of bleeding or bile leak. The laparoscopic energy device is used to control any small bleeders or oozing. Any larger vessels or bile leaks should be controlled with sutures.
- Place specimen retrieval bag through a Pfannenstiel or enlarged periumbilical incision to extract the specimen.
- Incisions larger than 12 mm are closed with the 0 Vicryl using the Carter-Thompson device or with a standard open closing technique.

TECHNIQUES

LAPAROSCOPIC SEGMENT 6 SEGMENTECTOMY

- A purely laparoscopic segment 6 segmentectomy can be attempted for hepatic lesions located within segment 6 of the liver (**FIG 8**).

Port Placement

- **FIG 9** shows the suggested port portions for a purely laparoscopic segment 6 segmentectomy. A 12-mm port at the periumbilical incision, a 5-mm port in right upper quadrant midclavicular line and 1 cm above the level of the umbilicus, a 5-mm port in right flank, and a 12-mm port subcostal/midclavicular line.

Mobilization of the Right Lobe of the Liver

- Mobilize the right lobe of the liver off the retroperitoneum as described earlier.
- Perform a laparoscopic cholecystectomy in standard fashion.
- Ultrasound the liver and confirm the lesion is in segment 6 of the liver. If a segment 6 segmentectomy is planned, then mark the liver surface that is approximately 2 cm around the lesion(s). Confirm the transection plan by ultrasonography of the shadow from the marked cauterized surface of the liver. This line starts along the transection plane of a right posterior sectionectomy but then takes a sharp left turn toward the lateral surface of the right lobe of the liver as confirmed by ultrasound to achieve a margin of at least 1 to 2 cm by ultrasound along each transection plane.

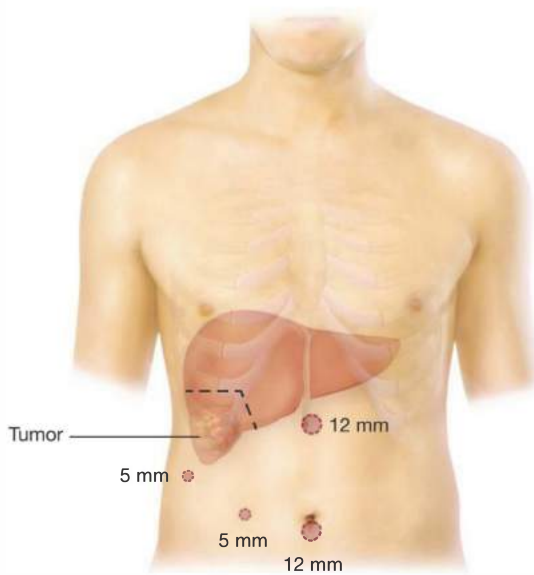

FIG 9 ● Port positions for purely laparoscopic segment 6 segmentectomy.

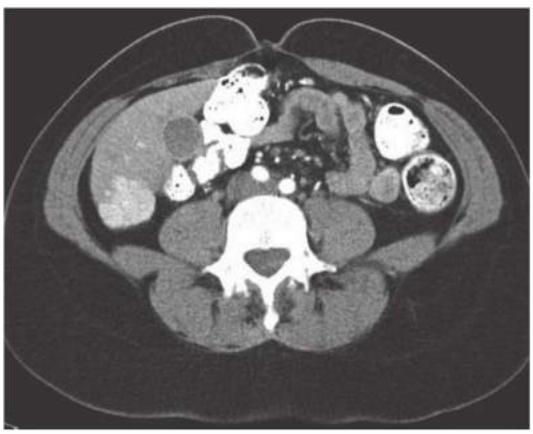

FIG 8 ● Segment 6 pedunculated hepatic adenoma.

Parenchymal Transection of the Liver

- This should be performed along the anterior and posterior surface of the liver along the planned transection plane. The laparoscopic energy device can be used to dry the cut surface of the liver periodically.
- To control the segment 6 portal veins, biliary branches, and hepatic vein branches, a vascular stapler is applied as earlier. In contrast to earlier, this load is typically inserted transversely via the subxiphoid port.

Chapter 23

Right Hepatectomy

Neil H. Bhayani Niraj J. Gusani Kevin Staveley-O'Carroll

DEFINITION

- A right hepatectomy (or hemihepatectomy) consists of surgical resection of the right liver, consisting of Couinaud segments 5 to 8 (**FIG 1**). Nomenclature for liver resections was standardized in the Brisbane conference.[1]

PATIENT HISTORY AND PHYSICAL FINDINGS

- Medical evaluation and suitability for major abdominal surgery is tantamount.
- Health of the liver can be ascertained by questions regarding episodes of jaundice, hepatitis exposure, alcohol, illicit drug abuse, and treatment with chemotherapy.
- In addition to standard preoperative laboratories, it is our practice to obtain a complete viral hepatitis panel on all potential surgical candidates. Regardless of the metric or risk scoring system employed, thorough assessment of the health of the remnant liver is mandatory.
- Previous history of abdominal surgery, especially abdominal foreign bodies (e.g., mesh), may alter the approach.
- Physical exam findings of chronic liver disease or hepatic insufficiency should prompt more invasive testing if the patient remains a surgical candidate.
- If performing a metastasectomy, there should be a thorough evaluation for extrahepatic disease. Computed tomography (CT) is considered standard of care; a positron emission tomography (PET) scan is currently considered optional but used commonly by the authors. Findings of extrahepatic disease should prompt reconsideration of hepatectomy or planning for multiple staged procedures.
- In appropriate, medically operable patients, resectability is now only limited by the need to preserve adequate functional hepatic reserve.

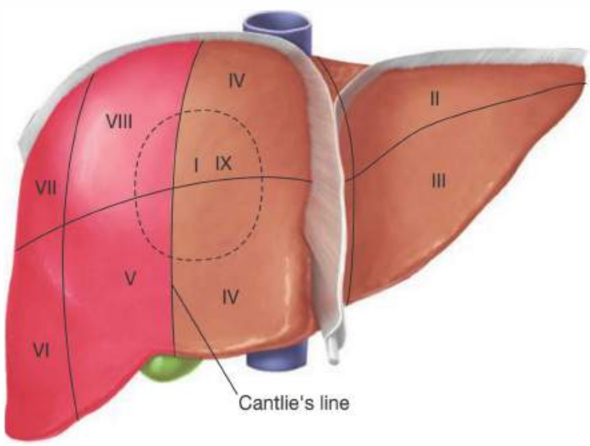

FIG 1 ● Couinaud segments with right hepatectomy pictured.

- Liver function can be assessed by the Child-Pugh classification or Model for End-Stage Liver Disease (MELD). Neither metric has been definitively shown to be superior.[2,3]
- Specific biochemical testing of liver function is more prevalent in Asia but rarely performed in the United States.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Noncontrast, arterial, and venous contrast cross-sectional imaging is essential in diagnosis and evaluation of suitability for surgery. CT and magnetic resonance imaging (MRI) are of similar sensitivity.
- In a normal, healthy liver, a remnant measuring 25% of a complete liver volume should constitute sufficient functional liver. However, in a damaged or cirrhotic liver, a remnant of greater than 40% is recommended. When performing a right hepatectomy, the remnant hemiliver is usually of adequate size in a healthy liver. In most cases, this does not require formal volumetric analysis; however, liberal use of volumetry should decrease the risk of postoperative hepatic insufficiency (**FIG 2**). In the event of marginal remnant volume, preoperative portal vein embolization on the side of resection can induce hypertrophy of the planned liver remnant.
- Hepatic steatosis can be evaluated by comparison of the densities of liver and spleen on noncontrast images. Alternatively, biopsy of the liver can provide quantitative assessment of fat content. Significant steatosis can suggest a liver remnant at risk of postoperative failure. Current practice would advocate strategies for preoperative hypertrophy to ensure a remnant that is at least 30% of the native volume of the liver.
- Patients with history, laboratory, or radiographic findings concerning for significant hepatic injury or dysfunction are referred for invasive testing of the liver, such as transjugular measurement of the portal pressure gradient (normal <5 to 8 mmHg) and biopsy (to evaluate steatosis or cirrhosis).
- Patients with evidence of decompensated cirrhosis (Child's B and C) are not candidates for right hepatectomy but may be candidates for liver transplantation in clinical settings of hepatocellular carcinoma, cholangiocarcinoma, or metastatic neuroendocrine tumors.

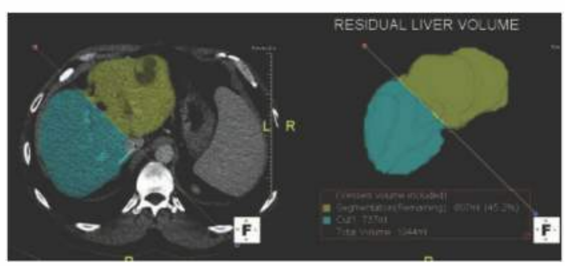

FIG 2 ● CT volumetry for a right hepatectomy. The calculated liver remnant represents 45% of the liver volume.

SURGICAL MANAGEMENT

- The indications for hepatectomy include diagnostic uncertainty, symptomatic benign lesions, and malignancy (Table 1).
- The strongest evidence for hepatic metastasectomy shows that R0 resection prolongs survival and is potentially curative for colorectal carcinomas and metastatic neuroendocrine tumors.

Preoperative Planning

- Preoperative cross-sectional imaging should be reviewed with skilled radiologists before surgery and be available throughout the procedure.
- Vascular, particularly hilar, arterial anomalies are common. Inadvertent injury at surgery may be prevented by thorough study and multiplanar analysis (**FIG 3**).
- Three-dimensional (3-D) reconstruction is not mandatory, but understanding of all the lesions and their relation to hepatic and portal venous structures is imperative. This should be combined with intraoperative ultrasound (IOUS).
- For postoperative pain control, preoperatively placed epidural catheters, administered by a dedicated pain service, have been shown to be effective and impact respiratory complication rates.
- Low central venous pressure (CVP) anesthesia is a cornerstone in reducing blood loss. To maintain low CVP (5 to 8 mmHg), good communication with the preoperative nursing and anesthesia teams is critical.
- Patients receive prophylactic antibiotics due to transection of the biliary tree (clean-contaminated surgery). The authors consider cases with an indwelling biliary device as contaminated.
- Patients undergoing hepatectomy are at high risk for venous thromboembolic (VTE) disease due to age, presence of malignancy, and complex, long major abdominal surgery. Unfractionated heparin is given subcutaneously prior to induction and redosed every 8 hours as needed.

Table 1: Indications for Hepatectomy

Diagnosis	Premalignant disease
Focal nodular hyperplasia vs. hepatocellular adenoma	Hepatocellular adenoma
	Biliary cystadenoma
Symptoms	Malignancy
Hemangioma	Metastasis
Simple cysts	Hepatocellular carcinoma
Benign disease	Cholangiocarcinoma
Refractory abscesses/cholangitis	
Severe hepatolithiasis	

Positioning

- Supine with arms abducted

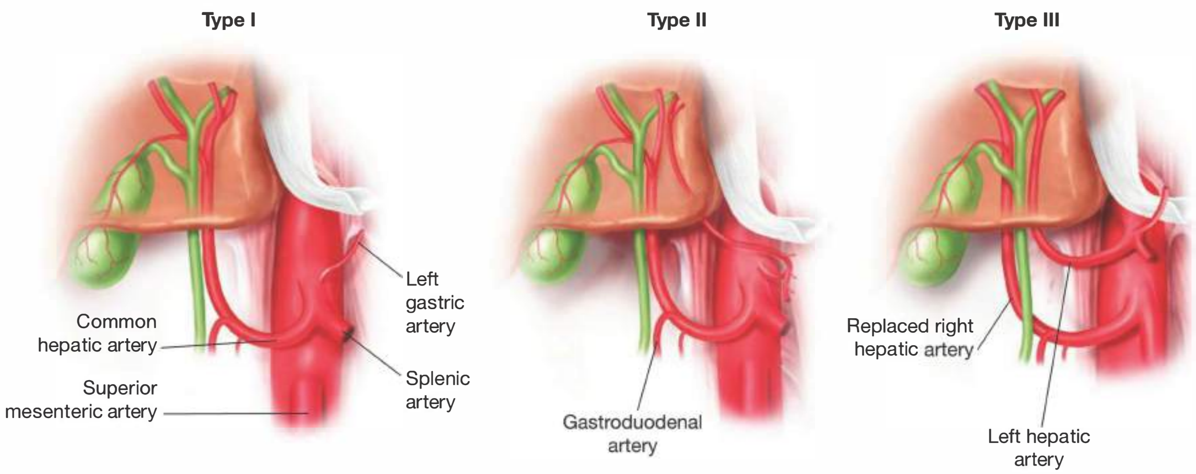

FIG 3 ● Common variants of hepatic arterial anatomy. Type 1 is considered "standard." Type 2 shows an accessory left hepatic artery (HA) (native left HA present). Type 3 shows an aberrant right HA (native right HA absent).

INCISION AND EXPOSURE

- A right hemihepatectomy can be performed through a subcostal, chevron, or midline incision. It is the authors' preference to operate through a midline incision.
- A fixed traction system is employed with emphasis on the cephalad and lateral retraction of the costal margin to provide adequate exposure.

MOBILIZATION

- The falciform ligament is ligated but kept long to use as a handle. The ligament is divided close to the liver surface to minimize interference with the ultrasound exam.
- Dissection continues at the apex of the right triangular ligament, working from medial to lateral. The peritoneum and areolar tissue surrounding the anterior and lateral aspects of the right hepatic vein (RHV) is cleared (**FIG 4**).
- To continue laterally and inferiorly, the liver can be retracted medially and compressed posteriorly. If caval compression induces hypotension, temporary release of retraction may be all that is required. Alternatively, raising the inferolateral edge of the right liver will expose the final attachments of the triangular ligament.
- Complete mobilization of the right liver requires extensive exposure of the lateral and anterior surface of the inferior vena cava (IVC). Medial retraction and cephalad rotation of the inferolateral edge raises the liver off the IVC (**FIG 5**).
- Variable short branches from the right hepatic lobe draining into the IVC (short hepatic veins) will be exposed from distal to proximal IVC. These should be carefully dissected and ligated using 4-0 silk ties and/or endoclips. Limit the use of endoclips on the hepatic side of these small vessels as they may interfere with parenchymal transection with staplers and are prone to dislodgement during subsequent retraction needed to provide adequate exposure (**FIG 6**).
- At the proximal and lateral aspect of the IVC, there is a ligamentous band/parenchymal bridge, which extends from segment 7 to the retroperitoneal tissue behind the IVC. Release of this band is critical in the exposure and safe dissection of the RHV. This band can be vascular and transection with a 45-mm endoscopic stapler with 2.0-mm staples (grey load) is an attractive, safe option.
- After mobilization of the liver, use IOUS to examine the hepatic parenchyma. This is cross-referenced with preoperative imaging. All known lesions are identified and the liver is examined for occult lesions. IOUS can confirm vascular anatomy, identify major vascular branches, and map the proximity of hepatic vein and portal vein branches near lesions.

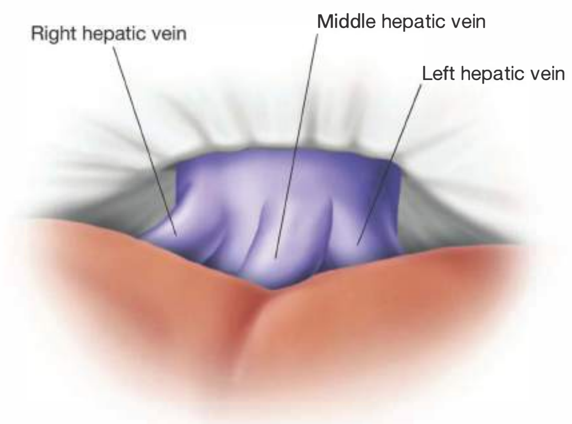

FIG 4 ● Hepatic veins at the apex of the falciform ligament. Dissection along the liver surface exposes this confluence. Dissection proceeds from medial to lateral, exposing the RHV without unnecessary dissection of contralateral structures.

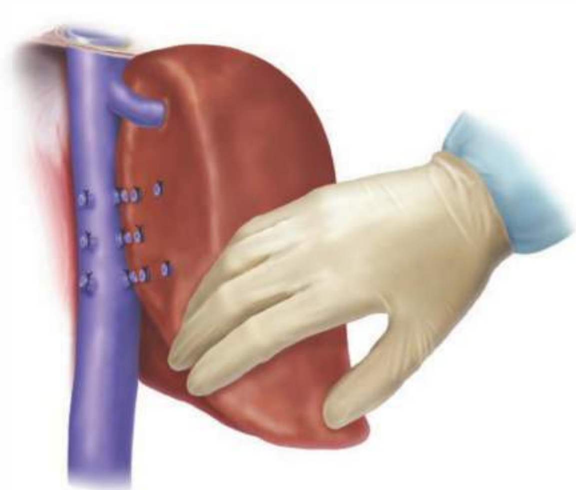

FIG 5 ● Exposure of the short hepatic veins and IVC. This exposure is obtained by medial rotation and anterior retraction of the right liver. The short hepatic veins from the IVC into the liver parenchyma are ligated.

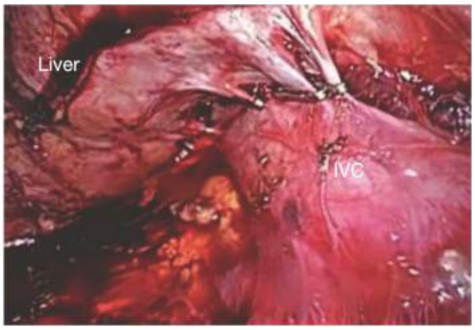

FIG 6 ● Laparoscopic view of right liver mobilization. The dissection of the IVC yields short hepatic veins for ligation with both clips and energy.

DISSECTION OF THE RIGHT HEPATIC VEIN

- In a formal right hepatectomy, it is ideal to isolate and ligate the RHV outside the liver. In "subtotal" right hepatectomies, intraparenchymal ligation may be employed to preserve liver tissue.
- Full exposure and control of the RHV prior to hilar dissection and inflow division is important. This sequence allows the surgeon to abort the procedure in the case of major venous injury to the outflow of the intended remnant and/or bleeding, prior inflow ligation, which is a "point of no return."
- The RHV is isolated only after the IVC is fully exposed. Liver retraction is released and dissection then resumes from over the top of the liver. The medial border of the RHV is dissected off the middle hepatic vein. The RHV is dissected close to the liver to leave a long cuff of RHV on the IVC in the event of injury. Once fully dissected, the RHV is isolated with a ¼-in Penrose drain or vessel loop.
- To avoid congestion of the liver, the hepatic vein is not ligated at this time.

HILAR DISSECTION AND VASCULAR CONTROL

- The exposure of the hilum is ensured by anterior and cranial fixation of the falciform ligament. Antegrade cholecystectomy is performed. The gallbladder can be removed at this time or may be left attached by the cystic duct.
- After creating an aperture through the gastrohepatic ligament, an umbilical tape is placed around the porta hepatis. Creation of a loose Rummel tourniquet permits a rapid Pringle maneuver in the event of bleeding.
- In the hilum, the dissection proceeds at the level of the hepatic plate. Dissection on the contralateral side should be avoided to prevent inadvertent injury and to minimize scarring in case subsequent hepatectomy is required.
- In the right hilum, dissection of the right hepatic artery (RHA) is the first priority. The RHA (or its branches) should be isolated as they enter the right liver. A vascular loop facilitates gentle traction, and a bulldog clamp is then placed on the segment of the artery to be divided.
- Perfusion in the proper hepatic artery as well as the opposite hepatic artery should now be assessed. IOUS in the hilum or of the parenchyma can be used for confirmation.
- If no deficit is noted, then the clamp may be removed and the RHA divided between 2-0 silk ligatures and 3-0 suture ligatures. Division should expose the right portal vein (RPV) posteriorly and cephalad to the RHA.
- The RPV dissection should establish enough length to permit safe ligation. The first branch, the RPV to the caudate, is often divided for adequate length. Dissection must be carried out to identify the bifurcation of the RPV into anterior and posterior branches and to ensure that the visualized vessel is the RPV and not the main portal vein. Isolation of the RPV may be confirmed by IOUS. The RPV is circled with a vessel loop or a ¼-in Penrose drain to allow gentle traction.
- We routinely transect the RPV with a vascular stapler. We typically use an articulating stapler to obtain the optimal angle for transection. Extreme care is taken during passage of the jaws of the stapler to avoid disruption of nearby vascular branches. If difficulty is encountered, try inserting the narrow jaw of the stapler into the opening of the Penrose drain that was previously looped around the RPV. Withdrawing the Penrose drain guides the stapler into place (**FIG 7**).
- At this point, the right liver should begin to demarcate, showing ischemia along Cantlie's line.
- Unless an oncologic margin is at risk, do not routinely perform extrahepatic division of the right hepatic duct (RHD). Rather, ligate and divide it intraparenchymally

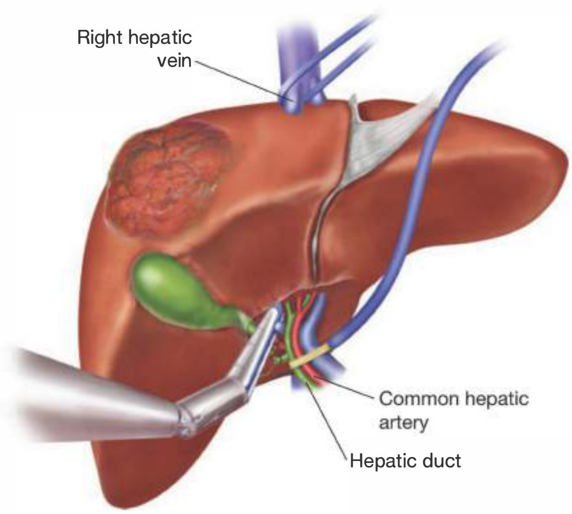

FIG 7 ● Stapler division of the RPV. The hilar structures are approached from the right lateral hilar plate. After thorough exposure of the anatomy, the portal vein can be ligated with a stapler.

with a stapler. This technique allows the safe sealing of the duct proximal to the bifurcation and avoids unnecessary hilar dissection, which can devascularize or injure the common hepatic duct.

- When ligating the RHD at the hilum, pass a clamp from the right edge of the gallbladder fossa through the hepatic parenchyma exiting at the caudate isthmus, thus creating a tunnel through which the narrow jaw of the stapler may be passed and fired.
- The previously isolated hepatic vein is divided using an articulating stapler. Vascular occlusion is now complete (**FIG 8**).

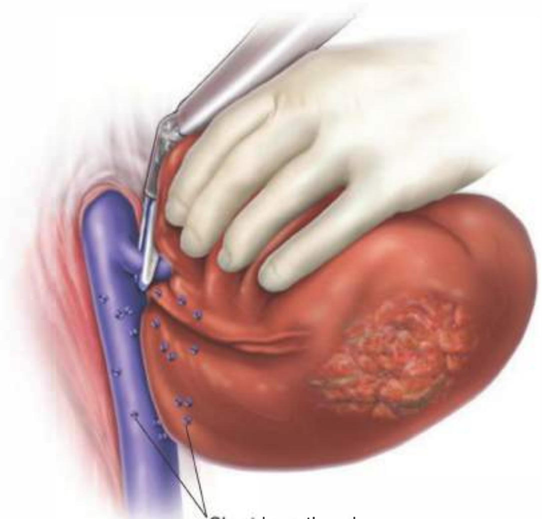

FIG 8 ● Stapler division of the RHV. This is the last step of the vascular isolation after completion of the inflow ligation.

PARENCHYMAL TRANSECTION

- To begin transection, use electrocautery to disrupt Glisson's capsule and mark the line of transection. For lesions of segment 5 or 8, IOUS may be helpful to mark an appropriate medial margin. This process is continued circumferentially.
- The next 1 to 2 cm of liver parenchyma can be transected with an energy source. Bipolar, radiofrequency, or ultrasonic-generated heat energy can be used at the surgeons' preference. The authors find superior hemostasis with saline-radiofrequency devices that purportedly seal vasculature and bile ducts.
- This circumferential groove will serve as a guide for the completion of the hepatic transection with staplers. The importance of creating a fully circumferential groove (especially posteriorly) in order to provide tactile and visual guidance for stapling cannot be overstated.
- At any point during the transection, IOUS can be used to confirm the line of resection to ensure adequate margins.
- A Pringle maneuver may be applied to occlude collateral flow through the liver remnant should brisk bleeding be encountered.
- Stapling of the hepatic parenchyma is our preferred means of transection. This is performed with two staplers on the surgical field. While one is in use by the surgeon, the other is being reloaded for use to ensure rapidity and avoid delays when encountering bleeding. The thin (narrow) end of the stapler is tunneled bluntly into the hepatic parenchyma. Alternatively, the path of the stapler can be guided by creating a parenchymal tunnel with a curved clamp. Closure of the stapler is analogous to crushing the hepatic parenchyma with a clamp, although much faster than the traditional crush-clamp technique (**FIG 9**).

FIG 9 ● Parenchymal transection. This step includes intraparenchymal ligation of the left hepatic duct. The stapler used to transect the liver obtains hemostasis and also ligates biliary radicals to help prevent bile leaks.

- If there is resistance to the passage of the stapler through the parenchyma, do not apply additional force. Instead, the stapler is redirected, as such resistance usually indicates that the stapler is encountering the sidewall of a vessel. Forcing the stapler through these branches will cause significant hemorrhage.
- Slow, sequential compression of the hepatic parenchyma avoids tearing of vessels and excludes excess tissue. Although the instinct is to grab large bites of parenchyma, smaller bites permit superior staple formation, minimizing the chance of bleeding or bile leak.
- Difficulty in closing or firing the stapler may be encountered when (1) too much tissue is between the jaws or (2) the RHD is ligated and divided.
- With the left hand holding the right liver, the line of transection can be controlled. With the fingers in the posterior groove, the IVC is protected and endpoint of transection is known at all times. The entire transection continues with repeated firings of the stapler.

COMPLETION

- After the parenchyma is divided, the specimen is removed from the field. Gross margins should be assessed by pathology intraoperatively (**FIG 10**).
- Hemostasis is achieved at the cut edge of the liver. Most bleeding is from venules and will cease with 10 minutes of gentle tamponade. The authors favor using a saline-perfused radiofrequency ablation (RFA) device to complete the process of obtaining hemostasis.
- Care should be taken to avoid coagulating major biliary branches, as this may lead to subsequent stricture. Any area of bile leakage should be controlled with fine monofilament sutures.
- For areas of bleeding near the hilum, energy devices may risk damage to crucial structures; employ manual pressure and/or topical hemostatic agents, that is, cellulose matrices or fibrin sprays or foams.
- A cholangiogram with methylene blue or other colored agents can mitigate against potential bile leaks.
- A large, closed suction drain may be placed adjacent to the transected parenchyma at the surgeon's preference.
- Reapproximate the falciform ligament to prevent lateral rotation of the remnant; kinking of the middle and left hepatic veins is incompatible with life.

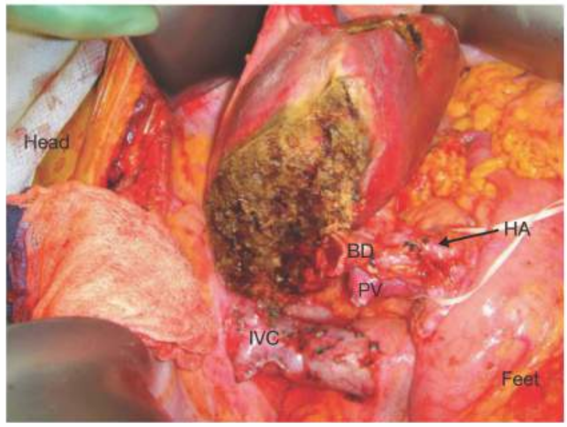

FIG 10 ● Completed right hepatectomy. *BD*, bile duct; *HA*, hepatic artery; *IVC*, inferior vena cava; *PV*, portal vein.

PEARLS AND PITFALLS

Patient history	■ Suggestion of hepatic insufficiency or damage should be aggressively evaluated to reduce postresection hepatic failure.
Imaging and testing	■ Liberal use of volumetry is warranted. ■ Vascular abnormalities should be detailed on preoperative imaging.
Vascular isolation	■ Early isolation of the RHV avoids hilar dissection if surgery is aborted. ■ Starting dissection at the right hilar plate minimizes risk of contralateral injury to the remnant vasculature. ■ Minimize dissection of the contralateral liver if there is a chance of repeat hepatectomy.
Parenchymal transection	■ Low CVP anesthesia is key. ■ A circumferential groove facilitates later transection. ■ Stapling the hepatic parenchyma is fast and seals vessels and bile ducts alike. ■ Small venous bleeders encountered during dissection can be simply tamponaded.
Hemostasis	■ Use of energy near major biliary or hilar structures should be avoided

POSTOPERATIVE CARE

- VTE prophylaxis is continued, including doses on the day of surgery as appropriate to the dosing schedule.
- Antibiotics are only continued to complete less than 24 hours of prophylaxis.
- All patients are given supplemental magnesium (6 g/IV once), phosphate (sodium phosphate, 30 mmol/IV TID), and vitamin K (phytonadione, 5 mg/SC q8h) to aid in liver regeneration. This is given regardless of serum levels.
- Drains are checked for bilirubin on postoperative day 3. If the level is less than serum levels and output is less than 100 mL per day, the drain is removed.

OUTCOMES

- In experienced centers, mortality is now less than 3% and morbidity is 20%.[4]
- Overall and disease-specific survival at 5 years can reach 69% and 72%, respectively.[5]
- Neoadjuvant or adjuvant systemic treatment is nearly universal.

COMPLICATIONS

- Volume-outcomes relationships are prominent in hepatic resection.
- Outcomes specific to hepatectomy include bile leaks (5.9%), perihepatic abscesses (3.7%), hemorrhage (0.9%), and hepatic insufficiency (3.1%).[6]
- Bile leaks can be managed by percutaneous drainage or endoscopic retrograde cholangiopancreatography (ERCP) with sphincterotomy to facilitate internal drainage.

Chapter **24**

Minimally Invasive Right Hepatectomy

Shirin Sabbaghian Allan Tsung

DEFINITION

- Minimally invasive right hepatectomy is defined as resection of segments 5 to 8 using minimally invasive techniques (see Part 3, Chapter 15, FIG 2). These techniques include the following:
  - Pure laparoscopic
  - Hand assisted—The surgeon's hand is used to assist during the laparoscopic approach.
  - Hybrid—The liver is mobilized laparoscopically followed by minilaparotomy to divide the liver.
  - Robotic—The liver is resected with robotic technique.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history and physical exam should be performed for each patient.
- A patient's history is important and should include careful attention to the following:
  - Medical history—Is the liver neoplasm benign or malignant? If the neoplasm is malignant, is it a primary of the liver or a metastasis? If the lesion is malignant, has the patient had chemotherapy? Does the patient have underlying liver disease such as cirrhosis? If cirrhosis exists, does the patient have manifestations of advanced liver disease such as esophageal varices, splenomegaly and hypersplenism, ascites, or hepatic encephalopathy? Is the patient healthy enough to withstand liver resection?
  - Surgical history—Has the patient had abdominal surgery in the past? If so, what type of operation and how many operations? Has the patient had prior liver or biliary tract surgery?
  - Social history—Alcohol use is important for consideration of concurrent liver disease.
  - Functional status should be considered when deciding goals of care and whether surgery is appropriate for an individual patient.
- Physical exam should include evaluation for the presence of advanced liver disease such as jaundice/scleral icterus (can also be present with biliary obstruction), gynecomastia, splenomegaly, ascites, and caput medusa. Findings of advanced malignancy, including supraclavicular lymphadenopathy, should be recognized.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Abdominal imaging using computed tomography (CT) or magnetic resonance imaging (MRI) within a short interval of time (within 4 to 6 weeks) prior to surgery is necessary. Attention should be focused on the number of lesions, the location of the lesions (particularly in relation to the hepatic and portal veins [PVs] as well as the inferior vena cava), the character of the background liver (normal, cirrhosis, steatosis), and the proportion of liver that will be left in situ once all hepatic disease is resected.
- For CT scan, a dynamic bolus, contrast-enhanced, multidetector CT using at least a three-phase protocol is ideal. Noncontrast images of the liver are followed by rapid bolus of contrast and images are immediately obtained during peak arterial enhancement (arterial phase) as well as during PV enhancement (portal venous phase). Hypervascular tumors and tumors that receive their blood supply primarily from the hepatic artery (HA) are best visualized on arterial phase. During the portal venous phase, the liver is maximally enhanced and hypovascular lesions on a background of bright-appearing parenchyma can be well-distinguished (**FIG 1**).
- Enhanced hepatic MRI is an equivalent alternative.
- Tissue sampling with core biopsy by ultrasound or CT guidance can be useful to make or confirm a diagnosis.
- Additional diagnostic studies that are necessary prior to operation are basic labs, including a hepatic function panel and coagulation studies. A complete blood count including a platelet count is important to help detect advanced portal hypertension if the patient has cirrhosis. If disease-specific tumor markers are elevated, they are helpful to confirm a diagnosis as well as to follow patients during treatment.

SURGICAL MANAGEMENT AND OPERATIVE TECHNIQUE

- There are several advantages of laparoscopic liver resection when compared to an open technique. These include decreased blood loss, less postoperative pain, quicker return to diet, and a shorter length of stay.[1] These advantages have been demonstrated in case-controlled studies. Additionally, oncologic outcomes (margins, survival) are not compromised when laparoscopic technique is used for patients with hepatocellular carcinoma and metastatic colorectal cancer.[2–4]

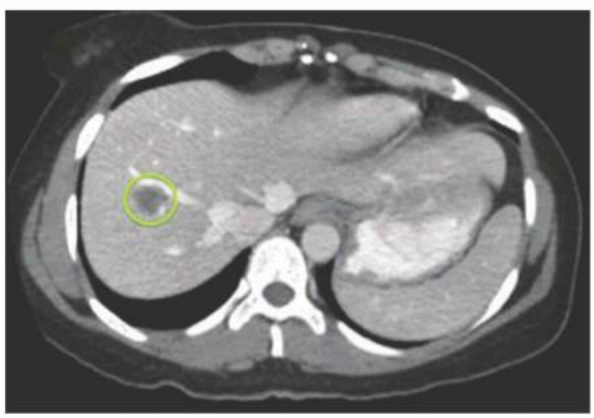

FIG 1 ● CT image of liver, portal venous phase. Encircled is a metastatic colon lesion to the right liver.

- During the World Consensus Conference on Laparoscopic Surgery in 2008, the international position on laparoscopic liver surgery was created—this should be used as a guide to determine which patients are eligible for minimally invasive hepatic resection.[5] This statement recommends surgery with minimally invasive technique for patients with a single lesion of 5 cm or less located in segments 2 to 6. It suggests that major liver resection can be performed with minimally invasive technique but only by those experienced both with liver surgery as well as minimally invasive liver resection. Some surgeons in high-volume centers may choose to operate beyond these criteria in certain settings. Importantly, the consensus conference suggests that the surgeon should be facile with minimally invasive technique, including the skill of intracorporeal suturing should bleeding become an issue.
- The decision to use hand-assisted versus pure laparoscopic technique is surgeon specific and mostly depends on comfort with either technique. As our own experience in laparoscopic hepatectomy has grown, so has our comfort with performing anatomic hepatic resection in a pure laparoscopic manner. When comparing pure laparoscopic technique to hand-assisted or hybrid technique in 113 patients undergoing anatomic liver resection, we found similar results for estimated blood loss and complications; however, interestingly, shorter operative times were noted in the pure laparoscopic group (188 minutes vs. 264 minutes for the pure vs. hand-assisted technique, $P < .05$).[6]
- Consideration of the background liver is important to help decide which patients are appropriate for resection—up to 80% of a healthy liver in a relatively healthy patient can be resected without major consequence. This percentage decreases if the liver is cirrhotic.
- The technique of minimally invasive right hepatectomy is, as intended, the same as for open surgery except minimally invasive equipment is used.
- Two surgeons who are experienced in hepatobiliary and minimally invasive surgery are appropriate for these cases. An assistant to hold the camera is optimal, thus allowing both hands of both surgeons to be free.

HAND-ASSISTED LAPAROSCOPIC RIGHT HEPATECTOMY

- The patient is positioned supine with the arms tucked. Padded barriers are secured at the patient's feet to prevent sliding with the anticipated use of steep reverse Trendelenburg during the case.
- Access is gained to the abdominal cavity via a 5-mm port ideally in the left upper quadrant (LUQ), and pneumoperitoneum of 12 mmHg is created. Additional ports are placed using a 5-mm 30-degree scope for visualization (**FIG 2**). These ports include an 8-cm hand access site in the supraumbilical position. Two 12-mm ports are placed in the subxiphoid and right paramedian position, and two 5-mm ports are placed in right subcostal positions. The camera is switched to a 10-mm 30-degree scope in the right paramedian port.
- The lesion is identified.
- Standing at the patient's left, the surgeon places his or her nondominant hand through the hand access device.
- The round and falciform ligaments are divided using a sealing device, exposing the anterior surface of the hepatic veins.
- The ligamentous attachments of the right liver are dissected. With the patient in reverse Trendelenburg position and with the right side up, the gallbladder fundus is retracted superiorly via a grasper in the LUQ port. The right lobe of the liver is retracted anteriorly using a closed grasper in the subxiphoid port. With a hand retracting the colon inferiorly, the hepatic flexure is dissected using a cautery device. The colon is reflected inferiorly. Attachments to the duodenum are dissected from the liver as necessary. Using hand assistance for ligament exposure, the right triangular and coronary ligaments are dissected up to the right hepatic vein (RHV)/inferior vena cava (IVC), also using a sealing device (**FIG 3**).
- Laparoscopic ultrasound of the liver is performed via the 12-mm subxiphoid port to confirm anatomy and ensure that the procedure will include the pathology that is anticipated.

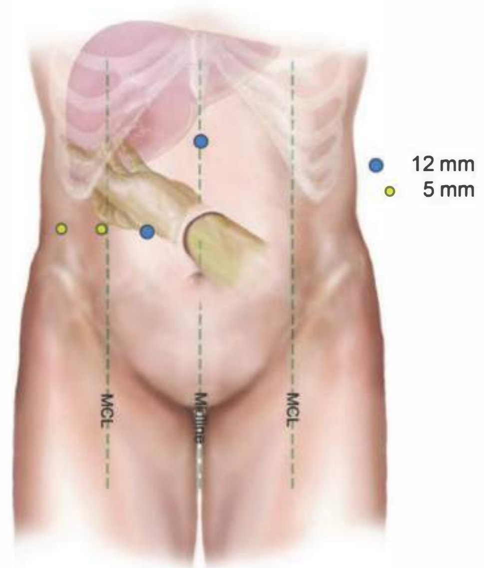

FIG 2 ● Port placement for minimally invasive right hepatectomy. For the pure laparoscopic method, a 12-mm port is used instead of a hand port in the supraumbilical position. *MCL,* middle clavicular line. Used with kind permission from Randal S. McKenzie/McKenzie Illustrations.

FIG 3 ● Dissection of the ligamentous attachments of the right liver. Used with kind permission from Randal S. McKenzie/McKenzie Illustrations.

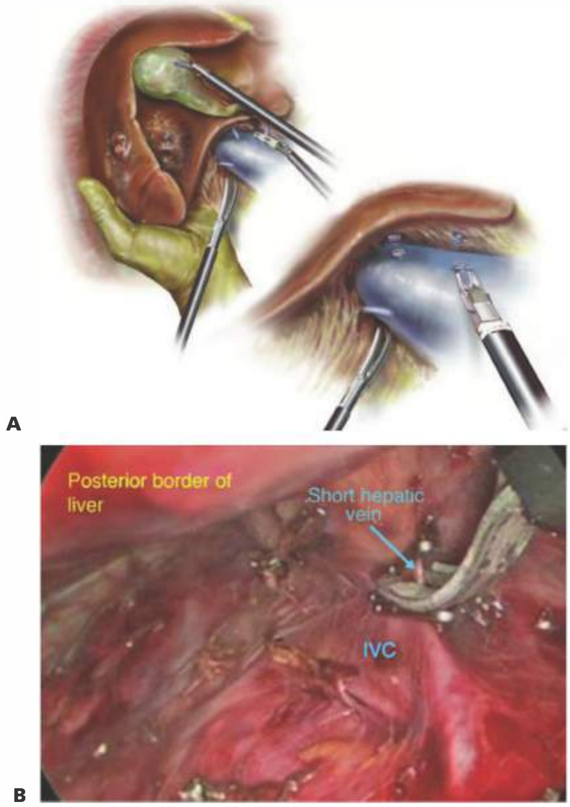

FIG 4 ● **A.** Dissection of the short hepatic veins from the IVC. Short hepatic veins are defined with a dissector and ligated using a sealing device or clips and shears. **B.** Dissection of the short hepatic veins from the IVC. Short hepatic veins are clipped and divided with shears. Used with kind permission from Randal S. McKenzie/McKenzie Illustrations.

- The IVC is dissected (FIG 4A,B). For exposure, the gallbladder is retracted superiorly from a grasper in the LUQ port. Hand assistance is used to retract the liver anteriorly, exposing the IVC. The liver is mobilized from the inferior vena cava by identifying and ligating short hepatic veins. Ligation is performed using clips, and endoscopic shears or a sealing device is used to cut the veins. This is performed up to the RHV.
- Cholecystectomy and portal dissection. The hand is removed from the abdominal cavity, and the liver is allowed to rest back in normal position. A 5-mm assist port is placed in the hand access device. The gallbladder is grasped and dissected for cholecystectomy in standard laparoscopic manner. After identifying the critical view, the cystic artery and duct are clipped. The cystic artery and duct are transected. While maintaining superior retraction of the gallbladder, portal tissue is retracted laterally via a grasper in one of the lateral 5-mm ports. The hepatoduodenal ligament is dissected using a combination of an endoscopic dissector and hook cautery via the subxiphoid port. The right HA is identified and defined (FIG 5). If space allows, this is stapled using a vascular load roticulating stapler through the 12-mm subxiphoid port. Otherwise, this can be tied laparoscopically, clipped, and then transected. Next, the right PV is identified and defined (FIG 6). A silk tie is placed around it (this is not tied), and a grasper in one of the right lateral ports retracts this tie superolaterally to ex-

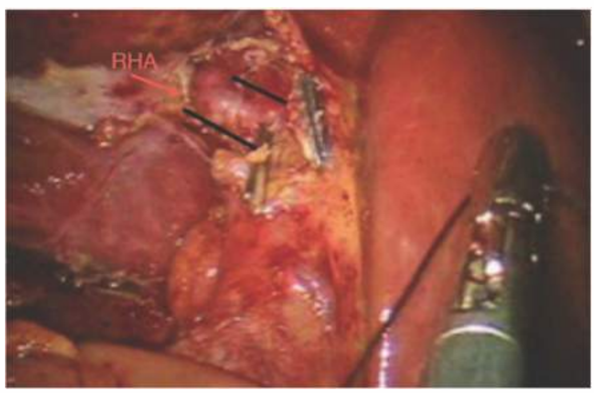

FIG 5 ● Portal dissection. Exposure of the right hepatic artery (RHA).

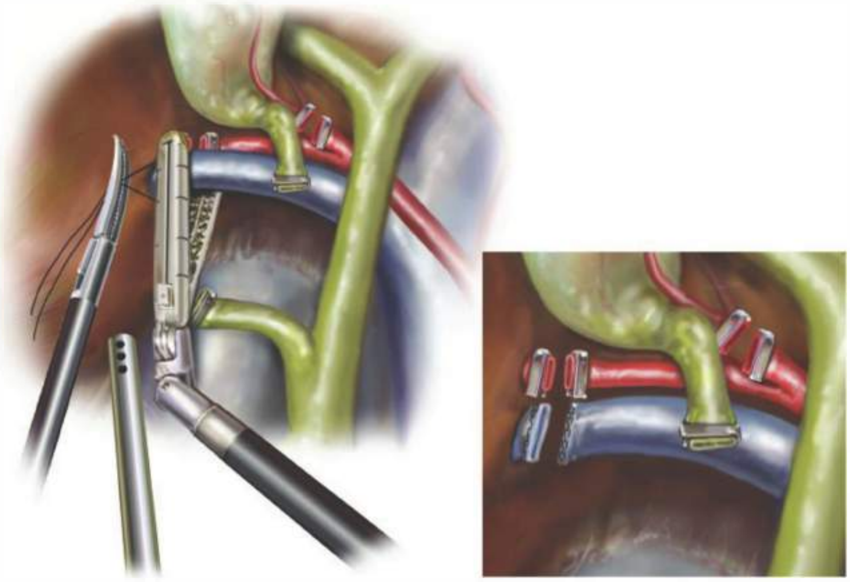

FIG 6 ● Portal dissection, ligation of the right PV. Used with kind permission from Randal S. McKenzie/McKenzie Illustrations.

pose the full length of the vein. A vascular load roticulating stapler is used to ligate and transect the right PV. The right hepatic duct (HD) is identified and defined. It is tied distally, then transected proximally. It is important to identify bile coming from the proximal duct (**FIG 7**). Once bile is identified, the proximal duct can be clipped to maintain a clean field. The free, distal end of the right HD is doubly clipped to prevent leak. After the portal dissection is completed, the gallbladder is dissected from the gallbladder fossa.

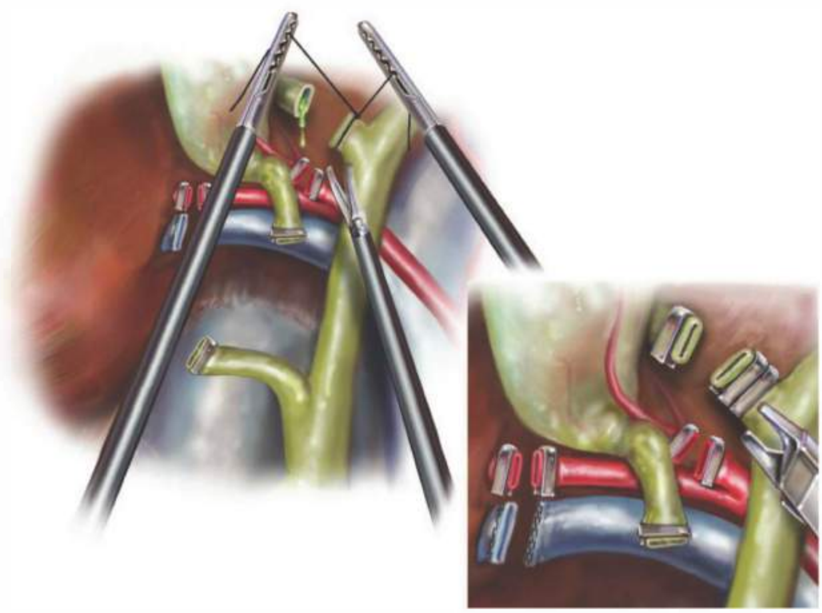

FIG 7 ● The right HD is identified and defined. It is tied distally, then transected proximally. It is important to identify bile coming from the proximal duct. Used with kind permission from Randal S. McKenzie/McKenzie Illustrations.

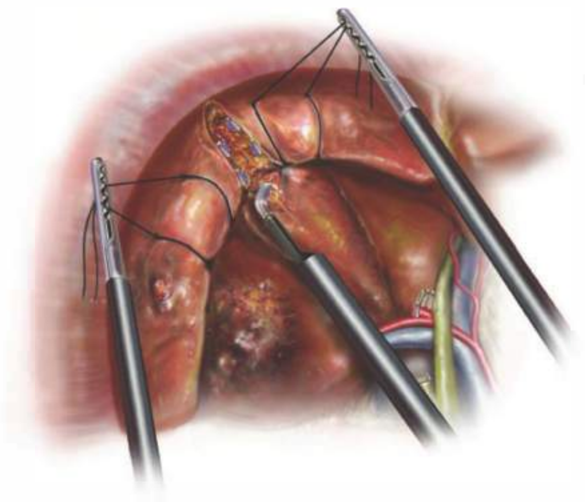

FIG 8 ● Parenchymal transection. Used with kind permission from Randal S. McKenzie/McKenzie Illustrations.

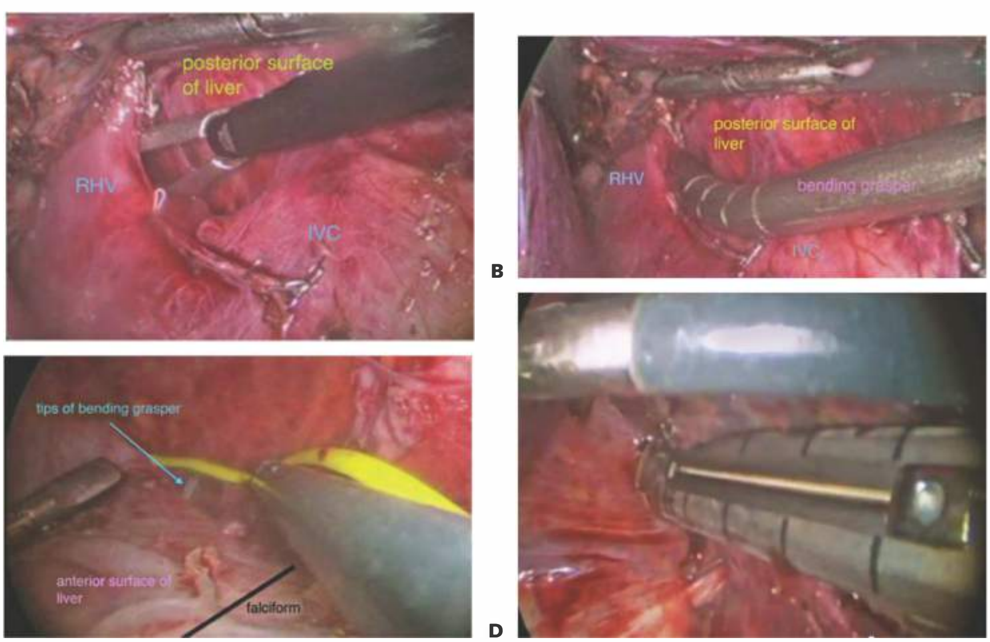
- The parenchyma is transected. All retracting instruments are removed, allowing the liver to drop. The line of transection is defined using hook cautery, following the line of demarcation on the liver's anterior surface. Ultrasonography is repeated to ensure again that the pathology will be included in the point of transection. Figure-of-eight stitches using 0-Polysorb are placed on either side of the line of transection, and these are retracted to either side with graspers (**FIG 8**). The parenchyma is coagulated, placing clips when appropriate. Progress is made along the line of transection until the RHV is encountered. Using a vascular load roticulating stapler through the 12-mm assist port, the RHV is stapled intraparenchymally. The remaining parenchyma is divided as necessary.
- For tumors that are close to the RHV-IVC junction, the RHV can be isolated and transected in an extrahepatic manner. To accomplish this, first the anterior surface of the RHV is dissected along its medial edge, creating a window to the undersurface of the liver. The short hepatic veins should have already been dissected and ligated along the IVC at this point. The RHV is dissected from the undersurface of the liver using a dissecting instrument while lifting the liver anteriorly (**FIG 9A**). A bending grasper is placed anterior to the RHV and advanced through the window that has been created toward the anterior surface of the liver (**FIG 9B**). The liver is allowed to fall back into place, and the bending grasper is visualized from the anterior surface of the liver through the window created. A vessel loop is fed to the grasper, and the grasper gently pulls back through to the undersurface of the liver. The other end of the vessel loop is fed around the lateral border of the RHV from an anterior approach as well. The lateral edge of the liver is retracted anteriorly again, and both



A B C D

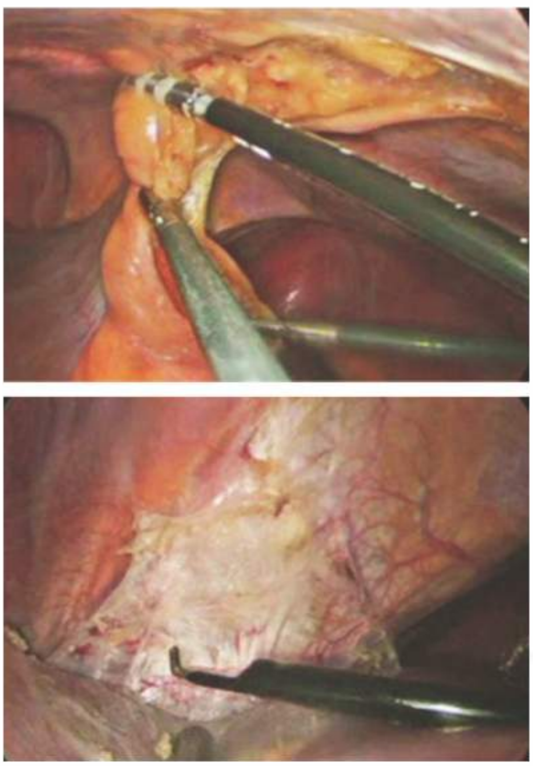
FIG 9 ● **A.** Dissection of the RHV extrahepatic ligation. **B.** Maneuvering around the RHV with a bending grasper. **C.** Isolating the RHV with a vessel loop. The bending grasper comes anterior to the RHV from the undersurface of the liver. With the liver allowed to fall back into place, a vessel loop is fed to this bending grasper, which then pulls the vessel loop under the liver.

ends of the vessel loops should be around the RHV, thus having a defined isolation of this vein (**FIG 9C**). The vessel loop can then retract the vein gently, acting as a guide while a stapler is introduced. The vessel is ligated and transected with a vascular load roticulating stapler.

- The specimen is collected using a laparoscopic bag. Hemostasis on the resection bed of the liver is ensured.
- Saline and contrast cholangiograms are performed through the cystic duct to confirm no biliary leak. The gallbladder is removed from the abdomen using a laparoscopic bag.
- The abdomen is closed. Laparoscopic equipment is used to remove ports under direct visualization and close fascia using a port site closure device. Fascia at the hand site is closed from the outside in standard manner. The skin is closed.

PURE LAPAROSCOPIC RIGHT HEPATECTOMY

- Patient positioning and port placement are similar to that used for the hand-assisted procedure described. Instead of a hand port, however, an additional 12-mm port is used in the supraumbilical position. All steps are the same as described for the hand-assisted procedure except that a laparoscopic instrument is used instead of a hand.
- The round and falciform ligaments are divided using a sealing device, exposing the anterior surface of the hepatic vein (**FIG 10A,B**).



A

B

FIG 10 ● **A.** Laparoscopic dissection of the falciform ligament. **B.** Exposure of the anterior surface of the left/middle hepatic veins after dissection of the falciform ligament.

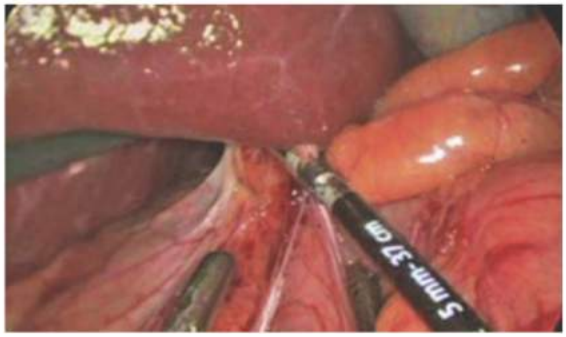


FIG 11 ● Laparoscopic dissection of ligamentous attachments of the right liver.

- The ligamentous attachments of the right liver are dissected. With the patient in reverse Trendelenburg position and with the right side up, the gallbladder fundus is retracted superiorly via a grasper in the LUQ port. The right lobe of the liver is retracted anteriorly using a closed grasper in the subxiphoid port. With a grasper retracting the colon inferiorly, the hepatic flexure is dissected using a cautery device. The colon is reflected inferiorly. Attachments to the duodenum are dissected from the liver as necessary. The right triangular and coronary ligaments are dissected up to the RHV/IVC (**FIG 11**).
- Laparoscopic ultrasound of the liver is performed via the 12-mm subxiphoid port.
- The IVC is dissected. For exposure, the gallbladder is retracted superiorly from a grasper in the LUQ port. A closed grasper is used via the supraumbilical port to retract the liver anteriorly, exposing the IVC. The liver is mobilized from the inferior vena cava by identifying and ligating short hepatic veins (**FIG 4B**).
- Cholecystectomy, portal dissection, parenchymal transection. This is similar to what is described in the hand-assisted section.
- The specimen is collected using a laparoscopic bag. Hemostasis on the resection bed of the liver is ensured.
- Saline and contrast cholangiograms are performed through the cystic duct to confirm no biliary leak. The gallbladder is removed from the abdomen using a laparoscopic bag.
- The abdomen is closed. Laparoscopic equipment is used to remove ports under direct visualization and close fascia using a port site closure device. The skin is closed.

PEARLS AND PITFALLS

Patient selection	■ A careful evaluation of history, exam, and laboratory findings is essential to avoid encountering unexpected liver disease. ■ High-quality imaging is essential for operative planning to ensure an adequate margin can be obtained.
Operative technique	■ Pre- and intraoperative restrictive resuscitation reduces blood loss. ■ Attention to hemostasis is essential for laparoscopic liver resection. ■ Use the shafts of instruments or specifically designed, expanding instruments to retract the liver—puncturing or lacerating the capsule must be avoided. ■ Be constantly vigilant of potential gas embolism—use reduced insufflation pressure when possible.
Postoperative care	■ Venous thromboembolism remains a risk, even if the international normalized ratio (INR) is elevated. Use chemoprophylaxis.

POSTOPERATIVE CARE

- It is imperative that postoperative care is maintained by a team of individuals familiar with these patients and cases. It is also imperative that care is maintained in a facility equipped to provide care for patients who suffer major postoperative complications, for example, patients who require prolonged intubation or urgent hemodialysis postoperatively. Labs, including a hepatic function panel and coagulation panel, should be followed and trended.

OUTCOMES

- Laparoscopic liver resection, including hand assisted as well as purely laparoscopic, has been used with increasing frequency. There are several advantages to this procedure and they include decreased blood loss, less postoperative pain, faster return to diet, and shorter length of stay when compared to open surgery. Oncologic outcomes are not compromised with these techniques, and survival is similar when compared to survival in patients with hepatocellular carcinoma or metastatic colorectal cancer who undergo open surgery. It is technically demanding and should be performed by surgeons experienced with hepatobiliary surgery.

COMPLICATIONS

- Bleeding
- Infection
- Bile leak
- Liver failure
- Kidney failure in association with liver failure
- Close or positive margins

Chapter 25

Left Hepatic Lobectomy

Jon S. Cardinal

DEFINITION

- The liver has a segmental anatomy that is defined by the intrahepatic distribution of the portal triad structures. There are eight liver segments (**FIG 1**) with the left hepatic lobe being constituted by segments 2 to 4 and the right lobe being constituted by segments 5 to 8. Segment 1, the caudate lobe, which is distinct from both the left and right lobes.
- The boundary between the right and left lobes of the liver is an imaginary line, known as Cantlie's line, which runs from the gallbladder anteriorly to the inferior vena cava (IVC) posteriorly.
- Left hepatic lobectomy is considered a major anatomic liver resection and is defined by the removal of the liver segments that constitute the left hepatic lobe (2 to 4).

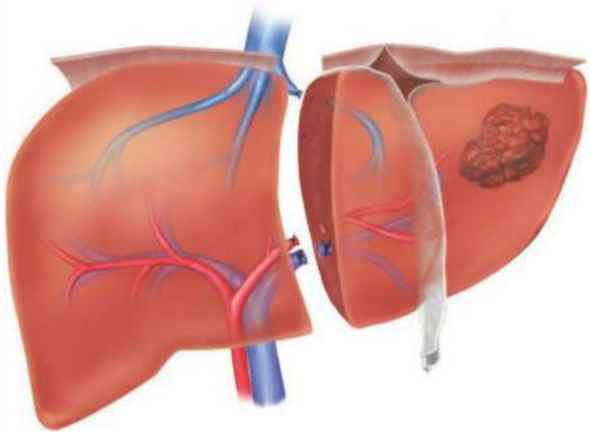

FIG 2 ● Drawing illustrating the segments to be excised during left hepatic lobectomy. Left hepatic lobectomy involves removal of segments 2 to 4 and requires division of the left hepatic artery and left portal vein (inflow structures) as well the left hepatic duct and left hepatic vein (outflow structures).

DIFFERENTIAL DIAGNOSIS

- Indications for left hepatic lobectomy include both benign and malignant etiologies, neoplastic and nonneoplastic processes, and conditions that are either primary or secondary to the liver itself.
- Generally, left hepatic lobectomy will need to be performed when the condition that is being treated requires division of any (or all) of the major inflow (portal vein, hepatic artery) and/or outflow (left or middle hepatic vein, left hepatic duct) structures to the left lobe of the liver (**FIG 2**).

PATIENT HISTORY AND PHYSICAL FINDINGS

- The single biggest preoperative factor to account for when considering patients for major anatomic liver resection, including left hepatic lobectomy, is the health of the native background liver.
- In a patient with a healthy background liver, anatomic trisegmentectomy can be performed and tolerated; however, in patients with chronic liver disease of any kind, the extent of resection needs to be carefully weighed against the possibility of postoperative liver insufficiency and/or failure.
- Among others, historical factors that may indicate the presence of underlying chronic liver disease include accurate quantification of alcohol use (current and past); identification of risk factors for viral hepatitis exposure (intravenous [IV] drug abuse, tattoos, promiscuous sexual behavior, history of blood transfusions); comorbidities that predispose to nonalcoholic fatty liver disease (NALFD) such as hypertension, hyperlipidemia, diabetes, and high cholesterol; prior chemotherapy exposure(s) in cases of patients who are being considered for liver resection for oncologic purposes, the type and duration of which can predispose to chemotherapy-associated steatohepatitis (CASH); and past history suggestive of liver decompensation including prior episodes of jaundice, gastrointestinal (GI) bleeding, ascites production, and so forth.
- Findings on physical examination of the stigmata of cirrhosis are indicative of advanced chronic liver disease and are generally considered as contraindications for major liver resection (Table 1).

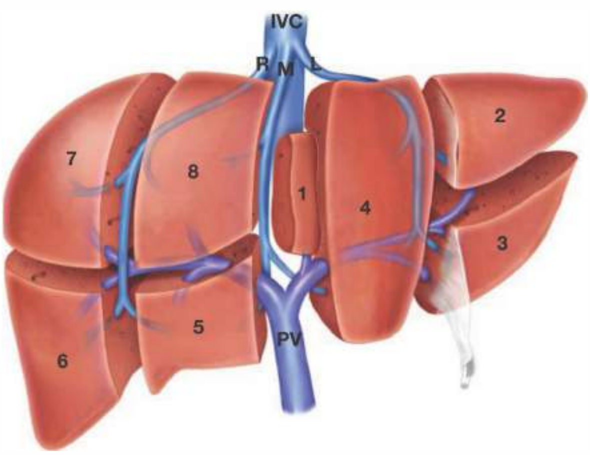

FIG 1 ● Drawing illustrating the segmental anatomy of the liver. The liver is divided into eight anatomic segments with the left and right lobes being separated by Cantlie's line (an imaginary line between the gallbladder fossa anteriorly and the IVC posteriorly). The left lobe is made up of segments 2 and 3 (left lateral segments) and segment 4 (left medial segment).

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Standard blood work including a complete blood count, complete metabolic panel, and coagulation panel are required prior to proceeding with any major liver surgery.

Table 1: Clinical History and Physical Examination Findings Associated with Cirrhosis

History
Fatigue or weight loss
Jaundice (icterus; skin, urine, and stool color)
Anorexia, cachexia
Abdominal pain
Edema
Ascites
GI bleeding, hemorrhoids
Loss of libido or menstrual cycle
Encephalopathy
Physical Examination
Malnutrition
Fetor hepaticus
Jaundice, scleral icterus
Spider angiomata
Clubbing, palmar erythema
Gynecomastia, testicular atrophy
Ascites
Abdominal hernia
Caput medusa
Hepatosplenomegaly
Asterixis

GI, gastrointestinal.

When the history and/or physical examination points to a chronic, underlying liver disease, additional serologic testing for any of the viral hepatitides as well as other obscure causes of cirrhosis (hemochromatosis, Wilson's disease, etc.) may be advisable. In cases of liver tumors, carcinoembryonic antigen (CEA), α-fetoprotein (AFP), and/or carbohydrate antigen 19-9 (CA19-9) levels occasionally can provide diagnostic clarity and therefore should routinely be obtained.

- Ultrasonography can identify cirrhotic liver morphology by providing information on the size, contour, and echotexture of the liver. While this modality has the advantage of being noninvasive, it is also highly operator dependent.
- When planning major liver surgery, high-quality cross-sectional imaging is a prerequisite. Either computed tomography (CT) or magnetic resonance imaging (MRI) can be used. Contrast enhancement, which should include both an early hepatic arterial phase as well as a delayed portal venous phase (so-called liver protocol scan), is the best manner in which to obtain detailed images of the liver as well as the relationship of tumor(s) to the major intra- and extrahepatic structures.
- Additionally, liver protocol scans can, in some instances, obviate the need for invasive biopsy and the risks associated therein due to the fact that certain liver tumors including simple cysts, hemangioma, focal nodular hyperplasia, and hepatocellular carcinoma have radiographic appearances that can be diagnostic in the appropriate clinical setting.
- MRI/magnetic resonance cholangiopancreatography (MRCP) may be preferred in cases in which bile duct resection/reconstruction is a possibility, as this modality provides superior anatomic definition of the biliary anatomy in comparison to CT scan alone.
- Specifically, in regard to left hepatic lobectomy, careful attention should be paid to the relationship of any tumor(s) within the left lobe to the left hilar structures as well as the left hepatic vein and/or common trunk (**FIG 3A**). Well-described anatomic variants, such as a replaced or accessory left hepatic artery (**FIG 3B**) or a right posterior hepatic duct arising from the main left hepatic duct (**FIG 3C**), should be carefully evaluated for as their presence may alter the conduct of the operation.

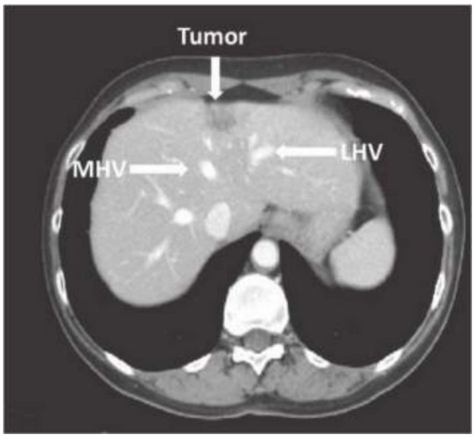
SURGICAL MANAGEMENT

Preoperative Planning

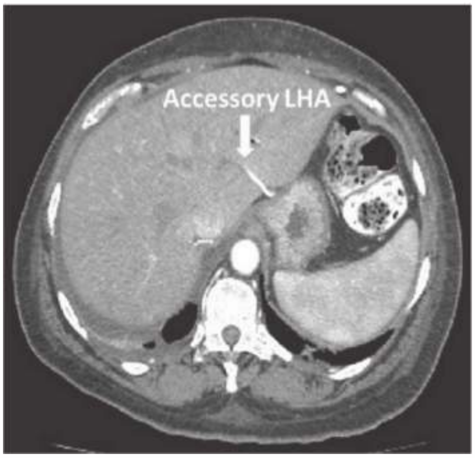
- The most important step prior to performing any major liver operation is thorough and careful review of the available preoperative imaging studies. Understanding the relationship of tumor to major intra- and extrahepatic structures allows the surgeon to anticipate and plan strategies for dealing with point(s) during the parenchymal transection that may be challenging or where close margins may be anticipated.
- Adequate preparation for major liver surgery involves having blood available (two to four units of crossmatched packed red blood cells [PRBCs]) in the event of intraoperative hemorrhage.
- Preoperative discussion with the anesthesiologist is advisable with important points of consideration to include possible epidural or paravertebral nerve block placement for perioperative analgesia as well as choosing which invasive monitoring devices will be required. For left hepatic lobectomy, it is recommended that a central venous catheter be placed so that low central venous pressure (CVP) (5 mmHg or less) can be maintained up until the point that the parenchymal transection is complete. Additionally, arterial line placement is warranted. A nasogastric tube (NGT) for gastric decompression is recommended.

Positioning

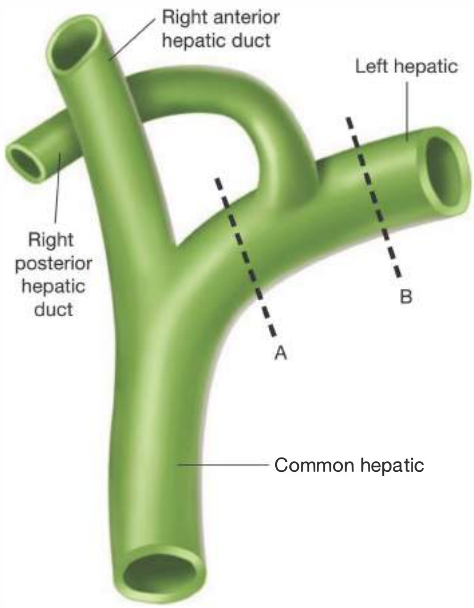
- For left hepatic lobectomy, patients should be positioned supine with the arms out on arm boards at 60 degrees. The area to be prepped and draped starts cranially at the nipple line, extends caudally to the symphysis pubis, and laterally carries down to the table on both sides. A Foley catheter is required, and both lower and upper body forced air heated blankets should be applied to maintain normothermia.



A



B



C

FIG 3 ● **A.** CT scan showing the relationship of a metastatic colorectal cancer tumor deposit to the middle hepatic vein (MHV) and left hepatic vein (LHV), respectively. **B.** CT scan showing an accessory left hepatic artery (LHA) coming off of the left gastric artery and coursing through the gastrohepatic ligament. **C.** Drawing showing the right posterior (RP) sectoral duct arising from the left hepatic (LH) duct. When this anatomic variant exists during a left hepatic lobectomy if the LH duct is transected in plane *A*, the RP segments (6 and 7) will be disconnected from the biliary tree. If the LH duct is transected in plane *B*, the RP ducts will remain connected to the main biliary tree and be able to drain.

STEP 1: SKIN INCISION/OPENING THE ABDOMEN

- The optimal incision for any major liver surgery is a right subcostal incision with an upper midline extension. The subcostal incision should be marked out three fingerbreadths below the right costal margin and be carried out laterally to where the floating 12th rib can be palpated (**FIG 4A**). Alternative choices for incision include a bilateral subcostal incision with (Mercedes) or without (Chevron) an upper midline extension. A long midline laparotomy can also be utilized.
- The skin and subcutaneous tissue is opened to expose the anterior fascia. The right anterior rectus sheath is opened first to expose the right rectus muscle, which is followed medially until the midline is identified. The midline is then opened, staying anterior to the preperitoneal fat pad up to the level of the xyphoid process, which can be removed to facilitate exposure if necessary.
- The right rectus and external oblique muscles are then divided with cautery (**FIG 4B**) and the posterior rectus sheath is exposed. Upward traction is placed on the upper and lower skin flaps and the peritoneal cavity is entered along the subcostal portion of the incision.
- The preperitoneal fat pad is excised off of the undersurface of the upper midline portion and the falciform ligament is divided. The round ligament is ligated and divided between 2-0 silk ties (**FIG 4C**).

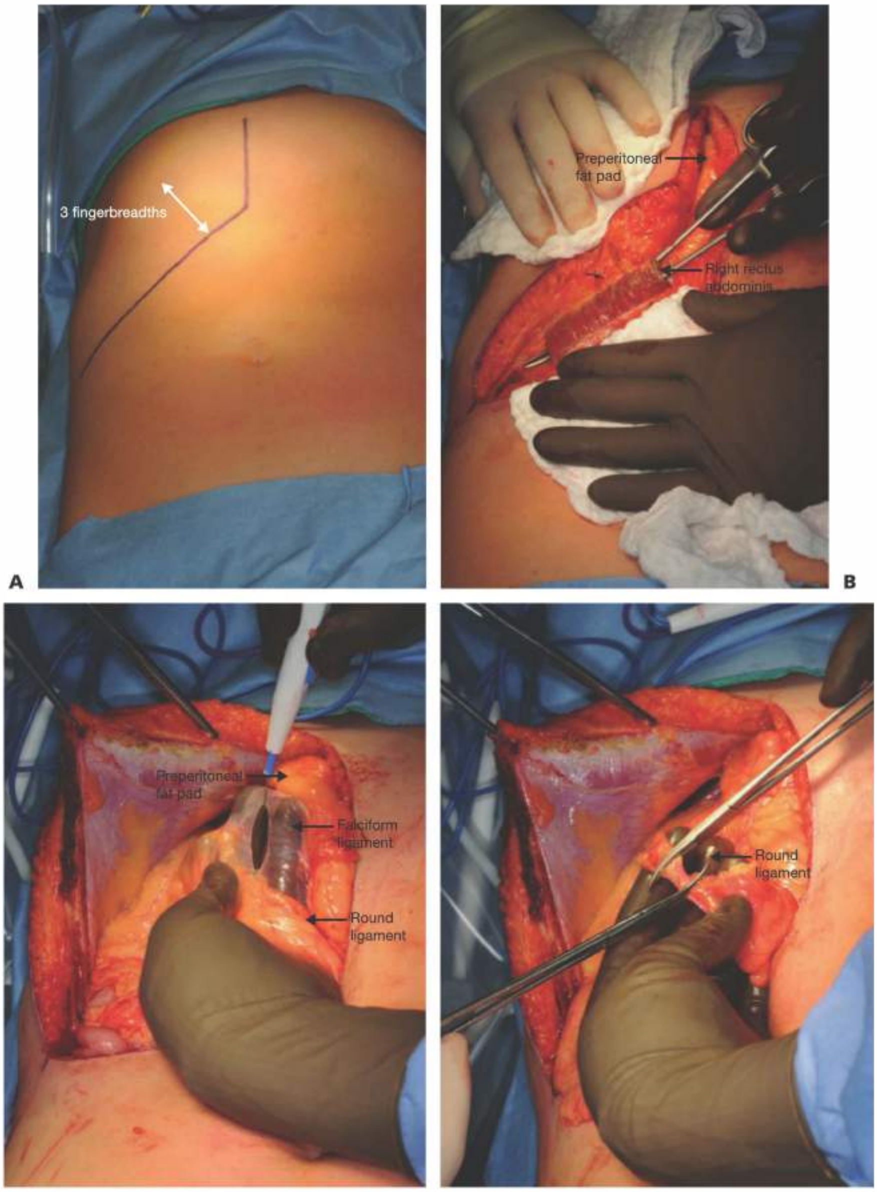


FIG 4 ● Intraoperative photo of proper placement of a right subcostal incision with upper midline extension. The subcostal portion of the incision should be placed three fingerbreadths below the costal margin. **B.** Intraoperative photo of the right rectus muscle which is eventually divided with cautery. **C.** Intraoperative photo showing the division of the falciform and round ligaments.

STEP 2: PLACEMENT OF THE TABLE-MOUNTED RETRACTOR

- Exposure during open liver surgery requires the use of a table-mounted retractor. The preferred retractor for this author is the Thompson-Farley liver retractor. Other options include the Bookwalter or Omni retractor systems.
- Regardless of the chosen retractor, the principles for exposure are the same and include cephalad and lateral retraction of the bilateral rib cages, caudal retraction on the right kidney, caudal and medial retraction on the second portion of the duodenum, and lateral retraction of the stomach (**FIG 5**).
- Initial exposure is gained with upward and lateral retraction on the bilateral rib cages and having the patient placed in slight reverse Trendelenberg position. It is during the hilar dissection that the right kidney, duodenum and stomach blades are placed to facilitate exposure of the hepatoduodenal ligament.

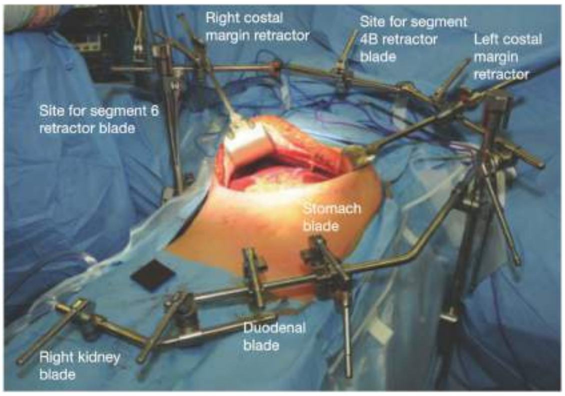

FIG 5 ● Intraoperative photo of the setup of the table-mounted retractor. A thin, malleable blade is used to retract segments 6 and 4B during the open cholecystectomy. Abdominal wall retractors are used to provide cephalad and lateral retraction on the right and left rib cages. The right kidney, duodenum, and stomach are retracted inferiorly, inferomedially, and laterally, respectively, using malleable blades.

STEP 3: EXPOSURE OF THE HEPATIC VEINS/LEFT LOBE LIVER MOBILIZATION

- With the rib cages being retracted as mentioned earlier and solid dorsal and caudal traction being applied to the anterior surface of the liver, the falciform ligament is divided midway between the anterior abdominal wall and liver capsule. The dissection is carried posteriorly toward the diaphragm and hepatic veins.
- Once the falciform ligament begins to splay apart into the right and left triangular ligaments, dissection with a tonsil clamp and cautery to release the right triangular ligament is performed. This will expose the anterior surface of the right hepatic vein. Medially, a notch between the right hepatic vein and the common trunk of the middle and left veins can be palpated with an index finger.
- Next, the left triangular ligament is divided in a similar manner to expose the anterior surface of the common trunk. The left phrenic vein, which drains into the left hepatic vein, serves as a reliable landmark that can aid in the identification of the left vein and common trunk (**FIG 6**).
- Once the anterior surfaces of the hepatic veins are exposed, a lap pad is placed under the left lateral segments of the liver and above the stomach, and the remainder of the left triangular ligament is divided. This exposes the lateral wall of the left hepatic vein and mobilizes the left lateral segments completely.
- The gastrohepatic ligament is opened widely, and an accessory left hepatic artery (if present) is doubly ligated between 2-0 silk ties and divided.
- The ligamentum venosum (Arantius' ligament) is divided caudally. This plane of dissection leads to the left-sided hilar structures.

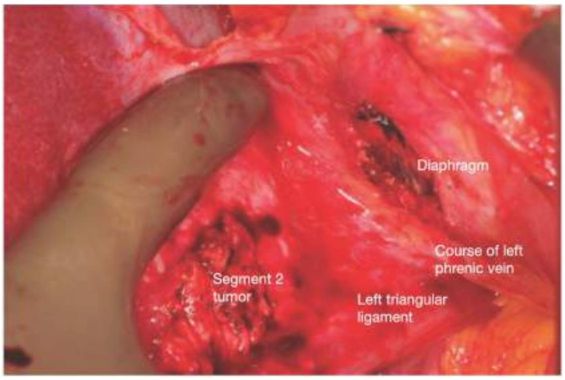

FIG 6 ● Intraoperative photo of a tumor in segment 2 of the left lobe. The relationship of the tumor to the left triangular ligament, diaphragm, and course of the left phrenic vein is identified in the photo. Releasing the left triangular ligament will allow for the left lateral segments to be rotated anteriorly and to the right. The course of the left phrenic vein is an important anatomic landmark during left hepatic lobectomy as it will eventually insert into the left hepatic vein.

STEP 4: OPEN CHOLECYSTECTOMY/ INTRAOPERATIVE LIVER ULTRASOUND

- If the gallbladder is still present, a standard top-down cholecystectomy is performed. The cystic artery is doubly ligated and divided, and the gallbladder is left attached to the cystic duct for saline and contrast cholangiogram at the completion of the case.
- An intraoperative ultrasound is performed next. The right and left hilar structures are easily identifiable by the white, echogenic halo which surrounds them. These structures are followed ultrasonographically into the

hepatic parenchyma and, if the surgery is being done for a neoplastic process, particular attention is paid to the relationship of tumor(s) to the left hilar structures. Similarly, the outflow structures (hepatic veins) are identified ultrasonographically and followed inside the liver with attention again being paid to the relationship of any tumor(s) to the left and middle hepatic veins. Next, a systematic intraoperative liver ultrasonography is performed to rule out any additional tumors within other segments of the liver.

STEP 5: INFLOW AND OUTFLOW CONTROL

- Apply a tonsil clamp to the divided round ligament and retract it with solid anterior and rightward traction.
- Any parenchymal bridges between the left lateral and left medial segments are divided, typically with cautery (**FIG 7**).
- The left hilum is dissected at the base of the umbilical fissure. The left hepatic artery is dissected circumferentially and doubly ligated and divided (after a test clamp is performed and maintenance of the right hepatic arterial pulse is confirmed).
- Next, the left portal vein is dissected at the base of the umbilical fissure and is transected distal to the takeoff of the caudate branch using a vascular load of a linear cutting stapler.
- Next, a hepatotomy is made 1 cm cephalad to the base of the umbilical fissure in segment 4B and a blunt Kelly clamp is passed through the hepatic parenchyma behind the left hilar plate. The Kelly clamp should emerge from the parenchymal tunnel anterior to the caudate lobe. A moistened umbilical tape is passed through the parenchymal tunnel and a vascular load of a linear cutting stapling device is used to transect the left hepatic duct.
- Next, the common trunk of the left and middle hepatic veins are encircled by passing a large, blunt right-angle clamp from the notch between the right vein and common trunk posteromedially behind the common trunk. Once isolated, the common trunk is divided using a vascular load of a linear cutting stapler.

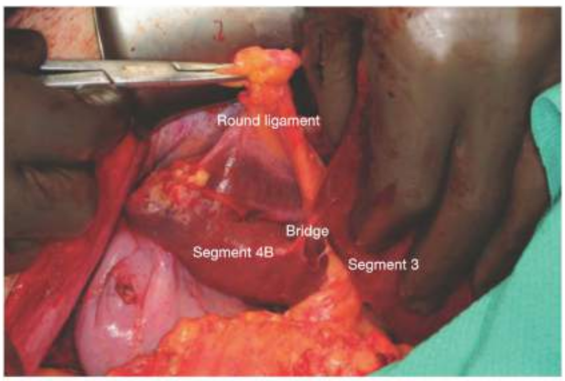

FIG 7 ● Intraoperative photo of a thin parenchymal bridge between segments 4B and 3, the thickness of which can vary. During left hepatic lobectomy, dissection of the left hilar structures begins by dividing this bridge, which allows for exposure of the base of the umbilical fissure, where the inflow structures to the left lobe can be safely identified and dissected out extrahepatically.

STEP 6: PARENCHYMAL TRANSECTION

- At this point, with the inflow and outflow divided, the left lobe will demarcate.
- Repeat ultrasound is performed to confirm the plane of parenchymal transection, which is marked on the liver capsule with electrocautery. Attention is paid to the course of the middle hepatic vein, which should not be bisected inside the liver. The plane of transection can be chosen such that a 1-cm bridge of devascularized liver can be safely left inside the patient in an attempt to avoid the intrahepatic course of the middle hepatic vein (1) if needed and (2) if the surgical margin is not compromised.
- Cautery is used to perform the initial 1 to 2 cm of parenchymal transection after which the LigaSure device is used. When the parenchymal slice is deepened and middle vein branches are encountered, a Pringle maneuver is performed by doubly passing a fat blue vessel loop around the hepatoduodenal ligament and cinching it down with a short, blunt right-angle clamp (**FIG 8**).
- The remainder of the transection is performed by using a blunt kelly clamp to make parenchymal tunnels around hepatic vein branches deep inside the liver through which vascular loads of the linear cutting stapler are fired.
- Once the parenchymal transection is complete, the cut surface of the liver is inspected for surgical bleeding which, when encountered, is suture ligated using figure-of-eight 2-0 silk sutures.
- After all surgical bleeding is controlled, the Pringle tape is released and the cut surface is dried using cautery (**FIG 9**).
- Instruct the anesthesiologist to give 1 L of normal saline and 500 mL of 5% albumin as a bolus due to the fact that up until this point in the case, the fluid administration should have been negligible to maintain an adequately low CVP (<5 mmHg).

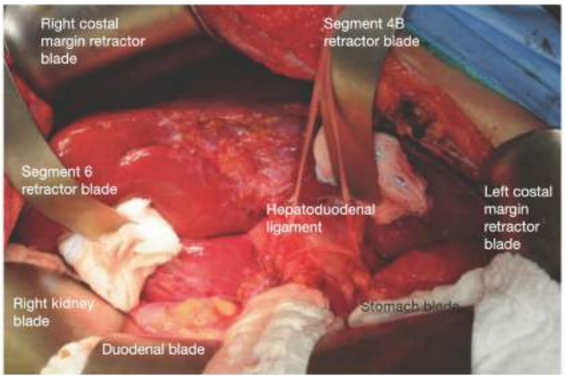

FIG 8 ● Intraoperative photo of a moistened umbilical tape doubly passed around the hepatoduodenal ligament. A fat blue vessel loop can also be used. As the parenchymal transection is deepened, inflow control to minimize bleeding (Pringle maneuver) can be performed by cinching down on the tape or vessel loop and clamping with a short, fat right-angle clamp.

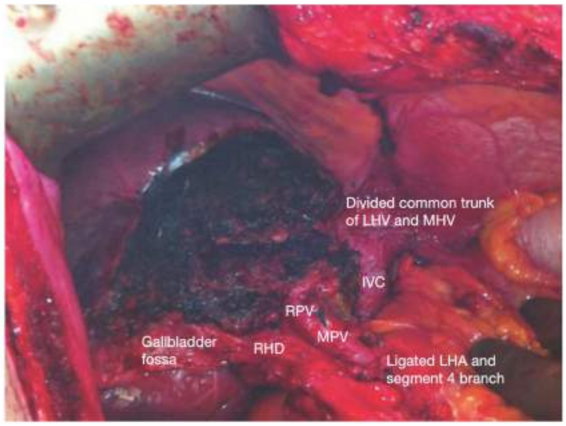

FIG 9 ● Intraoperative photo after completion of the parenchymal transaction. LHV, left hepatic vein; MHV, middle hepatic vein; IVC, inferior vena cava; RPV, right portal vein; MPV, main portal vein; RHD, right hepatic duct; LHA, left hepatic artery.

STEP 7: COMPLETION ULTRASOUND/ SALINE AND CONTRAST CHOLANGIOGRAM/PLACEMENT OF DRAINS AND ABDOMINAL CLOSURE

- A completion intraoperative liver ultrasound is performed with attention being paid to the inflow to and outflow from the remnant right lobe, which, once confirmed, concludes the need for any further ultrasound evaluation.
- A saline cholangiogram is performed through the cystic duct. The common bile duct and parenchymal cut surface are inspected for evidence of saline extravasation, which, if identified, is repaired as deemed appropriate. Next, a contrast cholangiogram is performed to exclude any distal obstruction as well as to confirm adequate biliary drainage from the remnant right lobe. After the completion saline and contrast cholangiogram, the cystic duct is ligated and clipped below the level of the ductotomy and then transected, and the gallbladder is removed and sent for pathologic analysis.
- A closed suction drain is brought through a stab incision in the right lower quadrant, with its tip being oriented along the cut parenchymal surface.
- The midline portion of the wound is closed with simple, interrupted 0-braided nylon sutures and the subcostal portion of the incision is closed in two separate layers using nonabsorbable monofilament suture and the subcostal portion of the incision is closed in two separate layers using absorbable monofilament suture run from lateral to medial and tied in the middle.
- The skin is closed with either surgical clips or, cosmetically, in a running subcuticular manner with 4-0 Vicryl.

PEARLS AND PITFALLS

Indications	■ Patients with chronic liver disease or cirrhosis have an increased risk of postoperative liver insufficiency or failure following left hepatic lobectomy.
Preoperative planning	■ Failure to have adequate IV access and two to four units of crossmatched blood available can lead to problems with resuscitation in the event of significant bleeding. ■ Low CVP (5 mmHg or less) anesthesia is critical for bloodless parenchymal transection.
Exposure of hepatic veins/left lobe liver mobilization	■ Capsular tears in the liver should be avoided as they cause unnecessary bleeding and lead to increased operative duration. ■ The right and left phrenic veins serve as reliable landmarks that can be followed back to their insertion on the right hepatic vein and common trunk, respectively. ■ Careful, steady dissection to expose the anterior surface of the hepatic veins is required as inadvertent injury to these structures can result in massive, uncontrolled bleeding.

Inflow and outflow control	■ Before taking the left hepatic artery, a test clamp should be performed and maintenance of pulsation in the right hepatic hilum should be confirmed. ■ Similarly, inadvertent ligation of the main portal vein as opposed to only the left portal vein can be avoided by taking the left vein high in the umbilical fissure, distal to the takeoff of the branch to the caudate lobe. ■ Dissection to gain control of the common trunk of the middle and left hepatic veins should be done effortlessly as attempts at passing a clamp against resistance can lead to iatrogenic injury to the back wall of the vein or the anterior surface of the vena cava. ■ The left hepatic duct should be taken inside the liver, when possible, in an attempt to stay above the takeoff of an anomalous right posterior duct arising from the left duct, which occurs in roughly 10% to 15% of patients (**FIG 3C**).
Parenchymal transection	■ Several different techniques for parenchymal transection exist. The method described in the text is the preferred method of the author. Familiarization with different techniques is of value; however, one method should be chosen and used as repeatedly as possible. ■ When using the technique described above, the stapler should not be fired until bipolar electrocautery is no longer planned on being used for parenchymal division, as the metal staples interfere with proper functioning of this device. ■ When creating parenchymal tunnels through which staplers can be fired, the Kelly clamp should be passed effortlessly as resistance indicates the presence of a major structure. When resistance is met, a new plane either above or below the one in which the resistance is being encountered should be chosen. ■ Bile leaks from the cut surface should be inspected for carefully and repaired immediately when found.

POSTOPERATIVE CARE

- Admission to an intensive care unit is not necessarily required following left hepatectomy; however, a monitored floor is recommended. This allows for rapid recognition of changes in the patient's vital signs.
- IV fluids should be given liberally (D5 ½ NS + 20 mEq KCl at a rate of 150 mL per hour) for the first 2 postoperative days (PODs).
- The Foley catheter should be maintained for the first 24 to 48 hours postoperatively to ensure adequate urine output. The NGT is left overnight from the night of surgery to the following morning and then is typically removed on POD 1 as long as the output is not too substantial. If removal of the NGT is tolerated, a clear liquid diet can be started on POD 2 and advanced ad libitum.
- While debate about the need for deep venous thrombosis prophylaxis following major liver surgery exists, most now agree that prophylaxis is indicated. Unfractionated heparin given subcutaneously two or three times a day is the preferred method.
- Daily laboratories including complete metabolic panel and blood count should be monitored. Aggressive electrolyte replacement and volume resuscitation are recommended. Particular attention should be paid to the phosphorus level as hypophosphatemia is a relatively typical electrolyte derangement following major liver surgery.
- The volume and character of the drain output should be noted at least once, if not twice daily. The drain can usually be removed the day before or the day of discharge as long as the output is nonbilious in character and not too substantial in regard to volume (<200 mL per day). If the drain is nonbilious but is draining an excessive volume, 25 g of salt-poor albumin (SPA) given twice daily for 48 hours with twice-daily furosemide injections can be given in an attempt to reduce the output. Occasionally, patients need to be sent home with the drain in place simply due to increased ascites production. If this is the case, they should be sent home with a prescription for oral furosemide and be seen back in the clinic in 1 week for possible drain removal.
- Adequate analgesia is a key component of the postoperative care following left hepatectomy. If the patient agreed to epidural or paravertebral catheter placement in the preoperative setting, these are extremely helpful. If regional anesthesia is not being used, a patient-controlled analgesia (PCA) pump is recommended. IV acetaminophen and ketorolac given on a scheduled basis are effective antiinflammatory adjuncts and can minimize the amount of narcotic analgesia that is required. When the patient is tolerating a diet, IV analgesia can be transitioned to an oral regimen.
- Early ambulation and aggressive pulmonary toileting is important to avoid pulmonary complications.

OUTCOMES

- Patients who have undergone an uncomplicated left hepatic lobectomy can typically expect to be discharged to home from the hospital anywhere between PODs 3 and 5.
- Most patients can have their drain removed prior to leaving the hospital (see above) and should be able to participate in most of their usual activities with a few exceptions. These include no heavy lifting (> 10 lb), no driving while requiring narcotic analgesics and no soaking the incision in water.
- When done for benign disease, patients who have undergone following left hepatic lobectomy do not necessarily need to be followed with any specific imaging or laboratory studies. In cases in which the hepatectomy was done for oncologic purposes, the recommended surveillance program includes every 3 months CT scans and tumor markers (when appropriate) for the first year postoperatively, followed by every 6 months for the second year, and then yearly thereafter.

COMPLICATIONS

- Bleeding
- Bile leak. If bilious drainage is noted to be coming from the drain, consideration should be given to endoscopic retrograde cholangiogram and common bile duct stent placement to relieve the back pressure on the biliary tree in an attempt to get the bile leak to seal spontaneously.
- Pulmonary complications
- Postoperative liver insufficiency or failure

Chapter 26

Minimally Invasive Left Hepatic Lobectomy

Trang K. Nguyen   Amer H. Zureikat

DEFINITION

- A minimally invasive left hepatic lobectomy (also termed left hepatectomy or left hemihepatectomy) is the resection of the liver medial to the midplane of the liver (Cantlie's line) using laparoscopic or robotic assistance and is formally defined as the resection of Couinaud segments 2, 3, and 4.[1]
- A left trisectionectomy or extended left hepatectomy (or hemihepatectomy) would also include the adjacent segments 5 and 8 with or without segment 1. A left lateral sectionectomy involves only segments 2 and 3.
- A liver resection is termed laparoscopic if it is a pure laparoscopic procedure, a hand-assisted procedure, or a hybrid technique procedure (which begins as a pure laparoscopic or as a hand-assisted procedure with the liver resection done through a minilaparotomy incision).[2]
- A left hepatectomy is performed for benign and malignant lesions and for living donor transplantation.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A comprehensive history and physical exam should be performed with attention to signs and symptoms of liver failure, coagulopathy, and cardiac disease.
- The same indications for an open left hepatectomy apply to a minimally invasive left hepatectomy and the indications for benign lesions should not be relaxed due to the minimally invasive approach.[2] The indications for resection include hepatic adenoma, symptomatic hemangiomas, symptomatic focal nodular hyperplasia, symptomatic giant cysts, hepatocellular carcinoma, and colorectal cancer metastases.[3]
- The contraindications for a minimally invasive left hepatectomy include those for an open resection, in addition to decompensated cirrhosis, the inability to tolerate pneumoperitoneum, dense adhesions that are not amenable to minimally invasive adhesiolysis, need for extensive portal lymphadenectomy, need for vascular resection, and lesions that are near major vessels.[3,4] Biliary reconstruction is a relative contraindication for robotic-assisted surgery depending on the experience of the surgeon.[5]
- Lesion characteristics that are most favorable for laparoscopic resection include solitary lesions, size of 5 cm or less, peripheral location, and a lack of involvement of the hilum, major hepatic veins, or the inferior vena cava (IVC).[2]

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Preoperative imaging is required to evaluate lesion resectability and for surgical planning. Imaging is useful for evaluation of lesion size, proximity to major vessels and bile ducts, aberrant anatomy, adequacy of anticipated postoperative liver volume, and for detection of lung or other abdominal metastases for malignant indications.
- Contrast-enhanced computed tomography (CT) (**FIG 1**), magnetic resonance imaging (MRI), and positron emission tomography (PET) can be used for preoperative evaluation.[6] A triple-phase CT (arterial, venous, and delayed venous phase) is useful for its spatial resolution and volumetric assessment. MRI is superior for detecting subcentimeter lesions. PET scans may be useful for detecting other sites of metastasis.

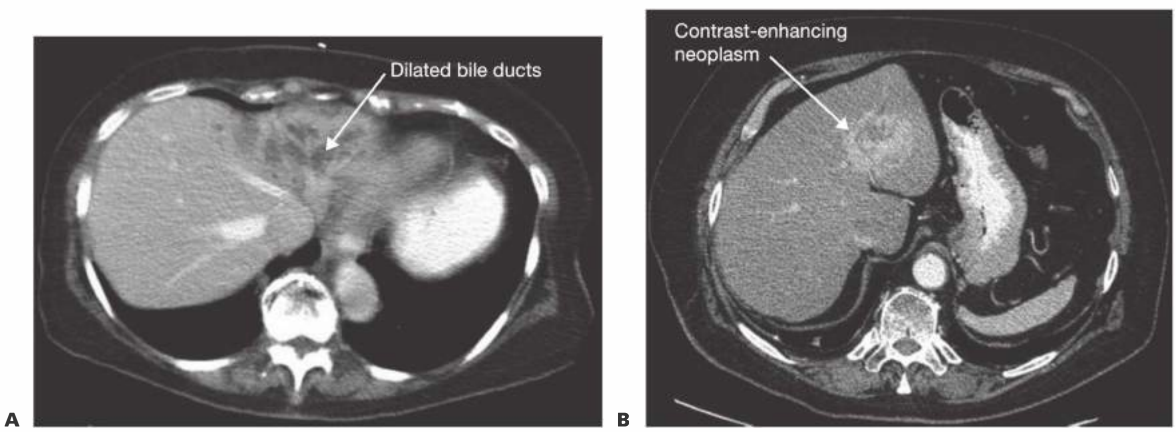

FIG 1 ● **A.** An 84-year-old female with a left hepatic cholangiocarcinoma. The neoplasm cannot be visualized; rather, the defining feature of this imaging is the intrahepatic biliary dilation that is confined to the left lobe of the liver and associated atrophy of the left lobe of the liver. **B.** A 71-year-old male with a left hepatocellular carcinoma (HCC). Consistent with the hypervascular features of many HCC lesions, this HCC enhances with contrast during the arterial phase. Also note the lack of features of cirrhosis. The spleen is small, varices or ascites are not observed, and the architecture of the liver is preserved with a smooth capsule.

- If a quantitative evaluation of liver function is needed, especially for patients who have undergone hepatotoxic chemotherapy, a monoethylglycinexylidide (MEGX) test or indocyanine green clearance test can be used.[6]
- Occasionally, preoperative liver biopsy may be necessary to document the presence or extent of cirrhosis.
- Preoperative laboratory tests include a complete blood count, liver function tests, coagulation profile, and relevant tumor markers in cases of malignant disease.

SURGICAL MANAGEMENT

Preoperative Planning

- Minimally invasive hepatic surgery should be performed by surgical teams experienced in both advanced minimally invasive techniques and major hepatic surgery.
- All potentially necessary equipment should be readily available and the patient should be counseled on the possibility for conversion to an open procedure.
- Preoperative portal vein embolization (PVE) can be considered in order to increase the size of the future liver remnant (FLR) to a minimum of 25% in the absence of cirrhosis and a minimum of 40% to 50% in well-compensated cirrhosis. PVE is less commonly needed in a left hepatectomy as compared to a right hepatectomy.[7]

Positioning

- Arrange the operating room so that the robot can be docked at the head of the table.
- Place the patient in supine position on a split-leg table in slight reverse Trendelenburg position. Video monitors are placed to the right and left of the head of the patient.
- Insert a central venous and arterial lines for hemodynamic monitoring. Give preoperative antibiotic prophylaxis and have crossmatched blood available.
- Judiciously administer intravenous fluids; keep the central venous pressure (CVP) less than 5 cm H_2O.
- For a purely laparoscopic resection (no robotic assistance), the operation can be performed with the surgeon standing between the patient's legs or with the surgeon at the patient's left during the hilar dissection and then moving to the right side for the parenchymal transection.[8]
- For a robotic resection:
  - Laparoscopic portion (liver mobilization): The surgeon stands on the left side, the assistant on the right, and the camera assistant between the legs.
  - Robotic portion (control of vascular inflow, parenchymal transection, hepatic outflow): The surgeon sits at the console and the assistant is between the legs (facilitates retraction, suction/irrigation, bipolar electrocautery, suture exchange, exchange of robotic instruments, and endovascular stapling).

PORT PLACEMENT

- Establish pneumoperitoneum via a 5-mm optical separator port in the left mid-abdomen approximately one handbreadth to the left and 2 in above the umbilicus.
- After pneumoperitoneum is established, place a 10-mm camera port in the right mid-abdomen approximately one handbreadth to the left and 2 in above the umbilicus. This position is a mirror image of the previous port.
- The abdomen is explored for metastatic disease.
- The full complement of ports is then placed as shown in **FIG 2**:
  - Three 8-mm robotic ports—R2 on the right and R1 (initial port upsized to robotic) and R3 on the left
  - One 12-mm camera port
  - One 12-mm laparoscopic assistant port in right lower quadrant (for stapling, suture access, energy device, suction, and clip applier)
  - One 5-mm laparoscopic assistant port in left lower quadrant cases (for energy device, suction, and clip applier)
- For hepatomegaly or with large tumors, the robotic ports are moved inferiorly toward the level of the umbilicus.[8]
- An intraabdominal pressure of less than 12 mmHg is recommended. Although a high intraabdominal pressure can theoretically improve hemostasis during liver transection, a high intraabdominal pressure could also potentially increase the risk of gas embolism, particularly if injury to the hepatic veins is encountered.[9]

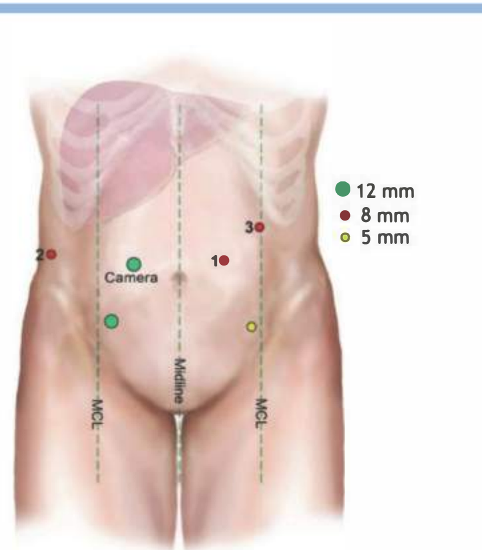

FIG 2 ● Port sites or left robotic hepatic lobectomy. *1*, Usually hook cautery or a grasper; *2*, PK bipolar forceps; *3*, grasper; *red*, robotic arms; *green (upper)*, camera; *green (lower)*, stapler insertion, passage of sutures, GelPort specimen extraction; *yellow*, laparoscopic assistant port (suction, LigaSure). MCL, midclavicular line.

EXPLORATION AND LESION EVALUATION

- The abdominal cavity and the liver surface are again examined for metastases. All suspicious lesions should be sent for frozen section biopsy.
- Laparoscopic ultrasound of the liver is then performed to confirm resectability of the targeted lesion(s) and the proximity to major vessels as well as to rule out other hepatic metastases.

LIVER EXPOSURE AND MOBILIZATION

- This portion of the operation is performed laparoscopically.
- Divide the falciform ligament and the ligamentum teres with hook electrocautery/bipolar electrocautery. Alternatively, this step can be performed prior to the intraoperative ultrasound. The ligamentum teres is left long enough to be used as a grasping point during the portal dissection.
- Divide the left triangular and left coronary ligaments using hook electrocautery or another energy device. (**FIG 3A,B**)
- Open the pars flaccida, staying close to the undersurface of the left lateral section and the caudate lobe. An accessory left hepatic artery may be encountered and is doubly clipped and divided.
- Incise Arantius' ligament using the hook cautery. It runs from the left branch of the portal vein to the left hepatic vein or the common (left and middle) hepatic vein truck. This maneuver must be performed with great care because injury to the left hepatic vein can occur. Alternatively, it can be done after the robot is docked to improve visualization.
- The bridge between the left lateral and medial sections (segments 3 and 4B) is divided.
- A cholecystectomy is performed to facilitate with exposure of the porta hepatis.[10]

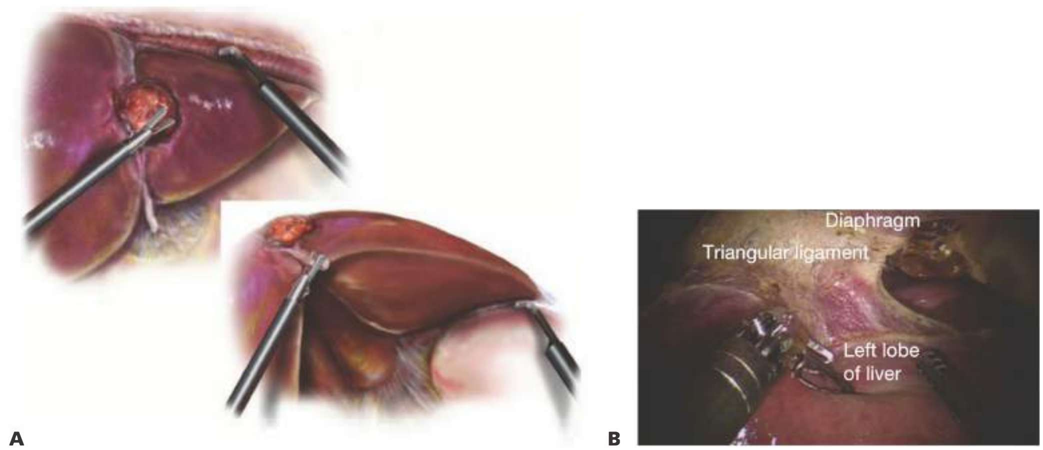

FIG 3 ● **A.** Divide the left triangular ligament using a laparoscopic or robotic hook cautery. Start the dissection lateral and work medial until the left hepatic vein is visualized as it enters the IVC. Using the falciform ligament as a handle *(inset)* for exposure, incise the pars flaccida to expose the ligament of Arantius. Dissect this ligament up to the left hepatic vein. **B.** Intraoperative view of the mobilization of the left lobe of the liver.

ROBOT DOCKING

- The robot is docked over the patient's head.
- The R2 (right) arm has the bipolar grasper, R1 (left) arm has the hook, and R3 (left) arm is a Cadiere grasper.

VASCULAR INFLOW CONTROL

- Encircle the hepatoduodenal ligament with an umbilical tape placed through the foramen of Winslow. This maneuver will facilitate an intermittent Pringle maneuver as needed to prevent blood loss.[11]
- Retract the ligamentum teres anteriorly and cranially to expose the base of the round ligament/umbilical fissure.
- The peritoneum of the left hepatic pedicle is incised and the left hepatic artery is identified, dissected, and vessel looped. After a test clamp ensuring a good pulse/flow

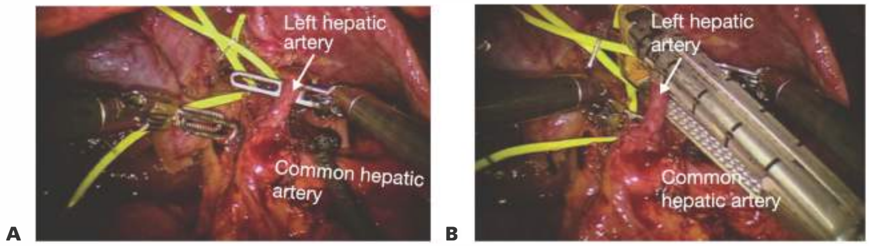

FIG 4 ● Porta hepatis dissection and division of left hepatic inflow. **A.** The left hepatic artery is isolated. **B.** The artery is controlled and divided between 2-0 silk ties reinforced by surgical clips or the use of a vascular staple load.

(on ultrasound) in the right porta, transect the left hepatic artery, either between 2-0 silk ties reinforced by clips or by a stapler vein (**FIG 4A,B**).

- Identify the left portal vein; use a combination of the hook cautery instrument and the Maryland dissector. Control it with a vessel loop. Leftward traction on the vessel loop allows the stapler to transect the vein at an ergonomically comfortable angle that does not compromise the bifurcation of the main portal vein (**FIG 5A,B**).
- Follow the common hepatic duct (**FIG 5C**) superiorly, just beyond the bifurcation, to identify the left hepatic duct. Dissect the left hepatic duct along the undersurface of the liver using the hook cautery tool. The left hepatic duct is divided between double clips or ties reinforced with clips (**FIG 5D**).

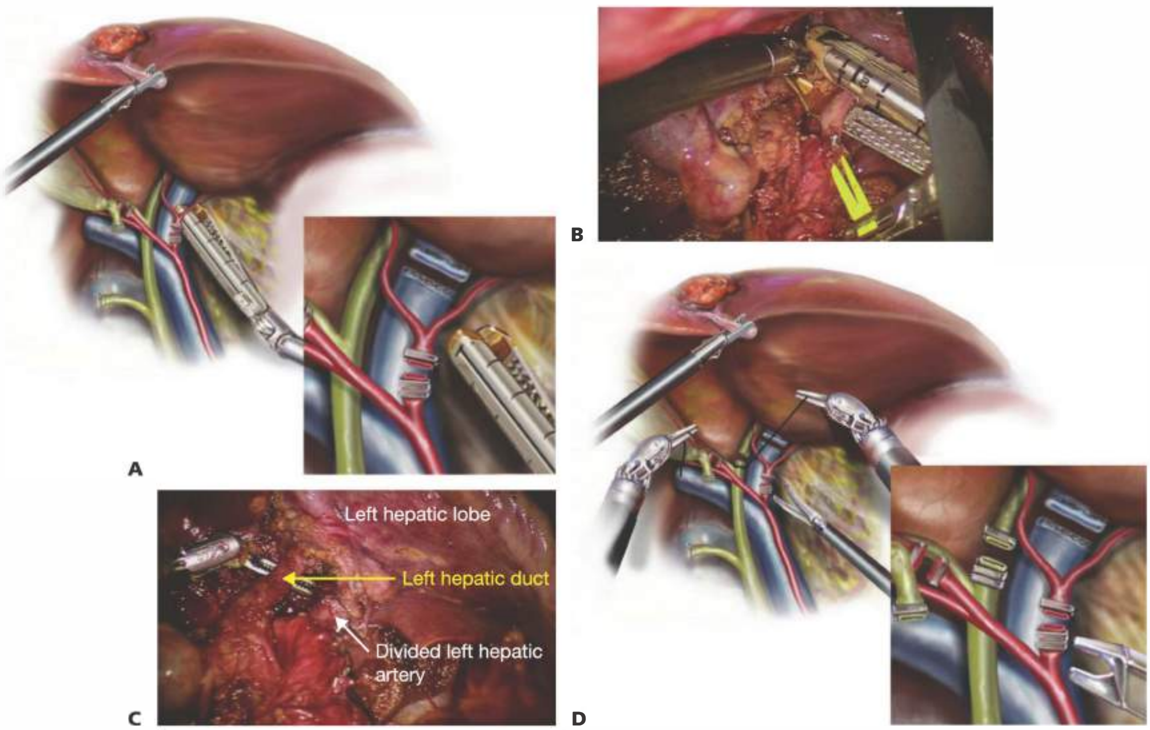

FIG 5 ● **A.** The left portal vein is transected using a vascular linear stapler. Traction on the bifurcation of the main portal vein using a vessel loop (**B**) prevents inadvertent injury or narrowing of the bifurcation. **C.** The left hepatic duct is taken between 2-0 ties reinforced by double clips. **D.** Artist's rendition of the completed dissection with control and division of the left porta hepatis.

PARENCHYMAL TRANSECTION

- Maintain a low CVP during transection to minimize blood loss. Pneumoperitoneum may interfere with CVP readings and visualization of the filling status of the vena cava may help determine if the CVP is, in fact, elevated. Ideally, the IVC will appear flattened by the pneumoperitoneum.
- Never ignore the risk of carbon dioxide (CO_2) venous embolism during parenchymal transaction; a drop in expired CO_2 is the first indication. Be prepared to emergently

decompress the abdomen and reposition the patient to manage this situation.

- Perform the parenchymal transection performed along the line of ischemic demarcation. Mark the plane of transection with electrocautery on the liver capsule just to the left of the line of ischemia. The marked line can be assessed by ultrasound as it appears as a hyperechoic line with an acoustic shadow.[8]
- Place two large figure-of-eight chromic sutures on either side of the ischemia line; use them as handles to help "open book" the liver (**FIG 6A**).
- Our preferred technique for parenchymal transection proceeds as follows:
  - Transection proceeds inferior to superior, anterior to posterior.
  - The first 1 to 2 cm of the transection is performed with robotic hook electrocautery.
  - The next 1 to 2 cm are performed with a bipolar electrocautery device.
  - Deeper dissection uses a combination of the bipolar (clamp and crush technique) (**FIG 6B**), and clips. Robotic stereotactic vision and magnification greatly enhances identification of small blood vessels and bile ducts.
- Other transection techniques have been described based on surgeon preference. Unlike open resections, argon beam coagulation is not used due to the increase in intraabdominal pressure and the potential risk of argon embolism.[12]
- Vessels that are encountered during transection can be clipped and divided with titanium clips (vessels <5 mm), locking nylon clips (vessels <15 mm), or stapler (larger vessels).

FIG 6 ● Parenchymal transection. **A.** Place two figure-of-eight sutures (chromic 2-0 blunt needle) to use as handles to "open book" the liver for parenchymal transection. Use the robotic hook for the first 1 cm, then convert to the PK robotic bipolar or a similar laparoscopic energy device **(B)** for the deeper transection. Larger sized vessels and bile duct tributaries (>3 mm) are clipped as shown in the *inset*.

VASCULAR OUTFLOW CONTROL

- Posteriorly, transection of large tributaries of the left hepatic vein and the left hepatic vein is performed within the liver using vascular loads of the Endo GIA stapler. A total of two to three loads is usually necessary (**FIG 7A,B**).
- Traction on the middle hepatic vein and vena cava should be avoided.
- Alternatively, a technique where vascular inflow and outflow are controlled before parenchymal dissection has been described.[10] The left hepatic vein is located by identifying the Arantius' ligament after lifting the left lobe to the right.

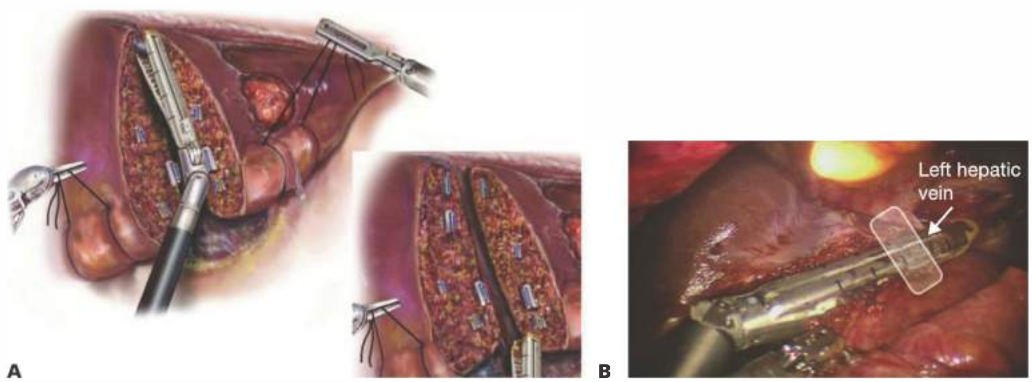

FIG 7 ● Control of the vascular outflow. As the parenchymal dissection nears the cephalad aspect of the liver, **(A)** and **(B)**, control and divide the left hepatic vein using an Endo GIA vascular load cartridge.

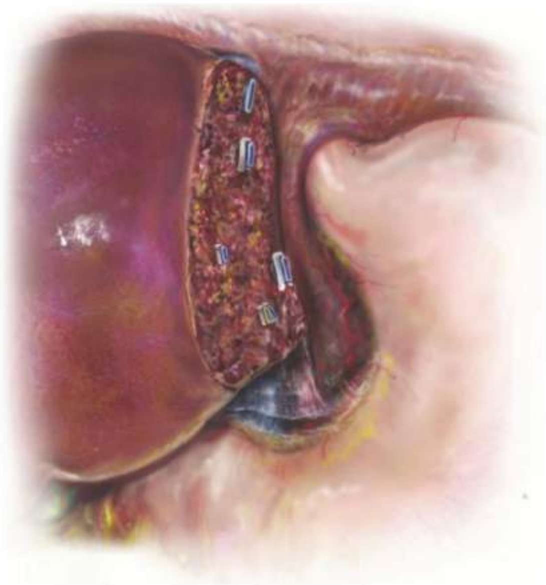
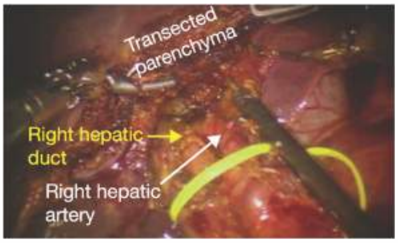
EVALUATION OF CUT SURFACE

- The mean arterial pressure and CVP are normalized and confirmation of hemostasis and absence of bile leak on the cut surface is assessed (**FIG 8A,B**).[8] Perform a Valsalva maneuver for further confirmation of hemostasis.
- Larger vessels should be suture ligated robotically with ease using 2-0 silk sutures in a figure-of-eight fashion.
- Fibrin and thrombin sealants may be used.
- A routine cholangiogram is not performed.



A



B

FIG 8 ● **A.** Examine the cut surface of the liver for bleeding and/or bile leakage. The latter is better visualized after a white sponge/pad is used to compress the liver surface. **B.** The transected surface of the liver is seen in the left upper quadrant of the picture. Note that a loose vessel loop surrounds the porta hepatis (Pringle); this can be intermittently tightened when bleeding from the cut surface is significant.

SPECIMEN RETRIEVAL

- Use sutures to mark the specimen's orientation.
- Place the specimen in an impermeable plastic bag and removed from the abdominal cavity by enlarging the right lower quadrant incision in order to insert a single site GelPort (Applied Medical, Rancho Santa Margarita, CA) for extraction.
- Note that all robotic instruments should be removed before extracting the specimen to avoid injury when pneumoperitoneum is lost.

DRAIN PLACEMENT AND CLOSURE

- A 19-mm round Blake drain is placed based on the surgeon's preference at the resection site through the R3 port and sutured to the skin using 2-0 nylon suture (**FIG 9**).
- The 12-mm camera port site is closed with a Carter-Thomason suture passer in a figure-of-eight fashion using 0 absorbable suture.
- Pneumoperitoneum is then released as the ports are removed.
- The specimen extraction/utility incision is closed using interrupted 0 absorbable suture.
- The skin is closed using 4-0 absorbable monofilament suture.

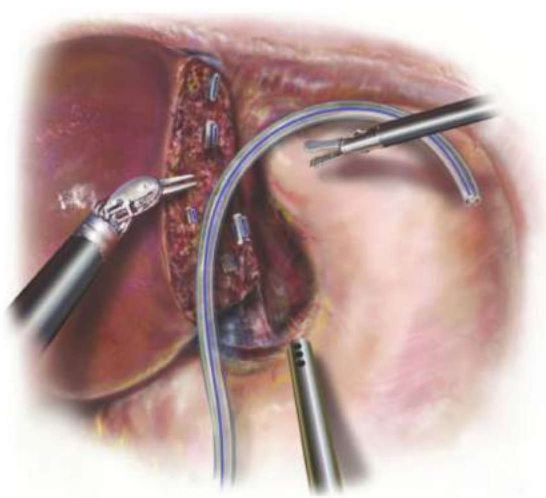


FIG 9 ● A 19-mm Blake drain is routinely used to drain the resection bed and, in the absence of a bile leak, is removed on the third or fourth postoperative day.

TECHNIQUES

CONVERSION

- Conversion should be considered for uncontrolled bleeding and failure to progress. It is recommended to place a minilaparotomy pad at the bleeding site with the administration of pressure by a laparoscopic grasper while emergent conversion occurs. This will minimize blood loss that can occur while converting to a laparotomy.

PEARLS AND PITFALLS

Port placement	▪ Keep a 5-cm distance between ports. Camera port and R1 (dissection arm) should be 5 cm to the right and left of the umbilicus and 2 in above it. This allows adequate visualization of both the hilar structures anteriorly/inferiorly and the parenchymal transection posteriorly. ▪ Robotic arms 2 (bipolar) and 3 (retractor) should be lateral and higher than the camera port and R1. ▪ Laparoscopic assistant ports in the right and left lower quadrants must be placed at a slanted angle into the fascia (rather than vertically). This allows minimal collision between the robotic arms and the assistant. It also facilitates easier stapler access to the liver hilum and parenchyma.
Liver mobilization	▪ Keeping the round ligament long facilitates its use as a handle for optimal inflow vascular dissection and parenchymal transection. ▪ Do not attempt to "overmobilize" the left triangular ligament; this may lead to injury of the left hepatic vein. ▪ Use a laparoscopic or robotic bulldog to loosely hold the two ends of the Pringle umbilical tape. In the event of needing a Pringle maneuver, the bulldog can be expeditiously "cinched down" to provide good compression of portal inflow.
Inflow control	▪ The robotic Maryland is the most optimal instrument to get around the left portal vein. It is pointed enough to dissect perivascular tissue easily but not sharp enough to readily injure the vessel. ▪ Do not grasp vascular structures with the robotic graspers. Use the periadventitial tissue to stabilize the vessel while dissecting it. Lack of tactile feedback can lead to crush injuries to the hepatic artery. ▪ A right posterior or anterior duct may insert proximally into the left hepatic duct. This may be injured if the left hepatic duct is not dissected fully.
Parenchymal transection	▪ Avoid creating valleys or pits into the liver parenchyma during transection. This makes it difficult to visualize the cut surface and to control bleeding.[8] ▪ Have an extra load of the vascular stapler available.
Vascular outflow control	▪ This is best approached within the liver. ▪ When dividing the middle hepatic vein or left hepatic vein, ensure that the tip of the stapler is seen beyond the vessel.

POSTOPERATIVE CARE

- The orogastric tube is removed at the end of the case.
- Intensive care unit (ICU) admission for major hepatectomy depends on surgeon preference.
- Subcutaneous heparin prophylaxis is started on evening of surgery.
- Clear liquids are administered on postoperative day 1.
- The Foley catheter is removed on postoperative day 1.
- Diet is advanced as tolerated.

OUTCOMES

- In experienced centers, laparoscopic liver resections are safe and feasible. In a review of 2,804 patients, of which 6.8% were left hepatectomies, the overall mortality was 0.3% and overall morbidity was 10.5%.[3] Postoperative morbidity from laparoscopic liver resection is most commonly from liver failure. A conversion rate for laparoscopy to open laparotomy was 4.1% and for laparoscopy to a hand-assisted procedure was 0.7%.
- Compared to open hepatectomies, the advantages of laparoscopic hepatectomies are less blood loss, less time with the Pringle maneuver applied, less postoperative analgesia requirements, a shorter length of stay, and fewer overall complications.[13–15]
- For patients with hepatocellular carcinoma or metastatic disease, margin status, disease-free survival, and overall survival following laparoscopic resection appear comparable to open resection.[16–20]

- Although the operative costs of a minimally invasive hepatectomy are higher than an open approach, this difference may be offset by reduced nonoperative costs due to the shorter length of stay following a minimally invasive resection.[15,21]
- A robotic-assisted approach with the da Vinci Surgical System (Intuitive Surgical, Sunnyvale, CA) alleviates some of the limitations of laparoscopic surgery such as the fixed pivot point of the instruments, a two-dimensional view, and only 4 degrees of freedom while adding tremor reduction.[5] The advantages of a robotic over a laparoscopic approach are most appreciated during suturing of bleeding parenchyma, performance of the hilar dissection, and for resections that may require intricate biliary-enteric anastomoses.
- Robotic-assisted liver resections are being increasingly performed. Early results show that it is safe and feasible with a low conversion rate, low estimated blood loss, short length of stay, and limited postoperative morbidity that may be comparable to a laparoscopic approach.[22–24]
- In a matched comparison of robotic versus laparoscopic hepatectomies at the University of Pittsburgh Medical Center, there was no significant difference in estimated blood loss, transfusion rate, R0-negative margin rate, postoperative peak bilirubin, postoperative intensive care admission rate, length of stay, and 90-day mortality. Robotic-assisted hepatectomies had a significantly higher overall operating room time (median: 342 vs. 261.5 minutes) and operative time (median: 253 vs. 199 minutes).[25] However, more robotic-assisted hepatectomies were performed in a purely minimally invasive manner, 81%, versus only 7.1% for the laparoscopic approach, with the rest of laparoscopic operations involving a hand-assisted procedure or a hybrid technique procedure. The rate of conversion to open laparotomy was similar for robotic and laparoscopic hepatectomies.

COMPLICATIONS

- Bile leak
- Hepatic insufficiency
- Close or positive margins
- Hemorrhage
- Wound infection

Chapter 27

Robotic Liver Resection

Mohammad Khreiss   Allan Tsung   David L. Bartlett

DEFINITION

- The use of robotic-assisted surgery for liver resections is mostly dependent on tumor location and the experience of the surgical team. Indications for the use of robotics have been reported in the Louisville Statement in 2008, which set forth the guidelines for laparoscopic liver resection. Patients with solitary lesions, 5 cm or less, and located in segments 2 to 6 were considered eligible for robotic-assisted surgery. The use of robotics should not compromise the aforementioned principles or nomenclatures.[1]
- The indication has been extended by most experienced robotic liver surgeons to include all resections, which would be considered for laparoscopic resection. The contraindications include large lesions that will prevent safe mobilization of the liver without an open incision. The space in an insufflated abdomen may not be enough to allow for manipulation of an exceedingly large tumor. The tumors that are close to major intrahepatic pedicles may also be unsafe to approach minimally invasively. Also, the sick livers with high intrahepatic portal venous pressure will lead to excessive blood loss and may not be appropriate for a minimally invasive approach.

DIFFERENTIAL DIAGNOSIS

- The differential diagnosis of a liver mass includes both benign and malignant processes. Benign processes are either cystic or solid. Malignant processes are usually solid (Table 1).

PATIENT HISTORY AND PHYSICAL FINDINGS

- The evaluation of a patient with a liver mass should include a complete history and physical exam.
- History should include questions regarding presence of abdominal pain, weight loss, alcohol use, viral hepatitis, liver disease, tattoos, blood transfusions, personal history of cancer, family history of liver, and colon cancer. History should include use of oral contraceptives for women.
- Physical exam should be directed toward findings such as presence of abdominal mass, hepatomegaly, splenomegaly, ascites, jaundice, scleral icterus, flapping tremor, and caput medusa.

Table 1: Differential Diagnosis of Liver Mass

Benign	Cystic	Pyogenic abscess
		Amebic abscess
		Hydatid cyst
		Simple cyst
	Solid	Hemangioma
		Adenoma
		Focal nodular hyperplasia
		Biliary hamartoma
Malignant		Hepatocellular carcinoma
		Cholangiocarcinoma
		Gallbladder cancer
		Metastatic colon cancer
		Metastatic neuroendocrine cancer
		Metastatic cancer of other etiologies

LABORATORY TESTS AND IMAGING

- Workup should include blood sent for the following:
  - Complete blood count
  - Platelet count
  - Blood urea nitrogen
  - Creatinine
  - Electrolytes
  - Liver enzymes
  - Albumin
  - International normalized ratio (INR)
  - Viral hepatitis screen
  - Serum ammonia level
  - Tumor markers (carcinoembryonic antigen, α-fetoprotein, cancer antigen 19-9)
- Imaging studies play a great role in the diagnoses of liver lesions and in the preoperative planning for liver resection.
- Ultrasound differentiates between solid and cystic lesions of the liver. It is usually used as a screening modality in patients with right upper quadrant pain. Its use is limited by interference secondary to presence of bowel gas, obesity, and overlying ribs.
- Contrast-enhanced, multiphasic computed tomography (CT) scans are used for diagnosis of liver lesions and preoperative planning for liver resections. These include arterial, venous, and portal phases. Their value lies in their ability to detect proximity of lesions to major arterial and portal structures and to asses for resectability.
- Volumetric analysis of functional liver remnant is used to assess feasibility of resection, and data supports its use because the remaining liver volume has been shown to predict mortality in cirrhotic patients. In general, a functional liver remnant of 20% is desired with a healthy liver and 50% with a diseased liver.
- Contrast-enhanced magnetic resonance imaging (MRI) is another imaging modality that is gaining acceptance for evaluation and characterization of liver lesions. It allows for better contrast resolution, avoidance of radiation exposure, and multiplanar imaging. The choice of CT versus MRI is institution dependent.
- Other imaging modalities used include positron emission tomography (PET) scan and CT-PET scans. PET imaging is ideal for many metastatic cancers to the liver, but it is best combined with an intravenous (IV) contrast CT scan so that anatomic relations can be made.

SURGICAL TECHNIQUE

- Patient positioning and room setup:
  - The robot is usually at the top of the operating table. The anesthesia area is on the left side of the patient's head.
  - The patient is placed in the supine position with the legs split and both arms tucked.
  - The first surgeon stands on the right side of the table while the second surgeon stands between the legs. An assistant stands on the left side of the table.
  - The patient is placed at 30-degrees reverse Trendelenburg at all times during the procedure (**FIG 1**).

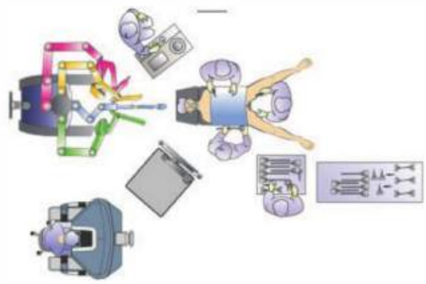

FIG 1 • Arrangement of the operating room and placement of the robot. The primary surgeon is positioned between the patient's legs during the laparoscopic portions of the procedure, with the first assistant to the patient's left. The scrub technician is to the patient's right. The anesthesiologist is positioned to the left to allow for access for the robot. (From Kim KC, ed. *Robotics in General Surgery*. New York, NY: Springer; 2014, with kind permission of Springer Science+Business Media.)

RIGHT HEPATECTOMY

- Port placement
  - Pneumoperitoneum is established through placement of a 5-mm port in the left upper quadrant. This will be exchanged at the end of port placement to become the third robotic port.
  - A 12-mm camera port is placed to the right of the umbilicus.
  - First robotic port is placed at the level of the right anterior axillary line in the midabdominal region.
  - Second robotic port is placed at the level of the midclavicular line in the midabdominal region.
  - A 12-mm laparoscopic port is placed 8 to 10 cm inferior and lateral to the camera port. This port is handled by the bedside surgeon during the robotic part of the procedure for assistance.
  - Another 5-mm assistant laparoscopic port is placed 8 to 10 cm inferior and lateral to the second robotic port (**FIG 2**).
- Step 1 (laparoscopic): The falciform and round ligaments are divided using electrocautery. This exposes the anterior surface of the liver up to the fibroareolar tissue investing the hepatic veins (**FIG 3**).
- Step 2 (laparoscopic): The patient is positioned right side up by rotating the operating table. The hepatic flexure is mobilized to inferiorly reflect the colon. The right lobe of the liver is retracted superiorly. The duodenum is reflected medially. Gerota's fascia is retracted inferiorly and the right triangular and coronary ligaments are divided up to the right hepatic vein (**FIG 4**).
- Step 3 (laparoscopic): Intraoperative ultrasound (IOUS) of the liver is then performed using the 12-mm laparoscopic port. This locates the mass in relation to the segmental anatomy of the liver and drives the planning of the resection plane.
- Step 4 (laparoscopic): The short hepatic/caudate veins that insert into the retrohepatic vena cava are divided between clips or with a coagulation device.

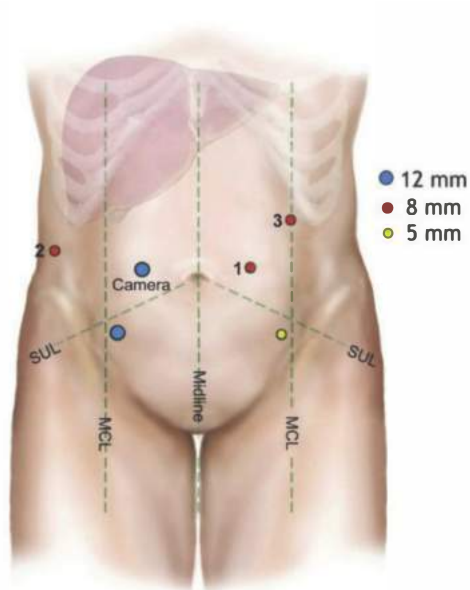

FIG 2 • Port placement for right hepatectomy. A 12-mm camera port is placed to the right of the umbilicus. The first robotic port is placed at the level of the right anterior axillary line in the midabdominal region. The second robotic port is placed at the level of the midclavicular line in the midabdominal region. The third robotic is positioned in the left upper quadrant. A 12-mm laparoscopic port is placed 8 to 10 cm inferior and lateral to the camera port. This port is handled by the bedside surgeon during the robotic part of the procedure for assistance. Another 5-mm assistant laparoscopic port is placed 8 to 10 cm inferior and lateral to the second robotic port. (From Kim KC, ed. *Robotics in General Surgery*. New York, NY: Springer; 2014, with kind permission of Springer Science+Business Media.)

TECHNIQUES

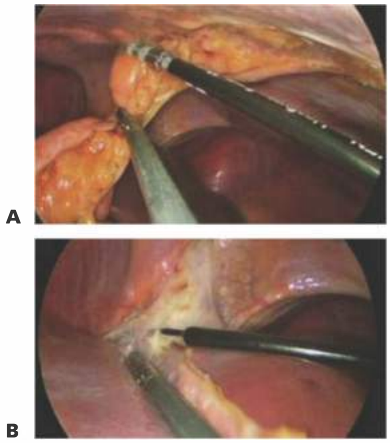

FIG 3 ● **A.** The round ligament is divided using bipolar electrocautery. **B.** The falciform ligament is divided at the level of the hepatic parenchyma up to the level of the hepatic veins.

- Step 5 (laparoscopic): The right hepatic vein is encircled with a vessel loop.
- Step 6: Docking of the robot is performed using the first, second, and third robotic ports for the respective robotic arms. The camera is aligned with the head at this time.
- Step 7: The gallbladder, if present, is retracted cephalad and blunt dissection of triangle of Calot performed so that both cystic artery and duct are identified (**FIG 5**). These are ligated after establishing the critical view. The gallbladder is not dissected off the liver bed as it is useful for retraction while dissection is performed at the level of the porta hepatis. The right hepatic artery is identified and ligated between clips and/or ties (**FIG 6**). A vascular load for the Endo GIA stapler may be used for the same purpose. The right portal vein is then dissected and identified along its full length. Another load of the vascular stapler is used to transect it (**FIG 7**). After transecting the hepatic artery and vein, the right hepatic duct is identified. This is ligated distally then transected (**FIG 8**). It is important to make sure that bile is flowing from the proximal side before ligating the structure as lymphatics and connective tissue can be misidentified as the biliary tree. After completing the dissection at the level of the porta hepatis, the gallbladder is dissected off the gallbladder bed and removed.

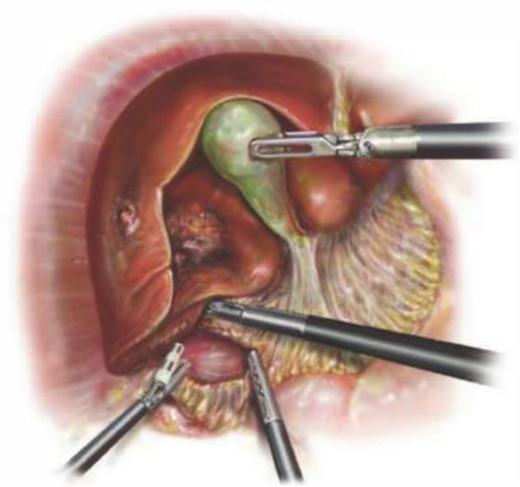

FIG 4 ● The right lobe of the liver is fully mobilized by dividing the triangular ligament. The gallbladder, if present, is a useful point of retraction. (From Kim KC, ed. *Robotics in General Surgery*. New York, NY: Springer; 2014, with kind permission of Springer Science+Business Media.)

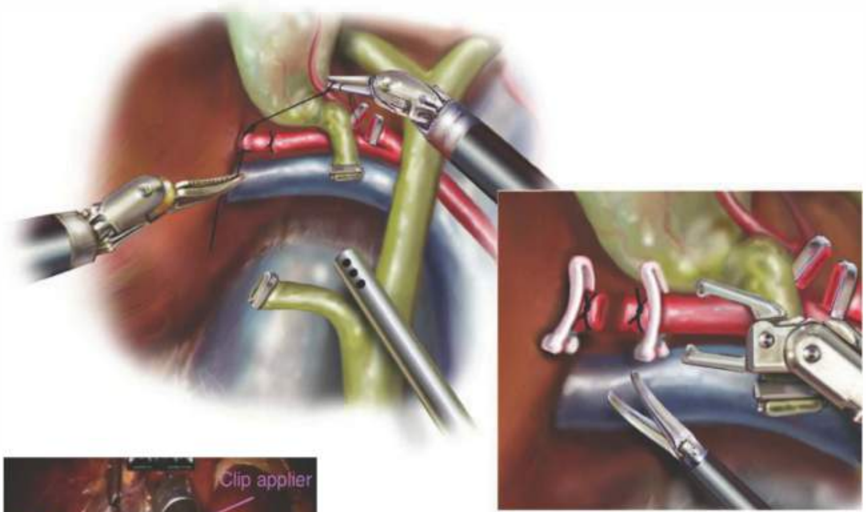
FIG 5 ● The portal dissection is most safely initiated by identifying the cystic artery and duct (structure being clipped in the figure). These structures are bluntly dissected to their origin as a safe means to identify the right hepatic artery and hepatic duct.

- Step 8: The right hepatic vein can now be divided extrahepatically if desired, and this is preferable if this region is important for an adequate margin. Alternatively, the vein can also be divided during the parenchymal dissection (**FIG 9**).
- Step 9: After completing the aforementioned dissection, the parenchyma of the liver is transected. The liver is allowed to drop and the line of transaction is based on the demarcated ischemic liver. Hook cautery is used to divide the capsule of the liver. IOUS is performed again to ensure the planned margin. Two figure-of-eight sutures are placed on each side of the line of demarcation and retracted using the robotic arms (**FIG 10**). A heat sealing device is used for transecting the parenchyma of the liver. We use a crush technique with the PK Gyro device. Clips are applied to larger vessels and the vascular stapler for vessels too large to clip. This is continued until the right hepatic vein is identified. If the right hepatic vein has not been previously divided, a vascular load is applied across the right hepatic vein to complete the resection.
- Step 10: The specimen is retrieved using an EndoCatch bag, then removed through extension of the inferior 12-mm assistant port.
- Step 11: All laparoscopic trocar sites are closed in the regular fashion.



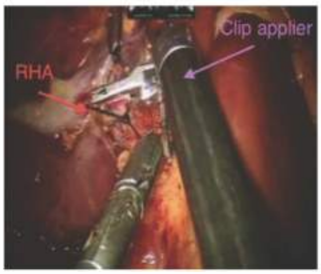


FIG 6 ● The right hepatic artery is dissected and controlled as it inserts into the liver parenchyma. It is typically posterior to the right hepatic duct and lateral and anterior to the right portal vein. It should be proximally controlled by ligation and a surgical clip. (From Kim LC, ed. *Robotics in General Surgery*. New York, NY: Springer; 2014, with kind permission of Springer Science+Business Media.)

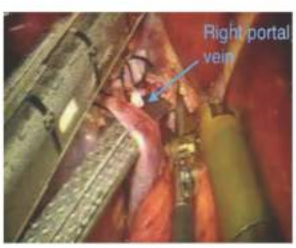
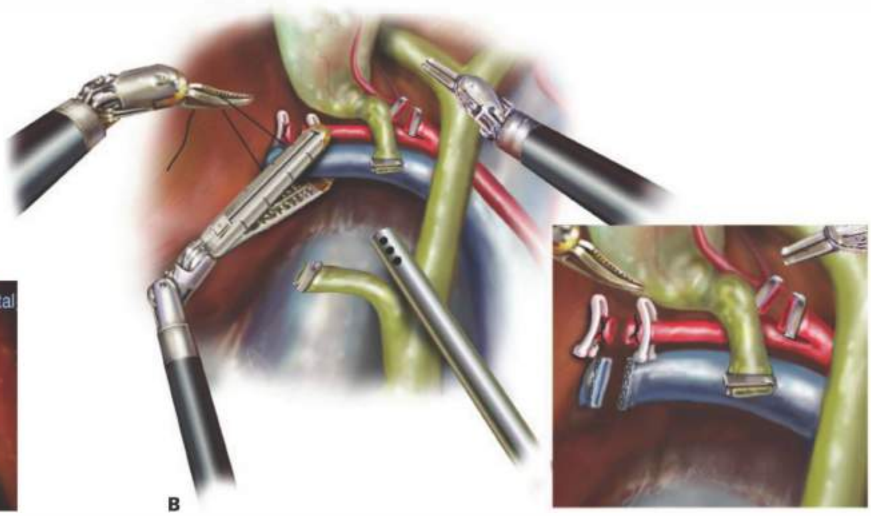


A



B

FIG 7 ● **A.** The right portal vein is circumferentially dissected and subsequently controlled by a vascular load of the Endo GIA stapler. Use caution during the dissection as a large branch to the caudate lobe is often present. **B.** Schematic rendition of the dissection and control of the right portal triad (part **B**: From Kim KC, ed. *Robotics in General Surgery*. New York, NY: Springer; 2014, with kind permission of Springer Science+Business Media.)

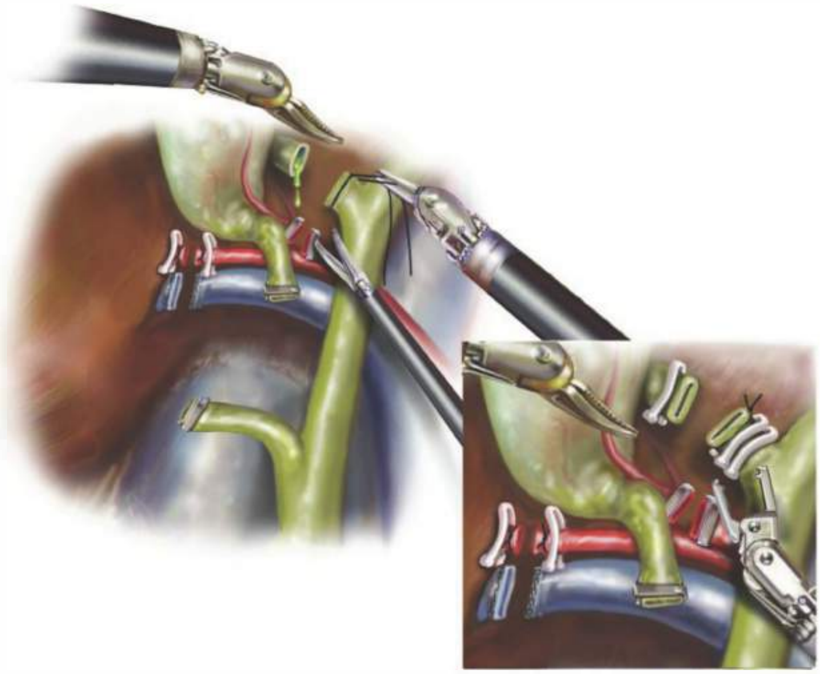


FIG 8 ● The right hepatic duct is controlled distally and divided. The authors strongly advocate identifying bile in the proximal duct to ensure a lymphatic or part of Glisson's capsule have not been inaccurately identified as the right hepatic duct. (From Kim KC, ed. *Robotics in General Surgery*. New York, NY: Springer; 2014, with kind permission of Springer Science+Business Media.)

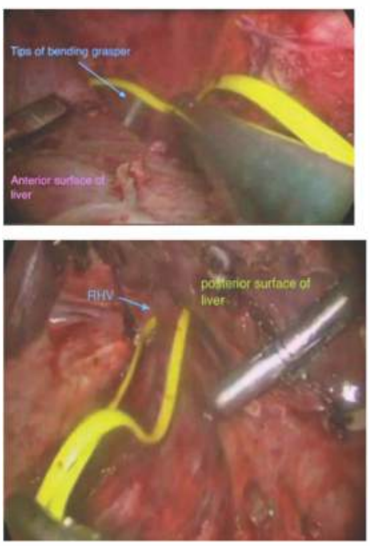

FIG 9 ● **A.** Anterior and **(B)** posterior views of the right hepatic vein after dissection.

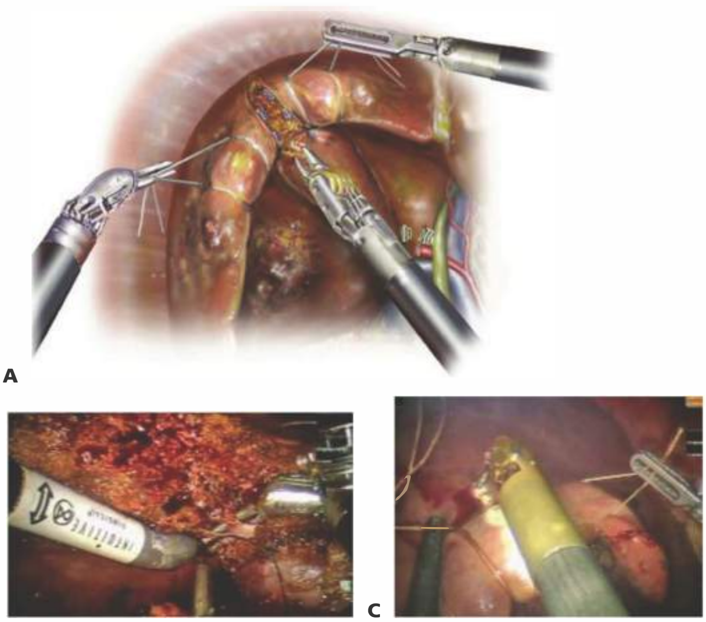

FIG 10 ● **A.** Figure-of-eight sutures on either side of the planned transaction plane are essential for elevating and separating the parenchyma to provide adequate visualization. **B.** A modified crush technique is used to identify intraparenchymal structures. Smaller structures are controlled with clips and/or cautery. (From Kim KC, ed. *Robotics in General Surgery.* New York, NY: Springer; 2014, with kind permission of Springer Science+Business Media.) **C.** Larger structures are controlled with stapler firings.

LEFT HEPATECTOMY

- Port placement
  - Pneumoperitoneum is established through placement of a 5-mm port in the left upper quadrant. This will be exchanged at the end of port placement to become the third robotic port.
  - A 12-mm camera port is placed in the supraumbilical area.
  - First robotic port is placed at the level of the right midclavicular line in the subcostal area.
  - Second robotic port is placed at the level of the left anterior axillary line.
  - A 12-mm laparoscopic port is placed 8 to 10 cm inferior and lateral to the camera port on the right. This port is handled by the bed side surgeon during the robotic part of the procedure for assistance
  - Another 5-mm laparoscopic port is placed 8 to 10 cm inferior and lateral to the camera on the left. This is also handled by the assistant (**FIG 11**).
- Step 1 (laparoscopic): The falciform and round ligaments are divided using electrocautery. This exposes the anterior surface of the liver to the hepatic veins.
- Step 2 (laparoscopic): With the patient in the left side up position, both left triangular and coronary ligaments are divided until the left hepatic vein is identified. The liver is then retracted cephalad and the gastrohepatic ligament is divided. Care is taken to identify a replaced left hepatic artery and properly control it prior to division, if present.
- Step 3 (laparoscopic): At this point, the left hepatic vein can be isolated and encircled with a vessel loop if the intention is to divide the vein extrahepatically.
- Step 4 (laparoscopic): IOUS of the liver is then performed using the 12-mm laparoscopic port. This helps confirm the presence of the mass in the planned resection specimen and its relation to the major structures in the liver. The middle hepatic vein should be preserved, unless this approach will compromise the margin.
- Step 5: Docking of the robot is performed using the first, second, and third robotic ports for the respective robotic arms. The camera is aligned with the head.

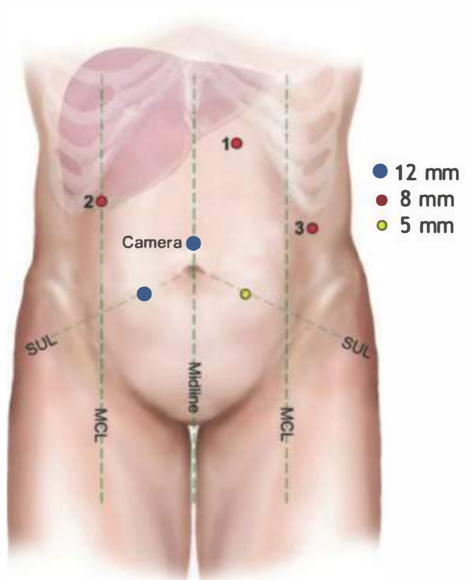

FIG 11 ● Port placement for a left hepatic lobectomy. *MCL*, midclavicular line; *SUL*, spinoumbilical line. (From Kim KC, ed. *Robotics in General Surgery*. New York, NY: Springer; 2014, with kind permission of Springer Science+Business Media.)

- Step 6: Dissection is then carried at the level of the porta hepatis. The ligamentum teres is used to retract the liver anteriorly. The left hepatic artery is identified and ligated between clips. A vascular load for the Endo GIA may be used for the same purpose, if feasible. The left portal vein is then dissected and identified along its full length. Another load of the vascular stapler is used to transect it. After transecting the hepatic artery and vein, the left hepatic duct is identified. This is ligated distally and then transected.
- Step 7: At this point, the left hepatic vein can be divided extrahepatically with a vascular stapling device.
- Step 8: After completing the aforementioned dissection, the parenchyma of the liver is transected based on the line of demarcation.

LEFT LATERAL SECTIONECTOMY

- Port placement is shown in **FIG 11**.
- Mobilization of the liver and control of the left hepatic vein proceeds as described for left hepatic lobectomy.
- The portal structures supplying segments 2 and 3 are controlled with a vascular staple load at the posterior aspect of segment 3 to the patient's right of the falciform ligament.

RIGHT POSTERIOR SECTOR RESECTIONS

- Positioning
  - The patient is positioned in the full right lateral position for posterior-lateral resections.
  - The robot is then brought in toward the left upper corner of the table.
- Port placement
  - In these cases, the ports can be placed laterally on the right side, including a robotic port through the diaphragm.
  - The camera port is at the costal margin, the left hand port is through the diaphragm, and the right hand port is along the anterior axillary line inferiorly.

- A third robotic port can be placed more medially at the midclavicular line on the right (**FIG 12**).
- Step 1 (laparoscopically): Mobilize the right lobe of the liver as aforementioned, fully exposing the anterior and lateral aspects of the right hepatic vein.
- Step 3: Docking of the robot is performed using the first, second, and third robotic ports for the respective robotic arms. The camera is aligned with the left nipple.
- Step 4: With the aid of IOUS, hook cautery is used to divide the capsule of the liver where the parenchymal transection will occur. Two figure-of-eight sutures are placed on each side of the line of demarcation and retracted using the robotic arms.
- Step 5: The parenchymal dissection is performed as previously described.
- Step 6: The robot is undocked.
- Step 7: The robotic port through the diaphragm is removed and the diaphragm is repaired with a single figure-of-eight suture.
- Step 8: A chest tube is placed to decompress the pneumothorax and then immediately removed.

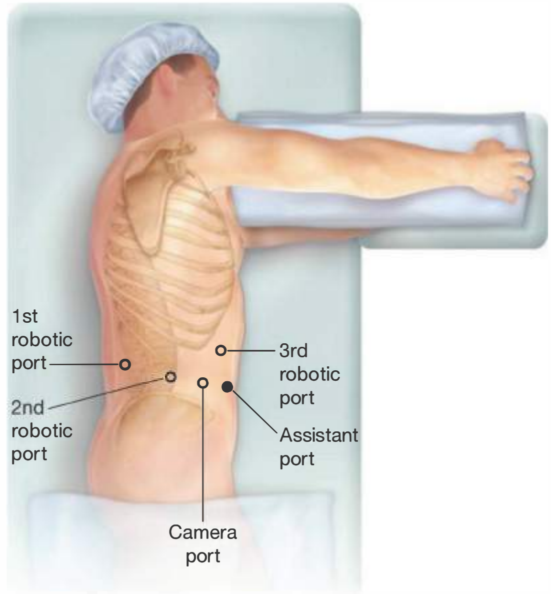

FIG 12 ● Port placement for a posterior sectionectomy.

PEARLS AND PITFALLS

Preoperative planning	■ Cirrhotic livers with significantly high intrahepatic portal pressures will be associated with significant blood loss and may be better approached as an open procedure. ■ Most resections tend to be nonanatomic with the goal to preserve parenchyma and anatomy for future resections. ■ Flexibility in port placement is important and may vary depending on the location of the lesion, the body habitus, the size of the liver, and so forth. For example, in some patients, the liver extends well below the costal margin and the ports will need to be placed below the level of the umbilicus.
Operative technique	■ A central line should be placed and the central venous pressure monitored and kept low. ■ Care should be taken to identify major hepatic veins or pedicles by ultrasound in advance of the parenchymal transection so that these are handled carefully. ■ Although air embolus is a theoretical concern, it is rare in practice. ■ A Pringle maneuver is recommended to reduce blood loss. ■ The line of parenchymal transection should be lined up with the camera and the assistant 12-mm port for stapling. ■ Obtaining adequate margins can be challenging without the ability to feel the tumor. Ultrasound needs to be used during the parenchymal transection to ensure that the margin is preserved, and the initial marking of the margin by cautery should be generous.

POSTOPERATIVE CARE

- No drain is left next to the resection bed unless a bile leak is identified.
- Orogastric tube is removed in the operating room.
- Patient is transferred to a regular floor monitored bed.
- Daily laboratories are ordered including complete blood count, blood urea nitrogen, electrolytes, liver enzymes, bilirubin, and coagulation studies.
- Clear liquids are given on postoperative day 1 and advanced as tolerated.
- Foley catheter is removed on postoperative day 1.
- Central venous catheter is removed on postoperative day 1.

OUTCOMES

- The advantages of minimally invasive surgery are well documented in the literature. These include decreased postoperative pain, early return of activity, decreased postoperative ileus, better cosmesis, and shorter hospital stays.[2]
- However, several limitations inherent to laparoscopic surgery are present. These include two-dimensional imaging, limited range of instrument motion, tremor amplification, and poor surgeon ergonomics.[3]
- The use of robotics offers multiple advantages to the operating surgeon such as improved three-dimensional imaging, near 360-degree movement of surgical instruments, along

Table 2: Comparison of Robotic and Laparoscopic Groups: Operative and Postoperative Parameters

	Robotic (n = 57)	Laparoscopic (n = 114)	*Overall P-value*
EBL, median mL	200 (50–337.5)	100 (50–350)	0.097
Transfusion rate (%)	2 (3.8)	7 (7.4)	0.372

with improved surgeon comfort and precision. Robotics also offers elimination of tremor.[4,5]

- This comes at the cost of prolonged operative times, absence of haptic feedback, higher costs, and a steep learning curve.[4,5]
- The current literature describes 19 publications that focus on robotic liver resections and provide a description of 217 cases.[6]
- Commonly reported procedures included robotic nonanatomic resections and segmentectomies (37.7%).[6]
- Right hepatectomies comprised 21.6% and left lateral sectionectomies 20.8%.[6]
- In a systemic review of the current literature, conversion rates were 4.6%. Most common reasons for conversion included confirmation of surgical margin, problems during hilar dissection, long resection planes, and obesity.[6]
- Operative times ranged between 200 and 507 minutes. Operative blood loss ranged between 50 and 600 mL with more blood loss associated with more complex procedures such as major hepatectomies.[6]
- Mean hospital stay after robotic liver resections was 5.5 to 11.7 days.[6]
- Oncologic outcomes were not well reported in the aforementioned series, although some authors believe that they are comparable to those of laparoscopic liver resections.[6]
- No surgical mortality was reported in the literature after robotic liver resections. The morbidity rates were around 20.3% on average.[6]
- In a matched series from the University of Pittsburgh comparing patients who received robotic and laparoscopic liver resections, there was no difference in estimated blood loss, hospital length of stay, morbidity, or mortality (Table 2). There was an increase in major hepatic resections performed. There was no difference in the conversion rate between the two groups (7% vs. 8.8%).[7]
- Upon comparison of early versus late experience with robotic cases, there was a significant difference in estimated blood loss (EBL), operative time, and hospital length of stay in favor of the later cases, which reflects the presence of a learning curve (Table 3).[7]

COMPLICATIONS

- Intraabdominal fluid collections
- Postoperative ileus
- Pleural effusions
- Minor wound complications
- Thromboembolic events are comparable to any major abdominal surgery.
- Hepatic failure

Chapter 28

Central Hepatectomy

Aijun Li   Mengchao Wu

DEFINITION

- Central hepatectomy, alternatively referred to as mesohepatectomy, central bisegmentectomy, middle lobectomy, or central trisegmentectomy, is an operation that removes segments 1, 4, 5, and 8 en bloc (or lesser resections) while leaving the left lateral and right posterior lateral segments in situ (**FIG 1**).
- It is a technically demanding operative procedure for large or deep-seated tumors located at the central part of the liver. It essentially requires two hepatic parenchymal dissections in close proximity to the hepatic veins and inferior vena cava (IVC) while preserving the portal pedicles to the remaining hepatic segments and results in two cut surfaces of the liver.
- Because it conserves more liver parenchyma, central hepatectomy should be considered (vs. extended hepatectomy) in patients with centrally located tumors and compromised liver function (**FIG 2**).

DIFFERENTIAL DIAGNOSIS

- Resection of benign neoplasms of the central liver is indicated for one or more of three indications: (1) to relieve symptoms, (2) because the diagnosis is uncertain, or (3) to prevent malignant transformation (**FIG 2**).
  - Hemangioma
  - Adenoma, angiomyolipoma (AML)
  - Complex cysts
  - Focal nodular hyperplasia (FNH)
- Liver resection remains the treatment of choice when appropriate for both primary and secondary central liver malignancies.
  - Hepatocellular cancer (HCC)
  - Metastatic cancers
    - Colorectal cancer
    - Breast cancer
    - Ovarian cancer
    - Lung cancer
    - Others
  - Sarcoma

PATIENT HISTORY AND PHYSICAL FINDINGS

- Hepatic neoplasms may present with abdominal, flank, and/or shoulder pain. Other symptoms include early satiety, weight loss, or increasing abdominal girth.
- With modern imaging, many hepatic lesions are an incidental finding in studies obtained as part of follow-up for a previously treated malignancy or for other unrelated indications.
- A history of previous hepatitis or jaundice should be solicited.
- A detailed history of alcohol consumption should be obtained.
- Symptoms of liver failure should be queried including fatigue, lethargy, encephalopathy, and increasing abdominal girth.
- The physical exam should focus on evidence of malnutrition including temporal and intrinsic hand muscle atrophy, the presence of ascites or peripheral edema, mental status changes of hepatic encephalopathy, asterixis, and telangiectasia.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- All potential liver surgery patients should undergo preoperative viral serologic testing, laboratory assessment of liver function including protein and coagulation profiles, and assessment of the Child-Pugh's classification score.
- Magnetic resonance imaging (MRI) or three-dimensional computed tomography (CT) reconstruction of the liver can help identify and map the variations of the intrahepatic vascular structures and their relationship to tumors (**FIG 2**).
- CT with volumetric assessment is useful to determine if the planned hepatic remnant volume is adequate.[1]
- Alternatively, hepatic functional reserve can be determined by indocyanine green (ICG) clearance or ICG 15 minutes retention (15-R). Central hepatectomy should be considered in patients with an ICG 15-R less than 20%.[2]

SURGICAL MANAGEMENT

Preoperative Planning

- A complete medical history is essential. In particular, underlying cardiac or pulmonary comorbidities should be thoroughly evaluated prior to determining whether a patient is a candidate for liver resection.
- For malignant lesions, the evaluation for extrahepatic metastases should include a chest CT.
- The risk of postoperative hepatic failure should be determined. Central hepatectomy is performed for patients with underlying liver disease. A preoperative liver biopsy to determine the extent of disease may be warranted in high-risk patients to avoid nontherapeutic laparotomy.
- The Child-Pugh score is the most commonly employed clinical tool for selection of surgical candidates. Most patients

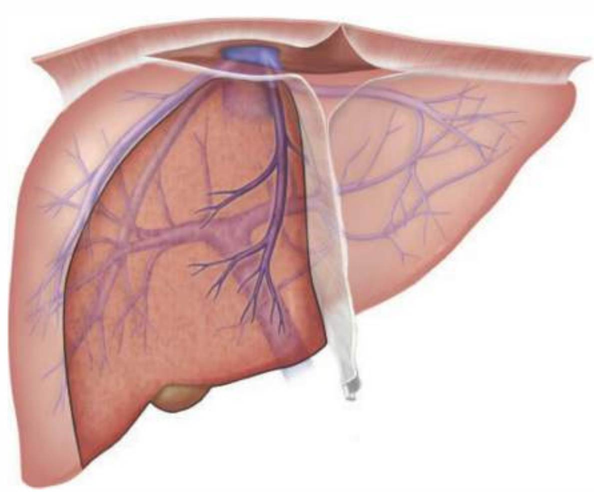

FIG 1 ● Resection area: Central hepatectomy removing part or all of the left medial sector and right anterior sector.

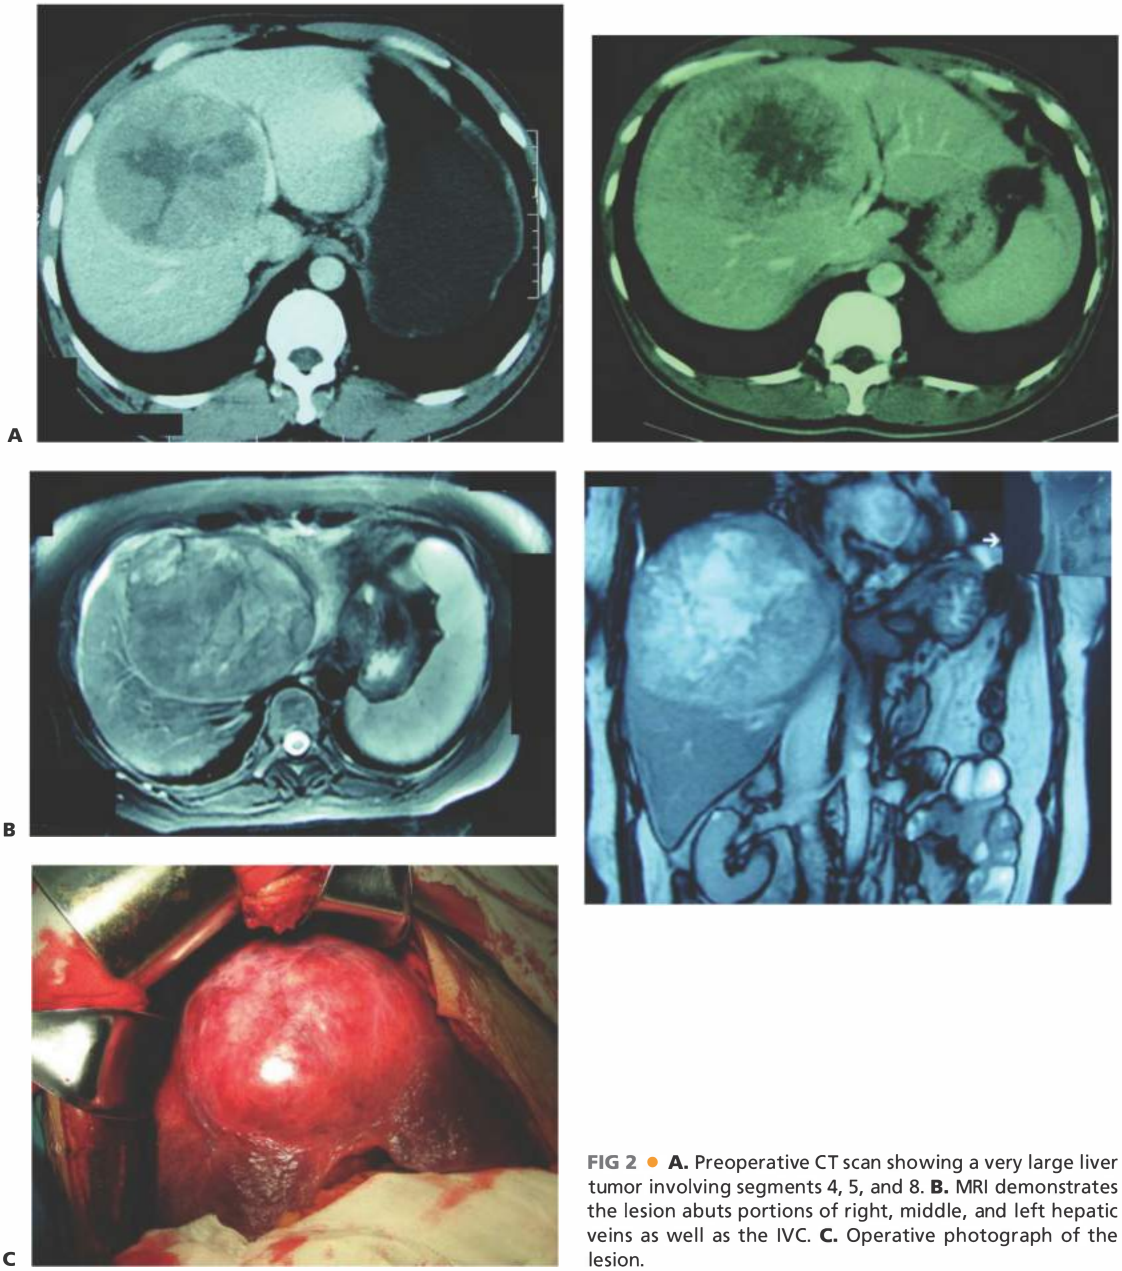

FIG 2 ● **A.** Preoperative CT scan showing a very large liver tumor involving segments 4, 5, and 8. **B.** MRI demonstrates the lesion abuts portions of right, middle, and left hepatic veins as well as the IVC. **C.** Operative photograph of the lesion.

being considered for central hepatectomy will be classified as Child-Pugh A.

- For central hepatectomy, preoperative portal vein embolization is rarely employed as it is often difficult to determine which side of the portal vein should be embolized. Although preoperative transarterial chemoembolization (TACE) has been suggested for reducing HCC tumor size and for facilitating the subsequent resection, in patients who underwent preoperative TACE, cholecystitis and dense adhesions around the liver hilum developed, thus increasing the operative complexity.

Positioning

- The patient should be positioned supine, in gentle reverse Trendelenburg, with both arms extended.
- If suprahepatic control of the IVC is planned or possible, the right arm should be tucked and the chest included in the sterile field.
- Arterial, central venous, and urethral catheters were inserted preoperatively to monitor vital signs, intravascular volume, and urine output during the operation.

- The essential principles of central hepatectomy are (1) control of inflow vessels, (2) control of outflow vessels, (3) parenchymal transection, (4) identifying and controlling potential sites of bile leak, and (5) preserving the vascular inflow and outflow of the hepatic remnant.

INCISION AND INITIAL EXPLORATION

- The abdomen is entered through a right subcostal margin or a bilateral subcostal margin incision. Most surgeons use a bilateral subcostal incision extended vertically to the xiphoid process.
- A right thoracoabdominal incision should be considered. This is particularly relevant when tumor is large and involving the dome of the liver. In this circumstance, control of the hepatic veins and the vena cava may prove very difficult. The morbidity of a thoracoabdominal incision is preferable to potentially catastrophic hemorrhage.
- The liver is bimanually palpated; hepatic metastases and the degree of cirrhosis are determined. Extrahepatic metastases and potential portal adenopathy are assessed, and specimens obtained for frozen section if indicated.
- Intraoperative ultrasonography is used to delineate the extent of the neoplasm, the relationship of the lesion to vital structures, and mark the plane of the parenchymal transection.

MOBILIZATION OF LIVER

- The round ligament is divided and the falciform ligament incised and separated from the anterior abdominal wall.
- The peritoneal reflections that form the triangular ligament are incised and the diaphragm fully mobilized from all attachments to the liver. If, in the course of mobilization, tumor is found to involve the diaphragm, the affected area of the diaphragm may be excised and subsequently repaired with pledgeted sutures.
- The suprahepatic IVC and the hepatic veins above the liver are dissected to facilitate the subsequent approach to the hepatic veins.
- The caudate lobe is fully dissected from the IVC, controlling the small hepatic veins that directly drain into the IVC with clips and/or ligatures. An accessory posterior right hepatic vein is often encountered and may require suture ligation to obtain reliable control of the vessel.

DISSECTION OF THE PORTA HEPATIS

- The classic approach involves extrahepatic control of the inflow vessels (hepatic artery and portal vein) and biliary tree.
- The sheath of the porta hepatis is opened laterally. The cystic duct and artery are ligated and divided. The gallbladder may be either removed or left attached to the liver to preserve a margin when appropriate.
- The portal vein is followed cephalad up to and above the bifurcation. There is usually a small branch that passes posteriorly from the right portal vein to the caudate lobe. Control and division of this vessel is important during middle hepatectomy.
- The right anterior branch and left medial branches of the portal vein and hepatic artery are circumferentially dissected, controlled with vessel loops, and then with vascular clamps prior to being divided and ligated (**FIGS 3** and **4**). These vessels supply the right lobe anterior segments (Couinaud's segments 5 and 8) and the left medial segment (Couinaud's segments 4a and 4b). The usual practice is to ligate the right anterior branch and left medial branch of the artery and portal vein (sometimes including hepatic duct), working from anterior to posterior.
- Typically, unless the tumor involves the middle hepatic vein close to its junction with the IVC, the middle hepatic vein is not controlled extrahepatically. It is identified, controlled, and divided during the parenchymal dissection.
- When feasible, the middle hepatic vein is extraparenchymally isolated, cross-clamped, and divided at its insertion (**FIG 5**). There are two methods for exposing the middle hepatic vein extrahepatically:
  - Method one: The left lobe is retracted anterior and cephalad, and the pars flaccida is incised to expose the caudate lobe. The superior pole of the caudate lobe is then retracted caudally and the medial wall of the IVC is exposed. The ligament of Arantius is divided to establish space between the left hepatic vein, the IVC, and the upper edge of the caudate lobe. The common venous trunk representing the confluence of the left and middle hepatic veins is then encircled with a vessel loop.
  - Method two: From an anterior approach, the fibrous tissue representing the remaining phrenohepatic ligament between the main hepatic veins (confluence of the left and middle veins, and the right hepatic vein) is dissected to develop a plane that extends posteriorly to the anterior surface of IVC. The parenchyma anterior to the left vein is incised for 1 to 2 cm to expose the anterior surface, often exposing the confluence of the left and middle hepatic veins. The middle vein is then controlled.
- The ability to dissect and define the anterior surface of the retrohepatic IVC at the level of insertion of the hepatic veins is often the final step in assuring resectability of lesions located in segment 4a.

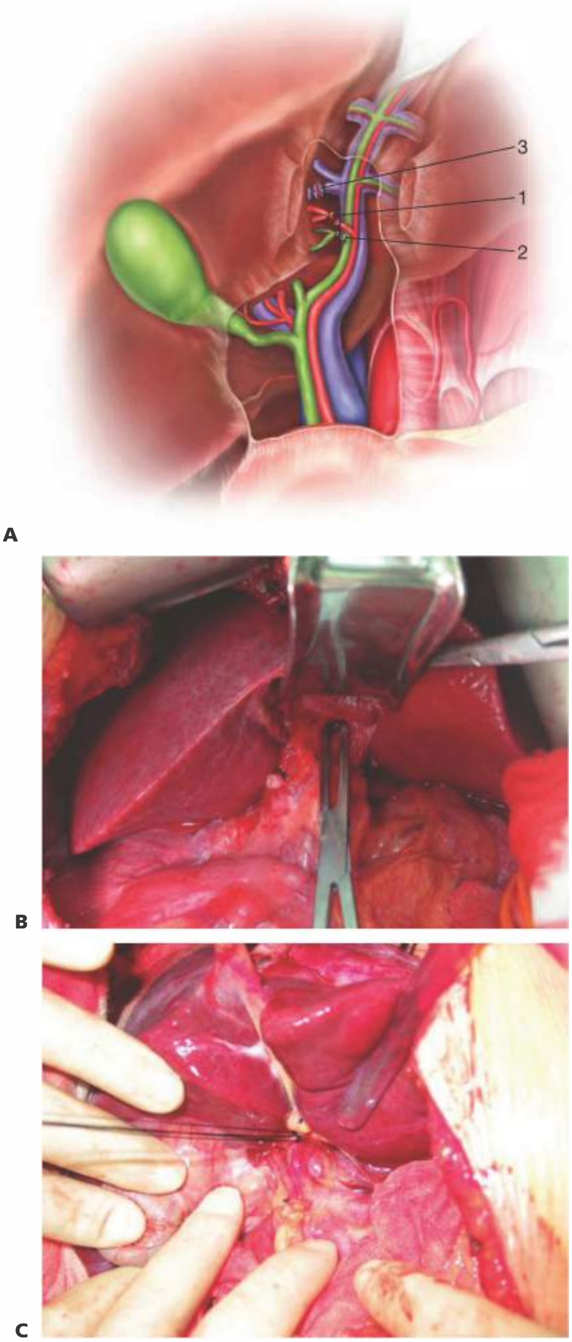

FIG 3 ● **A.** Separation and ligation of the left porta hepatis: *(1)* the left medial hepatic artery, *(2)* the left medial hepatic duct, and *(3)* the left medial portal vein. **B.** Operative photograph of exposure to the segmental branches of the portal structures to segment 4. **C.** Operative image of segment 4 portal structures after ligation and division.

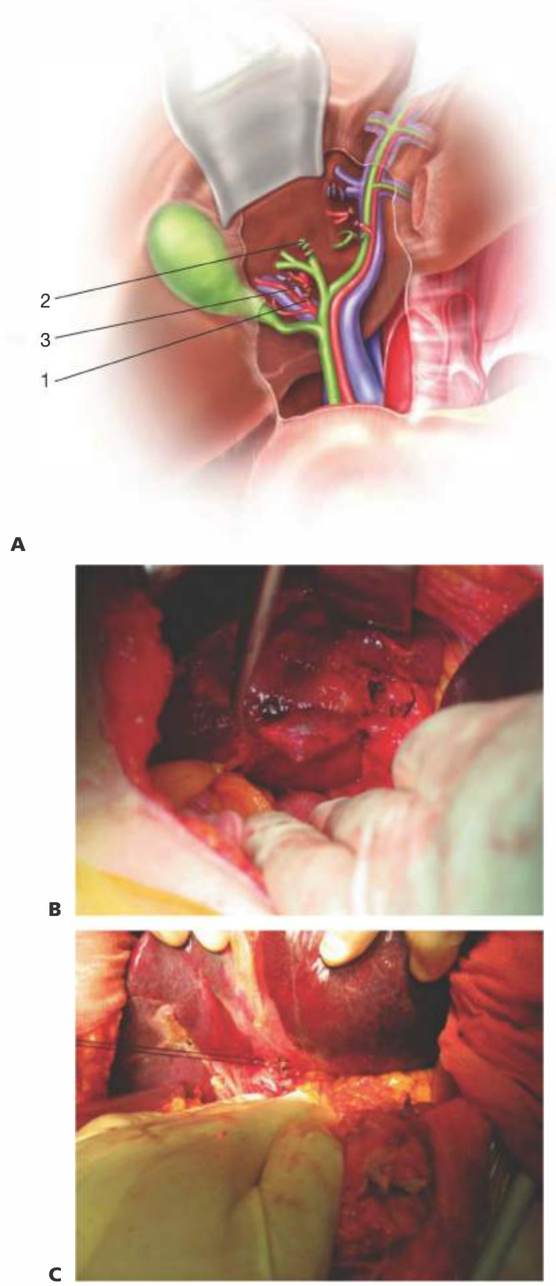

FIG 4 ● **A.** Separation and ligation of the right porta hepatis: *(1)* the anterior branch of the right hepatic artery, *(2)* the anterior branch of the right hepatic duct, and *(3)* the anterior branch of the right portal vein. **B.** Posterior retraction of the mobilized gallbladder to expose the segmental branches of the portal structures. **C.** Segment 5 branches after ligation and division.

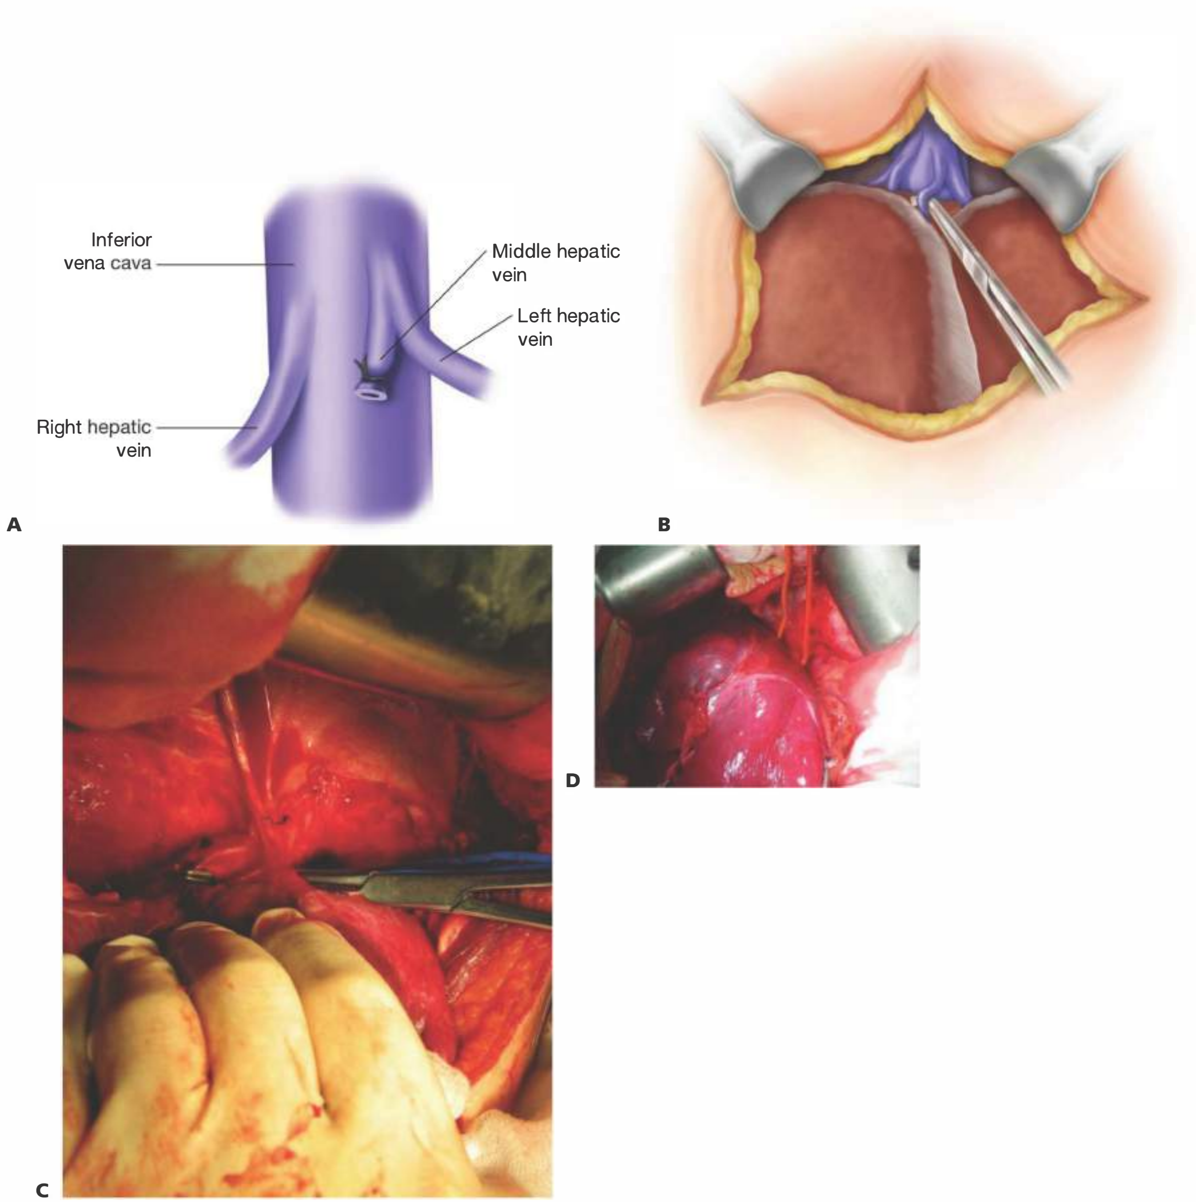

FIG 5 ● Extrahepatic control of the middle hepatic vein. **A.** Typically, there is a confluence of the middle and left hepatic veins prior to insertion into the vena cava. **B.** The confluence of the middle and left hepatic vein occasionally can be dissected extrahepatic, but often, this confluence is enveloped in hepatic parenchyma. **C.** Anterior retraction of the left lobe with posterior retraction of the caudate and vena cave (surgeon's hand) provides exposure to the left and middle hepatic veins. **D.** Anterior view of the looped confluence of the left and middle hepatic veins.

PARENCHYMAL TRANSECTION

- Many specialized instruments are available for use in the parenchymal transection, including argon beam electrocautery, bipolar electrocautery, cavitating ultrasonic aspirators, water-jet dissectors, and combinations thereof.
- The authors prefer to perform the liver parenchymal transection using finger fracture technique with hemihepatic inflow occlusion technique (cyclic clamping of the ipsilateral hepatic artery and portal vein) (**FIG 6**). Alternatively, intermittent application of Pringle's maneuver or total hepatic vascular exclusion may be employed (**FIG 7**).
- It is of paramount importance to preserve both the right and left hepatic vein. As the parenchymal transection must be performed along the course of these vessels, the most technically demanding aspect of central hepatectomy is prevention of injury to one of the hepatic veins draining the intended remnant liver. Such an injury leads to hemorrhage and the potential for air emboli. Also of concern is subsequent hepatic failure from venous congestion.
- Although transsection of the liver parenchyma should be performed as close as feasible to the lines of segmental anatomy, intraoperative ultrasound is of great value to obtain an adequate margin (ideally ≥1 cm) without undue risk to the hepatic veins.
- The first incision is made between the left medial sector (segments 4a and 4b) and left lateral sector (segments 2 and 3). The liver capsule is incised along the falciform ligament, and then the hepatic parenchyma is dissected (**FIG 8**). The vessels to the left part of segment 4 are ligated and divided to the right of the round and falciform ligaments. The full thickness of the parenchyma is sequentially divided with a combination of crushing and ligation.
- As mentioned earlier, ideally, the middle hepatic vein has been isolated, clamped, divided, and sutured outside the liver parenchyma. However, in situations where the tumor involves or is in close proximity of the root of

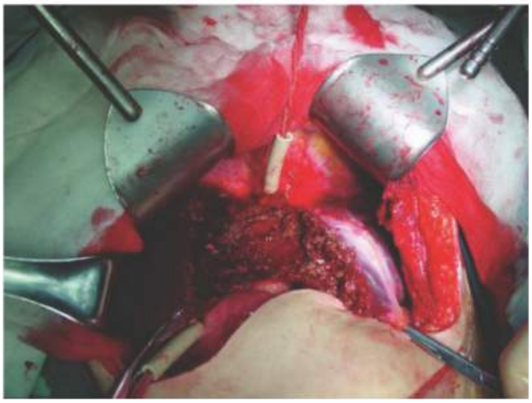

FIG 7 ● Total hepatic vascular isolation. In addition to control of portal inflow and hepatic vein outflow, occlusion of the suprahepatic IVC and infrahepatic IVC is obtained using two umbilical tapes. This intraoperative view is taken after the parenchymal dissection to facilitate visualization of the controlled IVC.

middle hepatic vein, the middle hepatic vein may need to be divided and ligated within the liver parenchyma (FIG 8). This can be particularly challenging as the middle hepatic vein is often compressed by tumor.

- The second incision is made between the right anterior sector (segments 5 and 8) and right posterior sector (segments 6 and 7); restated, the right resection line runs along the demarcation line between the anteromedial and posterolateral segments. The right anterior portal vein, hepatic artery, and bile duct should have already been managed extrahepatically (FIG 9). On the inferior surface of the liver, the resection line runs centrally along the hilar plate.
- The cut surfaces of the liver are then treated with a combination of electrocautery, argon beam coagulation, and thrombogenic agents.

ALTERNATIVE: HEPATECTOMY WITHOUT EXTRAHEPATIC DISSECTION OF THE PORTA HEPATIS

- Hepatectomy without dissection of key structures in the porta hepatis is a simplified surgical maneuver commonly used in clinical practice at present. This approach reduces the complexity of the procedure and is associated with reduced risk of accidental injury.
- Intraoperative ultrasound is used to identify the right and left hepatic veins. Their course is marked on the anterior surface of the liver with electrocautery.
- Using ultrasound and palpation, the liver capsule is marked to achieve 1-cm margins from the lesion.
- The combination of these surface landmarks is used to plan the resection. The liver capsule is then scored along the intended resection planes.
- The hepatic tissue is separated gradually from superficial to deep tissues using a Pringle maneuver to limit inflow. The liver tissue along the right lateral edge of the round ligament on the left is incised working caudad to cephalad and anterior to posterior. Priority is given to identification of the middle hepatic vein, which is then transected and ligated at the insertion.
- The hepatic parenchyma is dissected along a plane 1 cm to the left side of the right intersegmental fissure. The right resection surface should avoid the main right portal vein and right hepatic vein.
- The hepatic capsule is then incised at the posterior and inferior edge of the tumor at the anterior aspect of the confluence of the left and right hepatic ducts confluence to create a plane of dissection between the Glisson's pedicle and the hepatic parenchyma. As this dissection is carried cephalad, the level of dissection should proceed deeper (posterior) into the liver. During this portion of the dissection, care must be taken to not inadvertently enter the IVC.
- All portal branches should be ligated carefully to prevent hemorrhage and formation of biliary fistula.
- To avoid damage to the bile ducts with this technique, the use of a bile duct dilator advanced into the parenchyma from a ductotomy in the common bile duct can help avoid damage to the bile duct during the hepatectomy. Postoperative T-tube drainage is then used as a mitigation strategy against biliary fistula.

MANAGEMENT AND DRAINAGE OF THE HEPATIC WOUND

- After removal of the tumor, the hepatic wound has two raw surfaces. These must be carefully inspected for hemostasis (**FIG 10**). After further examination to assure that there is no biliary fistula, the cut surfaces of the hepatic remnants are appositionally sutured face-to-face, as long as the porta hepatis is not excessively compressed by this maneuver as this can lead to kinking and associated obstruction of portal structures (**FIG 11**).
- Similarly, obstruction of the hepatic outflow vessels due to compression of the hepatic veins may cause swelling and congestion of the liver. This is often apparent intraoperatively; the liver becomes purple and the edges become firm and blunted.
- This face-to-face suturing is not compulsory and should not be performed if it produces excessive tension or is at risk of causing hepatic ischemia or congestion. In such cases, the wound surface can be kept open and covered with a piece of isolated or pedicled greater omentum, or the wound surface can be treated with hemostatic spray gel or other hemostatic materials.
- The authors routinely place two drains under the right diaphragm and in Morrison's pouch.

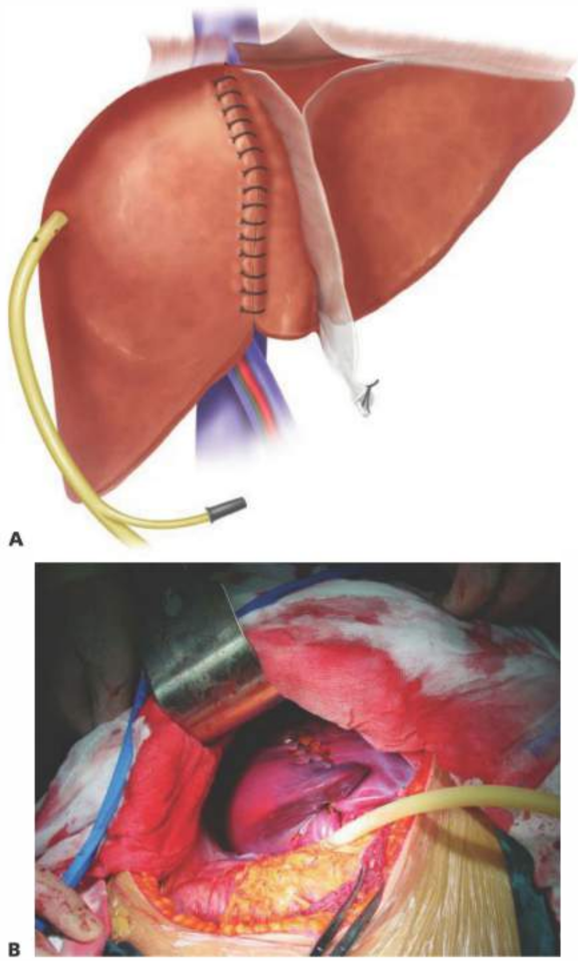
B

FIG 10 ● Uncovered (bare) cut surfaces of the residual liver. **A.** The operative field after the removal of segments 4, 5, and 8. Division of the right anterior branches and left medial branches of portal vein leads to full exposure, anteriorly and medially, of the preserved branches to segments 2, 3, 6, and 7. The vena cava is apparent above the bifurcation of the portal vein. **B.** Schematic visualization of the resection bed.



A

B

FIG 11 ● **A.** Schematic and operative image **(B)** of the liver parenchyma after it has been reapproximated using multiple sutures through the liver capsule. The authors believe that this maneuver reduces the risk of postoperative hemorrhage or bile leak.

PEARLS AND PITFALLS

Patient selection	■ Patients should have intrinsic liver disease or a marginal hepatic remnant to be considered for central hepatectomy.
Preoperative assessment	■ Use ICG clearance or CT volumetry to determine the adequacy of the intended hepatic remnant.
Surgical technique	■ Intraoperative ultrasound is essential to guide localization of vascular anatomy and plan resection planes for adequate margins. ■ Control of the middle hepatic vein at its insertion is paramount. ■ Inflow occlusion reduces blood loss. ■ Intrahepatic control of segmental branches of the portal structures is associated with fewer iatrogenic injuries.
Complications	■ Bile leak is more common given the larger cut surface area. ■ Liver failure is of greater concern as the indication for the procedure is intrinsic liver disease that precludes extended lobectomy.
Outcomes	■ Survival is comparable to that of patients that are candidates for extended lobectomy (**FIG 12**).

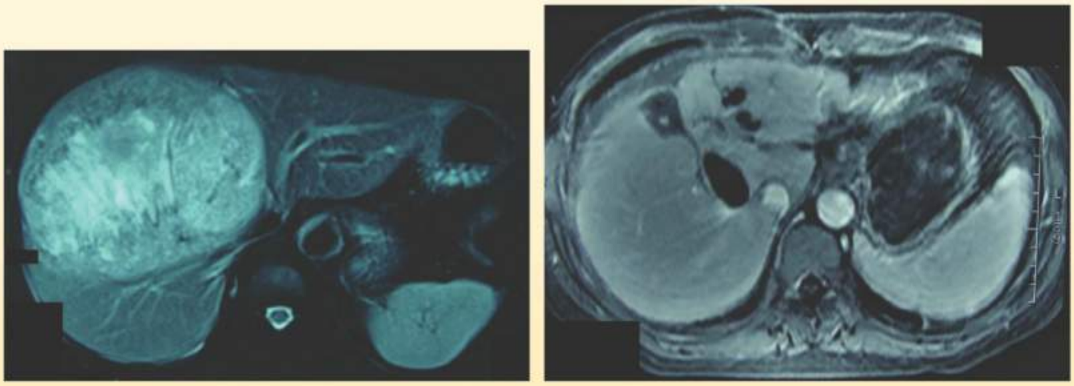


FIG 12 ● MRIs preoperatively and 3 months after central hepatectomy.

POSTOPERATIVE CARE

- The focus of postoperative care in cirrhotic patients is on management of aberrant hepatic synthetic and detoxification functions and portal hypertension. In most patients who undergo hepatic resection, transient hepatic insufficiency develops postoperatively, with hyperbilirubinemia, ascites formation, hypoalbuminemia, edema, and worsening of the baseline coagulopathy.
- Serum levels of aspartate aminotransferase (AST), alkaline phosphatase (ALP), total and direct bilirubin, partial thrombin time (PTT), electrolyte levels, and blood count are checked on the postoperative first, third, and seventh day, or prior to discharge. Serum bilirubin typically is elevated but should peak by postoperative day 2 and then return to normal levels within 1 week. A continued rise in the bilirubin is ominous for insufficient hepatic reserve.
- Sodium intake should be minimized.
- The regenerating liver requires phosphorus supplementation.
- Spironolactone is started in all cirrhotic patients as soon as oral diet is resumed and furosemide is added as needed to control ascites and/or peripheral edema.
- Postoperative pain control is best achieved with patient-controlled analgesia (PCA). Because of the decreased clearance of liver-metabolized drugs after a major hepatectomy, selection and dosing of pain medications should be adjusted accordingly.
- An oral diet can be resumed as early as postoperative day 3.
- The surgical drain can be removed on postoperative day 3 unless it is controlling a bile leak.
- If an unexplained fever occurs or the bilirubin level rises when other hepatic function parameters are normal, an intraabdominal bile collection may be present and a CT scan should be obtained. Percutaneous drain placement usually brings about resolution of such collections after a few days; reoperation is rarely necessary.

OUTCOMES

- Mehrabi et al.[3] reported 48 consecutive patients with centrally located liver tumors that underwent central hepatectomy. Postoperative surgical complications were seen in 18.8% of patients. The 3-year disease-free survival rate was 47.9%.
- As for oncologic outcomes, overall 1-, 3-, and 5-year disease-free survival rates range from 53% to 82%, 30% to 50%, and 17% to 30%, respectively.[4,5]
- Three retrospective studies have compared central hepatectomy to lobar or extended hepatectomy and found no difference in perioperative morbidity and mortality or mean postoperative hospital stay.[6–10] Wu et al.[11] found that central hepatectomy required a significantly longer inflow occlusion time for liver parenchymal transection

than did extended hepatectomies. Patients who underwent extended hepatectomy had worse 1-, 3-, and 6-year disease-free survival rates, but this did not reach statistical significance.

COMPLICATIONS

- Liver failure—The major advantage of a central hepatectomy is preservation of functional liver parenchyma.
- Hemorrhage—Extraparenchymal exposure of the hepatic veins with the possibility of clamping them in association with the Pringle maneuver, and the maintenance of a low central venous pressure during central hepatectomy, can substantially reduce operative hemorrhage.
- The most frequent causes of perioperative death are liver failure and hemorrhage.
- Bile leak—Central hepatectomy is an independent risk factor for bile leak; there are two transection planes and extensive dissection of the hepatic hilum.
- Hepatic venous outflow obstruction
- Ascites

Chapter 29

Vena Cava Resection during Hepatectomy

Aijun Li   Mengchao Wu

DEFINITION

- Hepatic neoplasms involving the inferior vena cava (IVC) have usually been considered unresectable because of the high surgical risk of massive bleeding and air embolism. However, aggressive surgical approaches for hepatic tumors involving the IVC have recently been reported to have been performed safely and have been shown to alter the natural history of the disease.[1–28]

DIFFERENTIAL DIAGNOSIS

- Intrahepatic cholangiocarcinoma(ICC)[29]
- Hepatocellular carcinoma (HCC)
- Renal cell carcinoma
- Metastatic disease

MEDICAL HISTORY AND PHYSICAL EXAM

- By far, the most frequent indication for IVC resection en bloc with hepatectomy is HCC. As cirrhosis is the major risk for HCC and also the major risk factor for postoperative liver failure, great attention must be paid to history, symptoms, and signs associated with underlying liver disease. In general, hepatectomy that also requires IVC resection is only performed in patients without intrinsic liver disease.
- History
  - Hepatitis
  - Alcohol consumption
- Symptoms
  - Fatigue
  - Encephalopathy
  - Rapid weight gain
- Signs
  - Ascites
  - Asterixis
  - Abdominal or thoracic telangiectasia
  - Cachexia
  - Morbid obesity (steatohepatitis)
  - Extensive pedal edema (IVC compression)
- A thorough evaluation of potential pulmonary and cardiovascular disease must be performed. Patients with significant comorbidities are not candidates for major hepatectomy with en bloc IVC resection.

IMAGING AND OTHER LABORATORY STUDIES

- Ultrasonography (US). US is often the initial diagnostic imaging modality employed but is inadequate to fully evaluate hepatic lesions and IVC involvement.
- Contrast-enhanced computed tomography (CT). In addition to providing information regarding the number, size, and location of lesions, CT is an effective tool to estimate the remnant liver volume (RLV).
- Magnetic resonance imaging (MRI) examination. MRI is valuable for characterizing lesions and defining vasculature. It is particularly helpful in diagnosing the extent of tumor thrombus (TT) within the IVC. Magnetic resonance angiography (MRA) is useful for identifying the major hepatic veins and the IVC and clarifying their relations to any tumor masses.
- Each of these modalities may reveal IVC compression or TT within IVC.
- Patients that are suspected of having malignant invasion of the IVC wall on preoperative radiologic studies should also have echocardiography to assess for extension into the right heart. Such extension is not prohibitive of resection but mandates an operative approach that provides access to the chest, thus increasing morbidity while hope for a surgical cure is fleeting.
- In addition to routine laboratories, all patients must undergo a careful preoperative assessment of liver function and potential underlying disease.
  - Liver function tests
  - Hepatitis serologies
  - Coagulation studies
  - Platelet count

SURGICAL MANAGEMENT

Preoperative Planning

- Preoperative ipsilateral portal vein embolization to create hypertrophy of the planned liver remnant may prevent postoperative hepatic failure after extended major hepatectomy.
- Low-volume resuscitation minimizes blood loss but exaggerates potential hemodynamic instability with clamping of the IVC.
- Venovenous bypass (VVB) with total hepatic vascular exclusion (THVE) facilitates resection of primary and metastatic hepatic neoplasms that invade the vena cava.[21,22] Given the prior pearl, be prepared to use VVB when IVC invasion is suspected (**FIG 1**). Preoperative communication and coordination with perfusion and anesthesia teammates is vital to success in this regard.

Anatomic Considerations

- *Characteristics of the posterior hepatic IVC.* The posterior hepatic IVC extends from the renal veins to the confluence of the right atrium (RA). This is further divided anatomically into the inner segment of the pericardium (intrapericardial IVC), the suprahepatic IVC below the diaphragm, the retrohepatic IVC, and the lower segment of the subhepatic renal vein. The IVC is thick-walled, tenacious, elastic, and not particularly susceptible to invasion. The hepatic veins are thin-walled but rapidly develop thicker walls as they insert into the IVC. Thus, the proximal portions of the hepatic veins are at greatest risk for injury during the operation.

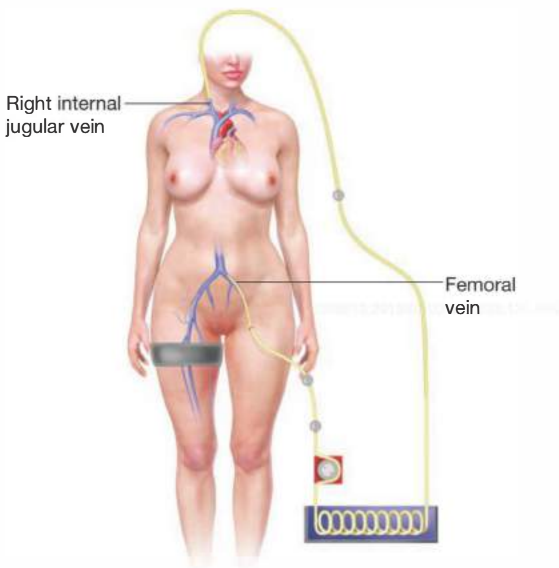

FIG 1 ● Schematic of a VVB circuit. The left femoral and right internal jugular veins are cannulated percutaneously. The patient is heparinized and the cannulae connected to a closed circuit containing a roller pump and a heat exchanger. Blood is drawn from the femoral site and infused into the jugular site.

Such injury invariably results in intraoperative hemorrhage and/or air embolism.

- *Characteristics of tumors that involve the IVC*. Most liver cancers near the IVC originate from hepatic segments 1, 4, 5, and/or 8, or in the paracaval portion of the caudate (referred to by some as segment 9).
    - *Caudate tumors*: Anatomically, the hepatic caudate lobe is divided into the left hepatic caudate lobe (Spigelian lobe, caudate lobe proper, segment 1) and right hepatic caudate lobe (dorsal sector). The right hepatic caudate lobe can be further divided into the paracaval portion (segment 9) and the caudate process (segment 10).[23–26] Caudal tumors may either extend anteriorly and thus invade the portal vein and/or the bile duct, resulting in obstructive jaundice, or extend posteriorly and thus invade the IVC. Generally, about one-fourth of caudate tumors involve the IVC.[27,28]
    - *Tumors arising near the root of the hepatic veins*: These tumors typically compress the anterior IVC between the mid and right hepatic veins or between the mid and left hepatic veins. Because the hepatic veins have no valves, are thin-walled, and fixed in the hepatic parenchyma, they are unable to retract upon injury and air embolism is liable to occur. To avoid air embolism and massive hemorrhage, the operative strategy should plan to isolate the hepatic veins extrahepatically and occlude them in advance.[17–19] The risk in resecting tumors that are near the confluence of the hepatic veins with the IVC is not rupturing the IVC but injuring the thin wall of the hepatic veins.
- *Characteristics of inferior vena cava tumor thrombus (IVCTT)*: IVCTT often spreads from the hepatic veins or hepatic short veins.[30–33] IVCTT is clinically classified into three types (**FIG 2**): (1) the posterior liver type (type I), where TT is located in the IVC behind the liver and below the surface of the diaphragm; (2) the superior liver type (type II), where TT extends into the IVC above the surface of the diaphragm but outside the atrium; and (3) the intracardiac type, where TT surpasses the surface of the diaphragm and enters the RA. The operative plan for patients with IVCTT completely depends on this classification of the IVCTT.

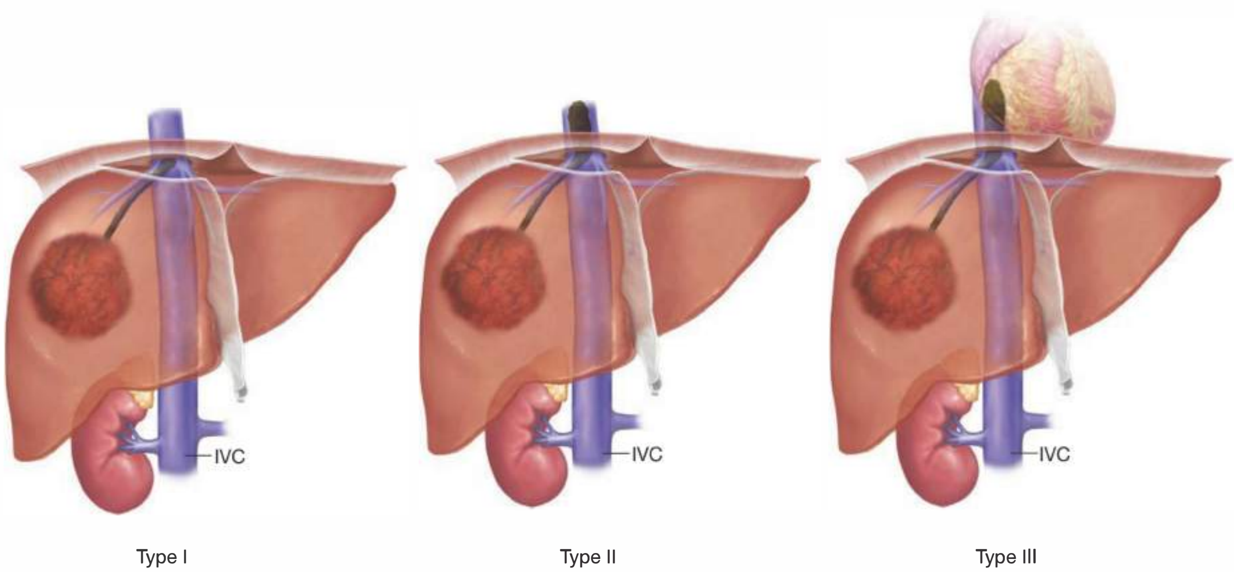

FIG 2 ● **A.** The posterior liver type (type I), where thrombus is located in the IVC behind the liver and below the surface of the diaphragm. **B.** The superior liver type (type II), where thrombus extends into the IVC above the surface of the diaphragm but remains outside the atrium. **C.** The intracardiac type, where thrombus surpasses the surface of the diaphragm and enters the RA.

Surgical Positioning

- The patient is positioned supine with both arms tucked (access to the chest may be required).
- The patient is prepped from chin to midthigh. The chest should be covered with sterile drapes, if sternotomy is not anticipated, to optimize maintenance of normothermia.
- The authors advocate placement of central lines in the left jugular vein and left femoral vein. These are the access points for VVB should it be required.

Incision

- A right subcostal incision with midline extension to the xiphoid process provides excellent exposure and facilitates extension should a sternotomy prove indicated.
- A fixed retractor is used that is capable of providing adequate exposure. The authors use a Thompson retractor.

HEPATIC NEOPLASM INVASION OF THE INFERIOR VENA CAVA WALL WITHOUT TUMOR THROMBUS

- The liver is fully mobilized.
- An umbilical tape is placed around the hepatoduodenal ligament and vessel loops are placed around the right hepatic vein as well as the confluence of the left and middle hepatic veins. Occasionally, lesion location will preclude this control of both veins. The authors advocate being prepared to perform THVE, and associated VVB if indicated, in this setting.
- Next, assess for IVC invasion versus compression. The underlying pathology will be somewhat predictive of encountering true invasion. HCC most typically will compress, but not invade the IVC (**FIG 3**). ICC or metastatic adenocarcinomas are more prone to truly invade the IVC.
- Dissect, control, and divide short hepatic veins working in a caudal to cranial fashion. When the IVC is invaded by a hepatic tumor, the wall becomes pale and stiff. More often than not, there is usually a plane between the tumor and the IVC for separation. Careful identification of this plane may completely avoid injury or need for resection into the IVC.

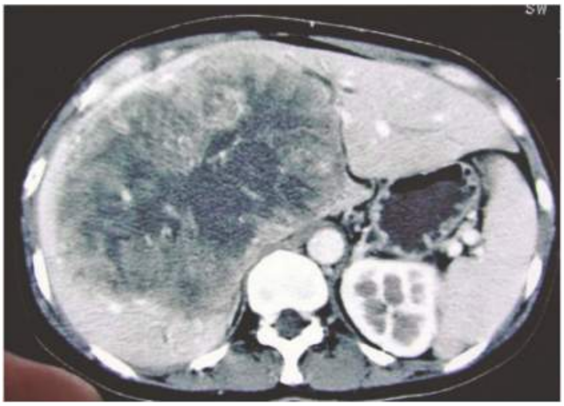

FIG 3 ● Preoperative CT scan showing a very large liver tumor located at segments 4 to 8 with infiltration into the caudate lobe. The IVC is not clearly identified and invasion of the IVC versus compression cannot be determined. Surgical exploration revealed the IVC was not involved. A right trisegmentectomy was performed.

- Sometimes, after tumors are stripped from the IVC or the IVC outer membranes are compromised by sharp dissection technique, the thinned IVC wall should be repaired with polypropylene 5-0 sutures ideally placed in the transverse axis to prevent narrowing of the lumen.
- If the IVC can be fully dissected, resection proceeds as described in other chapters.
- If the IVC is invaded, the next step is to determine if the segment is short enough to facilitate IVC resection with control using a side-biting vascular clamp such as a Satinsky clamp (**FIG 4**). This clamp is most easily placed after the parenchymal transection when the resection specimen can be retracted to elevate the final area of attachment on the IVC. You may not be able to determine the cranial extent of involvement until the liver has been divided.
- Prior to beginning the parenchymal dissection, get control of the suprahepatic and infrahepatic vena cava by circumferentially dissecting them and placing umbilical tapes (**FIG 5**). Identify and set aside the appropriate vascular clamps you will require should THVE prove indicated. A test clamp of the suprahepatic vena cava should be performed to determine the need for VVB, if THVE is required.
- Hepatic transection proceeds from superficial to deep tissues with the portal trial clamped. The left index finger should be placed up against the lateral wall of the IVC, and the left thumb is put on the medial/anterior aspect of the IVC. This maneuver provides proprioception for the operative surgeon during the transection.
- To facilitate vascular control for subsequent repair, clamp the IVC with a large Satinsky clamp to provide a margin for sharp resection of the involved segment of the IVC (**FIGS 6** and **7**).
- If the segment of IVC involvement proves to be more extensive, proceed with THVE to remove the tumor and repair the IVC.
- Sharply excise the lesion with a venous margin that ideally is greater than 0.5 cm.
- Alternatively, the resection can be performed in two steps: to resect and remove the main tumor first, then to clamp the affected part on the IVC wall with Satinsky forceps, cut off the remnant tumor, and finally repair the IVC.
- Assess whether a patch will be required versus primary repair.
    - Simple, longitudinal closure with 5-0 polypropylene is acceptable unless it results in narrowing of the IVC lumen greater than 25%.

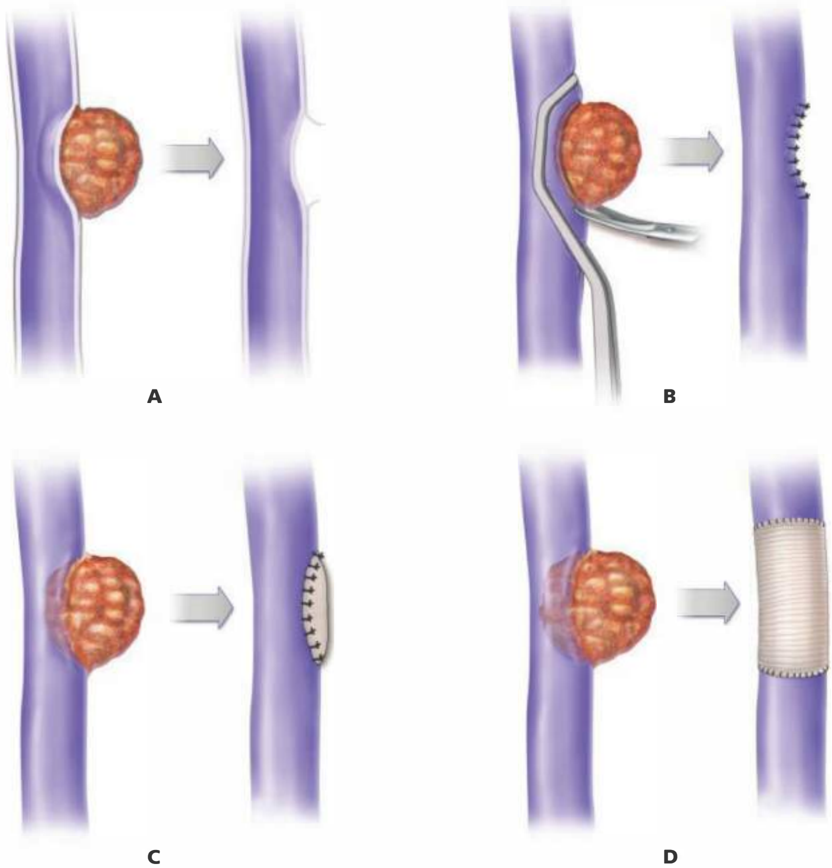

FIG 4 ● **A.** The IVC is not infiltrated, but the IVC was compressed and flat. The tumor is stripped from the IVC, or the IVC outer membranes are sheared by scissors. **B.** The IVC is partially involved but can be resected under side clamping and then primarily closed with direct longitudinal suturing (result should lead to less than a 25% narrowing of the IVC). **C.** When the IVC is extensively involved (>50% of the diameter), the IVC is resected and reconstructed using a patch (bovine pericardium). **D.** If the defect is large or the IVC is occluded, circumferential excision and primary anastomosis is warranted. An interposition graft should only be used only when a long segment of IVC (>3-cm length) is resected.

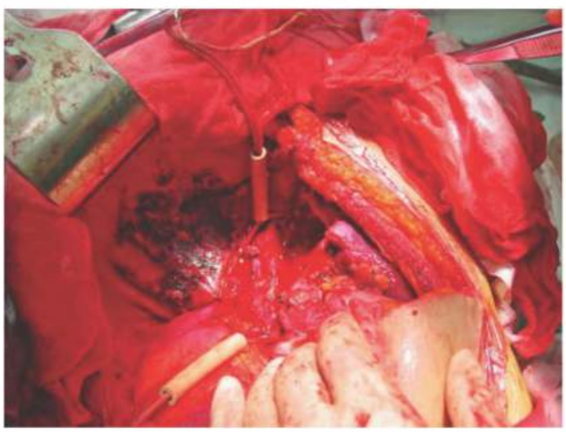

FIG 5 ● Occlusion of the suprahepatic IVC and infrahepatic IVC using two umbilical tape clamps (total hepatic vascular exclusion). This postresection image (to improve visualization of the placement of the umbilical tapes) was taken after a right trisegmentectomy was performed.

FIG 6 ● Preoperative CT scan showing a liver tumor located at the caudate lobe with probable invasion of the IVC.

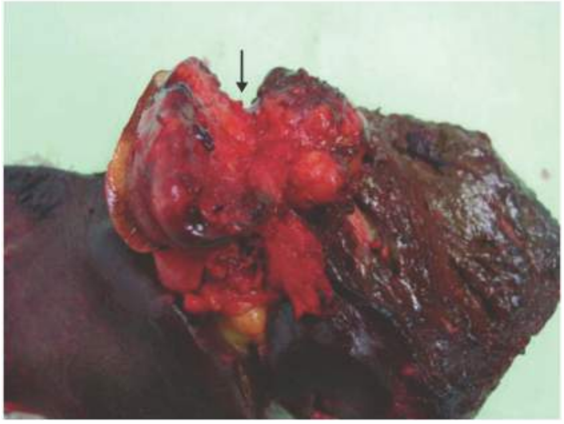

FIG 7 ● Macroscopic findings of resected specimen. A 4 × 5 × 5 cm IVC infiltrating-type tumor occupied the caudate lobe parenchyma sitting astride the IVC. The *black arrow* indicates the course of the IVC. This lesion was resected using a side-biting vascular clamp. The resultant defect in the IVC required a patch repair.

- Alternatively, if the resection exceeds about half of the circumference, a patch of autologous vein or bovine pericardium can be sewn circumferentially with running 5-0 polypropylene.
- Reported vein grafts for patch repair include saphenous vein, superficial femoral vein, or left renal vein.

- If the IVC is either extensively infiltrated or completely obstructed, the IVC should be resected and reconstructed using a graft. During segmental resection, vascular clamps should be placed at both proximal and distal sides of the involved part of the IVC. Umbilical tapes will not provide adequate hemostasis.
- Defects shorter than 3 cm can often be primarily reapproximated with 5-0 polypropylene.
- If the defect is longer than 3 cm or primary anastomosis is under undue tension, an interposition graft is warranted.
- Unfortunately, autologous vein grafts are too small to replace the IVC. The favored material for an IVC interposition graft is stented polytetrafluoroethylene (ePTFE).[14, 34–46] These conduits are available in varying sizes and are inserted using 5-0 polypropylene running suture.

HEPATIC NEOPLASM WITH INFERIOR VENA CAVA TUMOR THROMBUS

- Surgery selection depends on the level at which TT enters the IVC (**FIG 2**).
- In surgical manipulation of HCC with TT, it is critical to avoid squeezing the hepatic veins and the IVC in the process of dissecting the tumor, which may result in TT pulmonary embolism. However, "no-touch" technique is almost impossible in the process of dissecting a large tumor mass, and therefore, it is difficult to prevent TT from falling off completely.
  - One option to minimize this risk is to implant a device near the IVCTT proximal to the heart before tumor dissection so as to prevent TT fall off. B. Braun's Tempofilter II temporary IVC filter is a device designed for this purpose.[33]
  - The filter is implanted under local anesthesia via the right cervical vein 1 day before surgery or in the morning of surgery and fixed in the IVC by means of the delivery rod. It can be withdrawn easily after surgery.
  - The device can be fixed securely as long as there is a more than 2-cm distance between the TT and the right atrial orifice.
- For type I tumors
  - Explore the location and size of the tumor and location of the IVC first; completely mobilize the liver and expose the IVC above and below the liver.
  - The levels for vascular exclusion are at the suprahepatic IVC and infrahepatic IVC (between the adrenal vein and renal vein). Pass umbilical tapes at these levels.
  - Use care to minimize manipulation of the involved hepatic vein—tumor embolus is possible.
  - Transect the liver parenchyma under Pringle occlusion first, leaving only the affected hepatic vein in continuity with the specimen and the IVC.
  - Clamp the IVC.
  - Open the hepatic veins and the IVC under direct vision (open the IVC below the liver longitudinally); resect and remove TT under direct vision.
    - As most tumor thrombi are not attached to the wall, they can be removed or dissected from the IVC under direct vision.
    - In some cases where TT is attached to the wall or invade the IVC wall and cannot be removed completely, partial IVC resection plus repair can be performed.
    - In cases where TT has infiltrated the venous wall, adhered with it severely, and obstructed the IVC completely, resect the involved partial IVC together with TT.
    - In cases where complete removal of TT is impossible, IVC replacement can be considered. As the location of type I IVCTT is relatively low, venous TT can be removed surgically by using the standard radical hepatectomy and THVE.
  - To restore venous return, control the IVC with a side-biting vascular clamp and release the occluding clamps.
  - Irrigate the IVC and suture the luminal wall.
- In type II tumors, TT has surpassed the level of the diaphragm, thus the TT has to be removed by opening the diaphragm and the pericardium so that the level of

FIG 8 ● The CT of the case described revealed a large hepatic tumor with TT through the right hepatic vein to the IVC. The patient underwent a combined right hepatic and TT resection.

vascular isolation of the suprahepatic IVC is above the diaphragm but below the RA (**FIGS 8** and **9**).

- In type Ⅱ TT, subdiaphragmatic occlusion of the IVC is not appropriate, as it may cause TT rupture and fall off, resulting in cardiac tamponade, acute pulmonary embolism, and other serious complications.
- Dissect the infrahepatic IVC first and fully mobilize the liver.
- Open the diaphragm anterior to the suprahepatic IVC and enter the mediastinum to expose the right auricle (**FIG 10**).
- Control the suprahepatic IVC from within the pericardial space. Place an umbilical tape (**FIG 11**).

FIG 9 ● Coronal view of an MRI of the same patient demonstrating TT extending into the supraphrenic IVC *(black arrow)*, above the surface of the diaphragm but outside the atrium.

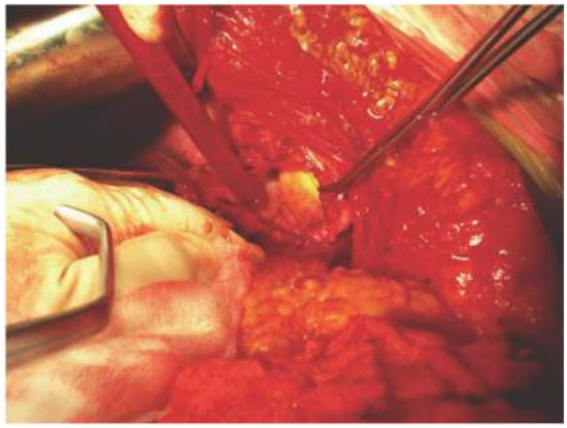

FIG 10 ● Exposure of the suprahepatic IVC above diaphragm. Note the white pericardium.

- Occlude the first portal (Pringle occlusion) and then the infrahepatic IVC.
- Occlude the right auricle with Satinsky forceps (**FIG 12**).
- Open the IVC longitudinally and resect the TT together with the tumor under direct vision.
- Before resuming blood flow, the residual TT and clots should be washed out with the help of the blood pressure still existing in the IVC for the sake of avoiding pulmonary embolism caused by air and blood clots.
- Close the IVC defect with running 5-0 polypropylene (**FIG 13**).
- Reversely, release the Satinsky forceps, and then the IVC below the liver, and the first portal occlusion (Pringle occlusion).
- Repair the pericardium and the diaphragm (**FIG 14**).
- **FIG 15** demonstrates the resected specimen with extension of TT that has been removed.

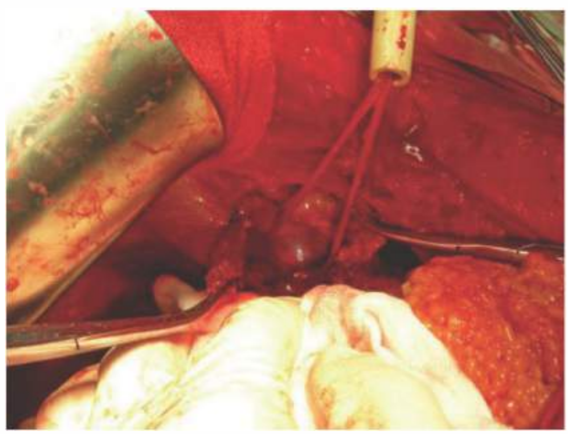

FIG 11 ● The suprahepatic IVC is circumferentially dissected within the pericardial space, above the diaphragm, and an umbilical tape passed.

FIG 12 ● The right atrial appendage was occluded with a Satinsky clamp.

- Type III TT can extend to the RA (**FIG 16**), and therefore, TT removal has to be performed under direct vision using extracorporeal circulation (under cardiopulmonary bypass).[31,32]
- Georgen et al.[31] describe an original finger-assisted thoracoabdominal approach for resection of HCC with thrombus extending into the RA, assisted by transesophageal echocardiography (TEE), which avoids the need for extracorporal bypass. There are three prerequisites for this procedure:
  - There are no adhesions to the venous wall of macroscopic thrombus in patients with HCC.
  - Complete mobilization of the liver allows caudal retraction of the liver and en bloc retraction of the tumor and the thrombus out of the RA.
  - After application of a vascular clamp on the suprahepatic portion of the IVC above the thrombus, a routine hepatic vascular exclusion can be performed to remove the tumor and the thrombus.

FIG 13 ● The IVC wall is closed using polypropylene 5-0 suture.

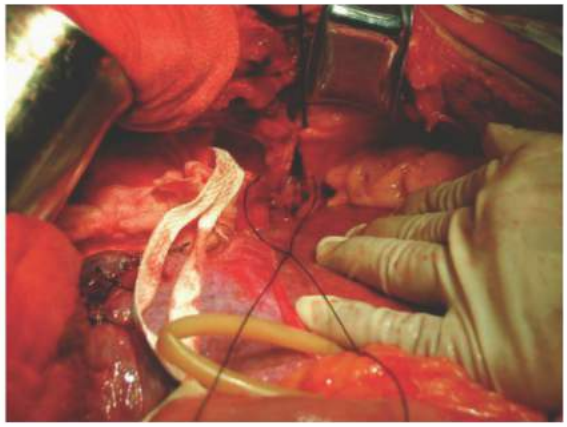

FIG 14 ● The diaphragm is repaired using interrupted sutures.

FIG 15 ● Liver tumor together with thrombus gross pathology. *Arrow* indicated TT in the right hepatic vein; TT of IVC *(right)*.

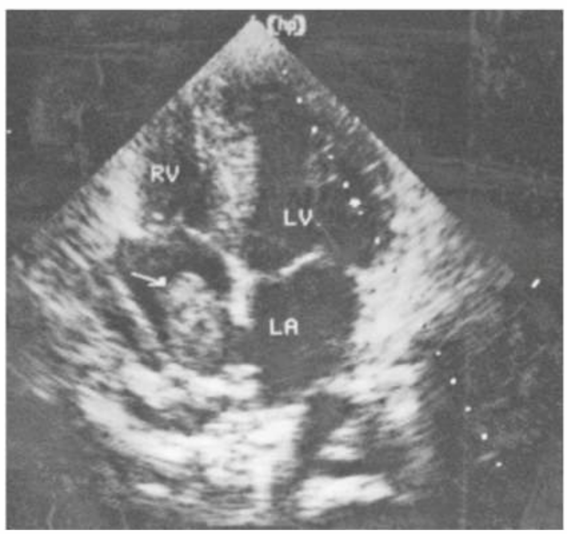

FIG 16 ● Echocardiography revealing TT *(white arrow)* extending into the RA.

POSTOPERATIVE MANAGEMENT

- Liver function, electrolyte levels, blood count, and prothrombin time (PT) are checked after the operation and then daily until discharge.
- Postoperative pain control is best achieved with patient-controlled analgesia (PCA). Because of the decreased clearance of liver-metabolized drugs after a hepatectomy, selection and dosing of pain medications should be adjusted accordingly.
- Phosphate supplementation is empirically provided as liver regeneration will consume large amounts of phosphate.
- An oral diet can be resumed as early as postoperative day 3.
- Fever, tachycardia, or hyperbilirubinemia when other hepatic function parameters are normal are signs that an intraabdominal bile collection may be present, and a CT scan should be obtained. Percutaneous drain placement usually brings about resolution of such collections after a few days; reoperation is rarely necessary.
- The focus of postoperative care in cirrhotic patients is on management of cirrhosis and portal hypertension. In most such patients who undergo hepatic resection, transient hepatic insufficiency develops postoperatively with hyperbilirubinemia, ascites formation, hypoalbuminemia, edema, and worsening of the baseline coagulopathy.

COMPLICATIONS

- Bleeding (hepatic wound surfaces, intraperitoneal, and gastrointestinal bleeding)
- Hepatic failure, renal failure
- Bile leak
- Subphrenic abscess
- Hepatic venous outflow obstruction
- The hepatic wound surfaces infection
- Pneumothorax, pleural effusion

OUTCOMES

- The reported 5-year survival for HCC invading the main trunk of the portal vein and the IVC is 20%,[34] and this was better than that of patients that received transarterial chemoembolization (TACE) alone.
- Arii et al.[35] reported IVC resection with reconstruction using ePTFE led to a 50% survival at 29 months. Patency of the graft was maintained for the long term without infectious complications. One-year, 3-year, and 5-year survival rates were 63.6%, 38.2%, and 25.5%, respectively.
- Azoulay et al.[36] reported their experience with concomitant hepatic and IVC resection in 22 patients with various liver tumors. Actuarial 1-, 3-, and 5-year survival rates were 81.8%, 38.3%, and 38.3%, respectively.
- Recent data[7,31,32,47–50] reported a 5-year survival rate of 20% to 30% and a median survival of 9.8 to 28 months, showing that patients who underwent complete resection of the tumor together with associated TT survived a long time.
- It is now generally accepted that the prognosis is good in HCC patients who received radical resection of the tumor together with dissection of the IVCTT as long as there is no local or distal metastasis.

Chapter 30

Right Hepatic Trisegmentectomy

Ivan R. Zendejas

DEFINITION

- Removal of all the liver located to the right of the falciform ligament; the left lateral segment represents the functional remnant. By the segmental anatomy of the liver (**FIG 1**), this represents the resection of the three liver segments located to the right of the falciform ligament including the middle segment (4A and 4B), the right anterior segment (5 and 8), and the right posterior segment (6 and 7).
- The resection may also include the caudate lobe and all the biliary ducts to the right of the umbilical fissure. This is most frequently indicated in hilar cholangiocarcinoma patients.

DIFFERENTIAL DIAGNOSIS

- Cholangiocarcinoma
- Metastatic carcinoma
- Hepatocellular carcinoma
- Gallbladder cancer
- Liver trauma

PATIENT HISTORY AND PHYSICAL FINDINGS

- Attention must be given to the potential for underlying liver disease. The intended hepatic remnant following right trisegmentectomy is inadequate.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Triphasic, contrast-enhanced abdominal computed tomography (CT) scan
  - Its main value is to identify the vascular structures involved, anatomic variations in the hilar vasculature, and margins to be preserved at the time of surgery (**FIG 2**).

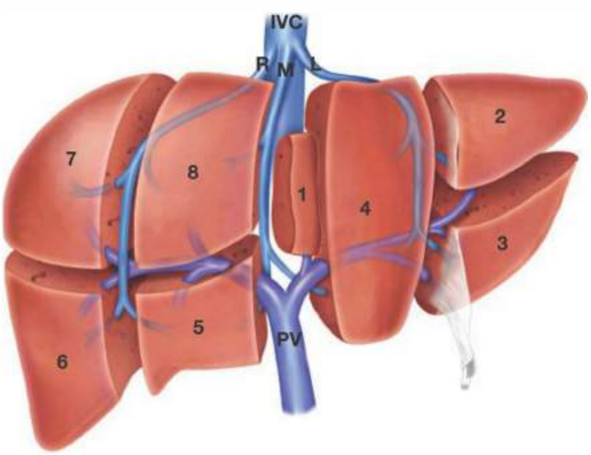

FIG 1 ● Anatomy of a right trisegmentectomy. Segments 7 and 8 are routinely removed. Segment 1 is selectively included in the resection, depending on the indication and ability to obtain a negative resection margin.

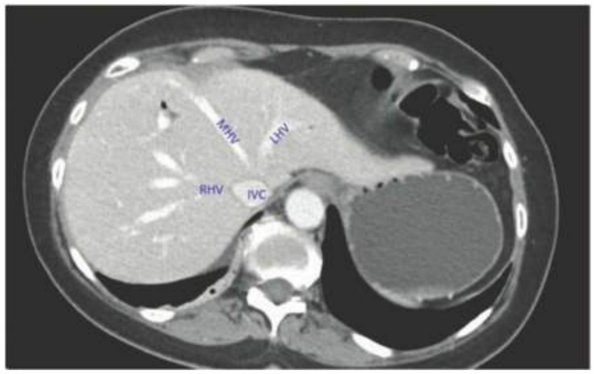

FIG 2 ● Anatomy of the hepatic veins. The transection plane for a right trisegmentectomy is between the middle hepatic vein (MHV) and left hepatic vein (LHV).

  - Examples of CT scans from patients with hepatocellular carcinoma involving the right side and middle segments (**FIG 3**) and a right dominant hilar cholangiocarcinoma are shown (**FIG 4**).
- Abdominal magnetic resonance imaging (MRI) with contrast and delayed liver phase
  - Equivalent to a contrast CT scan; slightly better at defining parenchyma abnormalities and in differential diagnosis
- Intraoperative ultrasound (IOUS)
  - Essential tool and skill needed during liver surgery. IOUS helps define margins, identify smaller lesions (<1 cm), and visualize the portal pedicles and hepatic veins (**FIGS 5** and **6**).

SURGICAL MANAGEMENT

Preoperative Planning

- The volume of the intended remnant liver should to be calculated with preoperative imaging and considered against the patient body weight. The author favors 3-D reconstruction of a CT scan with software rendition of the remnant volume (**FIG 7**).

FIG 3 ● Hepatocellular carcinoma involving the right and middle sectors.

FIG 4 ● Right dominant hilar cholangiocarcinoma. Note the dilated bile ducts in segment 4, to the right of the falciform ligament, suggesting the obstruction is distal to their confluence with the other ducts draining the left lobe.

FIG 6 ● IOUS of a hepatic neoplasm. The hypoechoic lesion is at the top of the image. The interface with normal parenchyma is readily apparent.

- The functional capacity of the remnant liver should be estimated.
- Portal vein (PV) embolization of the right lobe (and occasionally segment 4) is often indicated.
- If PV embolization is performed, CT scan volumetrics are repeated 3 to 4 weeks postembolization to assess for adequate hypertrophy of the planned liver remnant.
- Low-volume intraoperative resuscitation reduces blood loss. This approach requires preoperative communication with the preoperative nursing staff and anesthesiologist.
- Regional anesthesia approaches, such as epidural catheters, reduce pain scores and respiratory complications.
- Preoperative steroid (100 mg intravenous [IV] methylprednisolone) is associated with reduced peaks of liver injury test values but not improved outcomes.

Positioning

- The patient is placed in a supine position. Tucking the right arm is optional, depending on the retractor to be used.
- The patient is prepped from the nipples to the pubis on both sides.
- The authors routinely place an arterial line and central venous line.

FIG 5 ● Hepatic vein confluence under IOUS. Fluid-filled structures appear *black*. Doppler color facilitates identification of cystic lesions from vascular structures. In this image, the left hepatic vein is highlighted by the Doppler signal *(blue)* and the right hepatic vein is highlighted *red* as they insert into the inferior vena cava (IVC). The middle hepatic vein in this patient does not fuse with the left hepatic vein prior to IVC insertion and is seen above the IVC without Doppler enhancement.

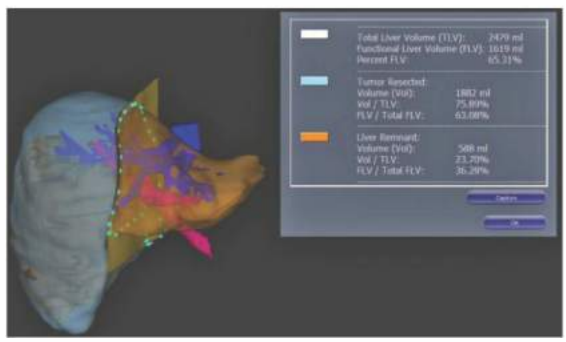

FIG 7 ● Tridimensional reconstructions showing the volume of the liver remnant. This particular software package provides the volume and percent of the total volume (table insert).

INCISION

- A number of options are possible (**FIG 8**) for appropriate exposure to perform a right trisegmentectomy.
- Bilateral, subcostal incision with upper midline extension (A + B + C)
- A right-sided, hockey stick–type incision (A + C)
- In children, a flat bilateral incision can be used (A + B).
- Removal of the xiphoid process is optional in order to get a better exposure of the suprahepatic abdominal vena cava.

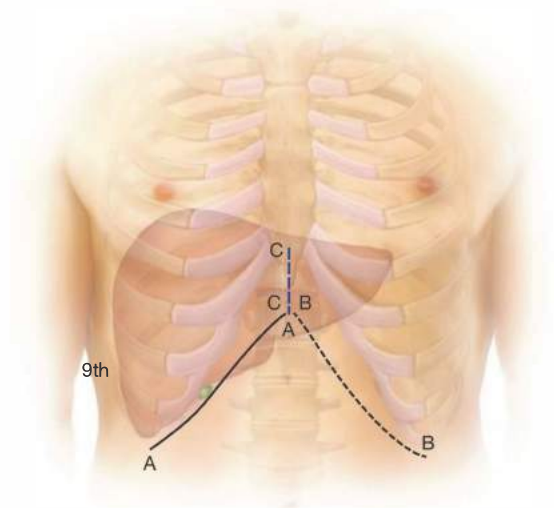

FIG 8 ● Types of incision for a right trisegmentectomy. The authors favor a right subcostal incision with midline extension to the xiphoid process.

EXPOSURE

- A Thompson retractor facilitates the application of adequate tension of the costal margin to provide exposure to the hepatic veins and suprahepatic vena cava.

HILAR PALPATION

- Bimanual palpation of the hilar structures through the foramen of Winslow quickly defines the arterial anatomy (**FIG 9**). A pulse felt posterior to the PV is a sure sign of a replaced right hepatic artery originating from the superior mesenteric artery. The gastrohepatic ligament is inspected for the presence of a replaced/accessory left hepatic artery supplying the left lateral segment. The best place to palpate the left hepatic artery is the umbilical fissure at the base of the liver. The arterial supply of the left lateral segment has to be clearly identified and preserved for a successful outcome.
- Nodal disease can be palpated and fixation of portal structures can estimate tumor extension.

FIG 9 ● Palpation of the porta hepatis facilitates definition of the arterial anatomy, the presence of involved lymph nodes, and pedicle encasement due to tumor extension.

LIVER MOBILIZATION

- The round ligament is ligated. The falciform ligament is taken down to the level of the hepatic veins. The gastrohepatic ligament is opened with careful attention to preserve the occasional replaced/accessory left hepatic artery. At this point, mobilization of the right lobe is performed (IOUS may be occasionally performed prior to mobilization depending on the tumor size and mobility of the liver) (**FIG 10**). The right lobe is mobilized by taking down the right coronary and triangular ligaments and lifting up the right lobe from the bare area with attention to the adrenal gland and the right side of the vena cava. The short caudate veins are isolated and controlled with ligatures, clips, and/or vascular stapler loads.

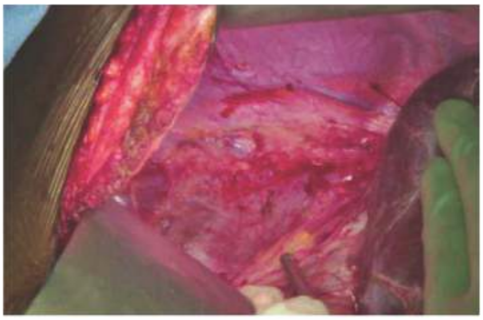

FIG 10 ● Mobilization of the right lobe. The liver is being manually retracted to the midline, revealing the exposed diaphragm after division of the triangular ligament.

HILAR DISSECTION

- The cystic duct and cystic artery are dissected, ligated, and divided. The right hepatic artery is identified on the right side of the bile duct, ligated, and divided (**FIG 11**). There are so many variations in the arterial anatomy that the left hepatic artery flow has to be felt by doing a test clamp on the right side. The lymphatic and nerve tissue in the porta hepatis will be cleared, and the right PV branches will then be visualized. Alternatively, the right PV can be identified by following the main PV situated laterally and posteriorly in the portal pedicle. The right PV is encircled with a vessel loop. If the vein is long, then it can be stapled using a vascular load. If it is short, then it will be divided in between clamps and then sutured with continuous 6-0 Prolene. After the inflow is occluded, the area of demarcation will be seen on the right lobe of the liver from the gallbladder fossa to the vena cava area.
- The common hepatic duct divides high up on the hilum and, in fact, the division may be within the substance of the liver and only visualized after incising the hilar plate (**FIG 12**). The right branch of the duct will be identified at the base of the liver and, once encircled, it will be ligated and divided. Before the division of the right duct is completed, a definite duct that passes into the left side has to be demonstrated (**FIG 13**).
- At this point, the retractor is adjusted to expose the area of the umbilical fissure (**FIG 14**). The fissure may need to be exposed by transecting the parenchymal bridges that occasionally join the medial and lateral segments. The transverse portion of the umbilical fissure is identified at the base of segment 4B. Except for a few posterior caudate branches, there are no other significant branches in this portion of the PV. If the caudate lobe

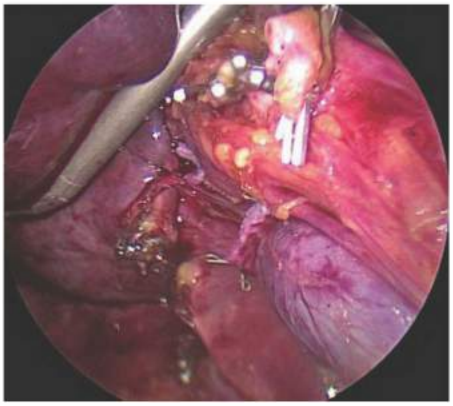

FIG 11 ● Ligation/stapling of the right-sided structures. The right PV has been divided with a linear stapler, and the right hepatic artery and hepatic ducts have been divided between surgical clips.

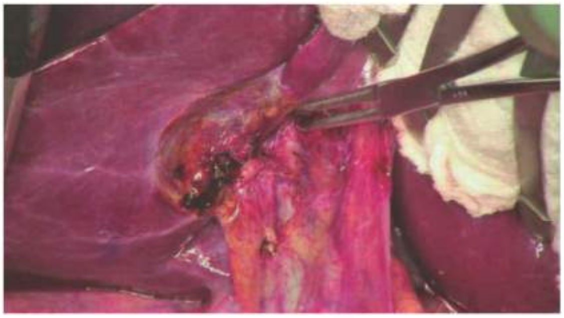

FIG 12 ● Dissection of the hilar plate. The bifurcation of the hepatic duct can be within the parenchyma of the liver. Glisson's capsule has been incised anterior to the hepatic duct in this example (tip of the surgical instrument).

FIG 13 ● Clear identification of the left bile duct. By elevating the hilar plate, the left hepatic duct is then clearly identified (tip of the forceps).

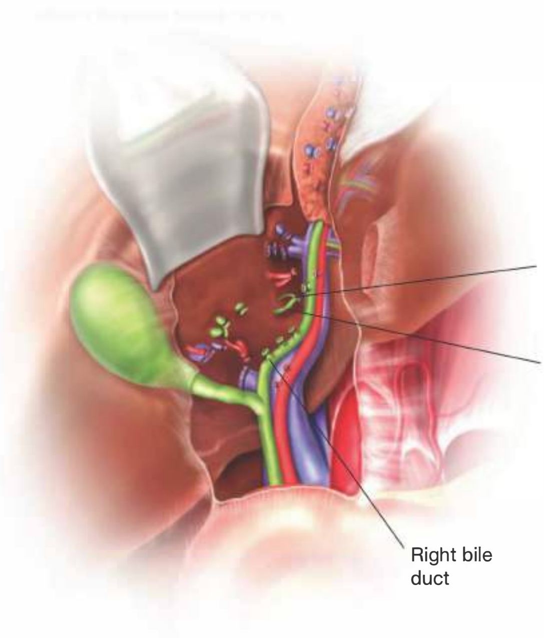

FIG 14 ● Dissection of segments 4A and 4B branches. Dissection is carried medial to the left hepatic duct. The dissection plane must be to the right of the falciform ligament to prevent injury to the structures essential to segments 2 and 3.

is to be removed, then these branches are ligated and divided. A replaced or accessory left hepatic artery will be identified at the base of the umbilical fissure. If present, this variant is an advantage by minimizing the risk of de-arterializing the remaining liver. The dissection is then carried out along the right side of the umbilical fissure, ligating all the medial branches to segments 4A and 4B. This can be done via the Glissonian approach (ligating and dividing them individually) or during the parenchymal transection.

HEPATIC VEINS DISSECTION

- With the right lobe of the liver fully mobilized to the left side of the vena cava, all the retrohepatic veins are ligated and divided including the right adrenal vein, right caudate vein, and several small posterior hepatic veins. The origin of the right hepatic vein is identified, encircled, and divided with a vascular stapler or between clamps, depending on the vessel length and proximity to the tumor (**FIG 15**). After this step, the only patent veins will be the middle and left hepatic veins. The middle vein will be divided during the parenchymal transection as this is typically the safest approach (injury of the left hepatic vein is catastrophic). Alternatively, when an adequate margin is at risk or the anatomy is favorable, the middle vein can be individually encircled by an anterior approach dissecting the tight space between the left and middle vein. A right angle can be used to find this groove, pointing it inferiorly. The left lateral segment is elevated to the right and the ligamentum venosus is divided. The left hepatic vein is identified and the dissection will be carried out on its back wall in a plane just anterior to the vena cava. With careful dissection, the left hepatic vein can be encircled as well as the middle vein. Once again, it is critical to leave the origin of the left hepatic vein intact to secure an adequate function of the remnant.

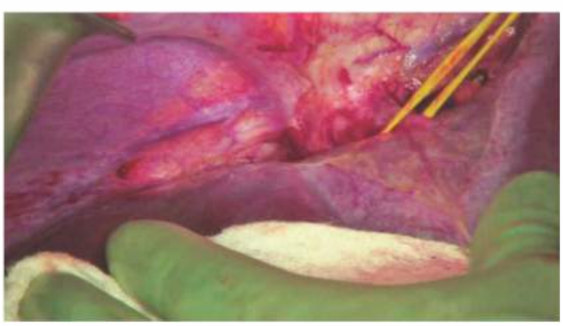

FIG 15 ● Left/middle hepatic vein isolation. The insertion of the middle hepatic vein into the left hepatic vein is most frequently within the parenchyma of the liver. Thus, it is safest to control and divide the middle vein during the parenchymal transection.

LIVER TRANSECTION

- The transection line for right trisegmentectomy is just to the right of the falciform ligament anteriorly, the umbilical fissure or the round ligament inferiorly, and the anterior surface of the vena cava posteriorly (FIG 16). A hanging maneuver using a long Penrose drain or an umbilical tape passed behind the substance of the liver can facilitate proprioception of the transection plane. The parenchyma can be divided with a combination of techniques including fragmentation, stapler, or precoagulation. Regardless of the method used, the small portal triads and hepatic vein branches should be clipped or ligated. As the transection continued, the middle hepatic vein will be divided as well. The cut surface of a right trisegmentectomy transection plane is generally small and relatively hemostatic (FIG 17). Hemostasis on the surface can be achieved with a combination energy devices and chemical products.

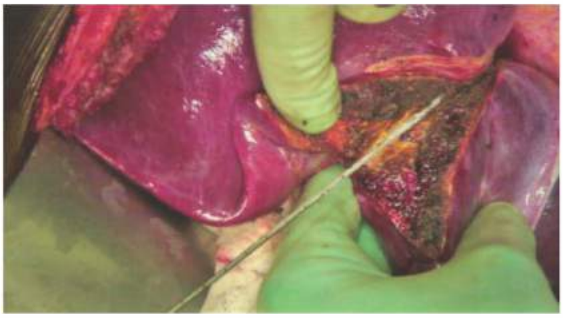

FIG 16 ● Parenchymal transection. The authors prefer a combination of cautery, clips, and ligatures to perform the transection. The use of a microwave probe is demonstrated in this example.

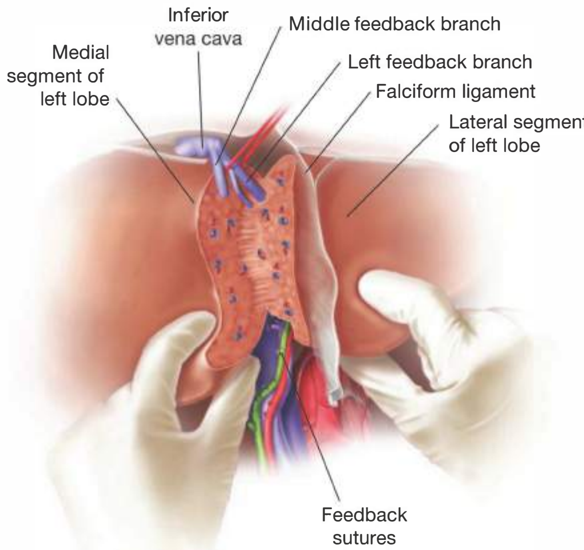

FIG 17 ● Completion of the parenchymal transection with preservation of the left hepatic vein.

CLOSURE

- The use of a drain is optional. The parenchyma and biliary pedicles are inspected for leaks and sutured as needed.
- The left lateral segment is attached to the anterior abdominal wall with a nonabsorbable suture to prevent potential torsion and the associated catastrophic compromise of vascular inflow or outflow.
- The abdominal wall is then closed in a single- or double-layer fashion with absorbable suture. Skin is then closed with subcuticular sutures or staples.

PEARLS AND PITFALLS

Preoperative planning	■ Right trisegmentectomy with caudate lobectomy is indicated for advanced hilar cholangiocarcinoma with involvement of the right-sided bile ducts. Only when the bile duct is divided at the left side of the umbilical fissure can significant negative margins be achieved. Performance of an R0 resection is essential for a good outcome. ■ Assessment of the planned liver remnant by volumetrics or other functional assessment is critical for trisegmentectomy patients. ■ PV embolization should be considered for all potential trisegmentectomy patients.
Intraoperative monitoring	■ Temperature: It is imperative to maintain adequate core temperature to avoid the mortal triad of hypothermia, acidosis, and coagulopathy. The core temperature can be measured with an esophageal probe; Foley catheter with thermometer of a PA catheter, if deemed necessary. ■ Hemodynamic monitoring includes central line for central venous pressure (CVP) and an arterial line to assure an adequate perfusion in real time.
Operative technique	■ The division of the intrahepatic bile duct is critical in the treatment of hilar cholangiocarcinoma because the tumor originates from and extends along the bile duct intramurally or superficially. ■ The blood supply and duct drainage of segment 4 originate within the umbilical fissure and feed back toward the right side buried in liver substance. These structures should be ligated and divided within the liver substance just to the right of the falciform ligament without entering the umbilical fissure, avoiding injury to the blood supply and drainage of the left lateral segment.

POSTOPERATIVE CARE

- Standard postliver resection precautions including minimal use of central nervous system (CNS) depressants to avoid aspiration
- Maintain a low CVP as long as the urine output is adequate.
- Monitor and correct international normalized ratio (INR), platelets, fibrinogen, and thromboelastogram, if needed, to prevent bleeding.
- Venous thromboembolism occurs in these patients. Prophylaxis is indicated.

OUTCOMES

- The 5-year survival for a margin-negative resection, regardless of underlying histology, is approximately 25%.

COMPLICATIONS

- Liver failure
- Hemostasis
- Bile leak
- Intraabdominal abscess
- Respiratory complications

Chapter 31 Left Hepatic Trisectionectomy

Jason A. Castellanos Kamran Idrees

DEFINITION

- First described by Starzl et al.[1] in 1982, this procedure entails a standard left hepatic hepatectomy (segments 2, 3, and 4) as well as resection of the right anterior sector (segments 5 and 8) (FIG 1).
- This operation is performed in a patient with a primary hepatic tumor or metastases involving the left liver invading across the middle hepatic vein toward the right hemiliver and/or portions of segments 5 and 8. Additionally, patients with hilar cholangiocarcinoma may require this procedure in order to obtain tumor-free margins.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Careful evaluation of the patient is required to ensure that the future liver remnant provides adequate liver function after resection. This should include assessment of liver function and exclusion of cirrhosis in addition to volumetric evaluation of the expected remnant liver volume on cross-sectional imaging.
- It is imperative to rule out portal hypertension or chronic liver disease, as a majority of the liver will be resected during this procedure.
- Details regarding prior therapy should be obtained.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Obtain either a liver-devoted magnetic resonance imaging (MRI) or contrast-enhanced, triphasic computerized tomography (CT) scan of the abdomen to identify tumor/s and its relationship to hilar structures and hepatic veins, anatomic variations of hilar vasculature, and assess for radiographic signs of cirrhosis (FIG 2).
- Identify tumor and assess margins for possibility of R0 resection as well as volumetric assessment of future liver remnant.
- For metastatic disease, perform a complete staging evaluation as appropriate for the particular primary neoplasm.
- Intraoperative ultrasound is essential to define margins; exclude presence of disease in the planned liver remnant and visualize hepatic inflow and outflow.

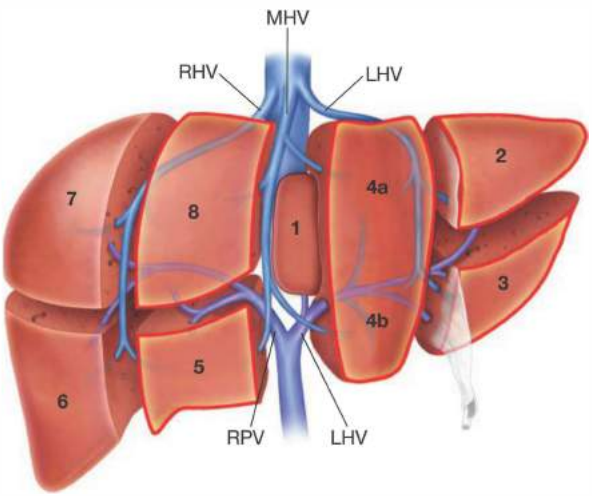

FIG 1 ● Liver anatomy for left trisectionectomy. Segments outlined in *red* signify the resection margin. RHV, right hepatic vein; MHV, middle hepatic vein; LHV, left hepatic vein; RPV, right portal vein.

SURGICAL MANAGEMENT

Preoperative Planning

- Assessment of the future liver remnant volume should be calculated with preoperative imaging to ensure adequate liver function after resection—greater than 20% in patients with normal liver function, greater than 30% for patients with evidence of liver disease (nonalcoholic fatty liver disease, chemotherapy-associated steatohepatitis, etc.), and greater than 40% in cirrhotic patients.[2,3] If the remnant liver volume is deemed to be too small, then portal vein embolization may be used as an adjunct therapy to hypertrophy the future liver remnant prior to hepatectomy.

Positioning

- The patient should be placed in the supine position with the right arm tucked and prepped from the nipples to the pubis bilaterally.

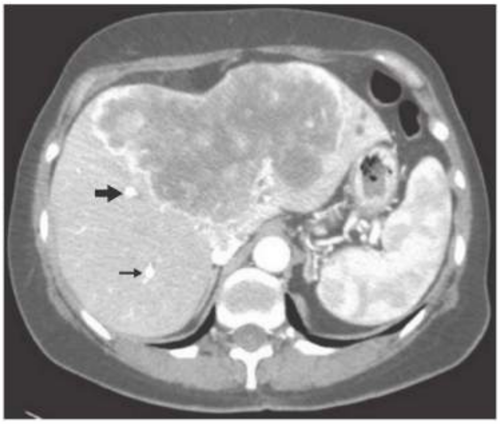

FIG 2 ● Triple-phase CT scan (portal venous phase) of a cholangiocarcinoma involving segments 1, 2, 3, 4, 5, and 8. The right anterior *(thick arrow)* and posterior *(thin arrow)* pedicles are visible. This patient underwent left trisectionectomy with excision of the caudate lobe, which resulted in R0 excision of the tumor and a favorable outcome.

DIAGNOSTIC LAPAROSCOPY

- Our practice is to perform an initial diagnostic laparoscopy to ensure that there is no evidence of peritoneal disease.
- A supraumbilical incision is made through the skin and subcutaneous tissue using the Hasson technique and a trocar is introduced into the abdomen, which is then insufflated to a pressure of 15 cm H_2O.
- The abdomen is explored including the hilum of the liver to assess for metastatic disease and periportal adenopathy. If there are no contraindications to operation, we then proceed to incision.

INCISION

- A bilateral subcostal incision is made, with superior extension in the midline to the xiphoid process, and a self-retaining retractor is placed. Another option is a midline incision to just above the umbilicus with a rightward extension (**FIG 3**).
- The xiphoid process may be excised in order to enhance exposure of the confluence of the hepatic veins into the suprahepatic inferior vena cava (IVC).
- The abdomen is inspected again for evidence of distant metastases that would contraindicate proceeding with operation.

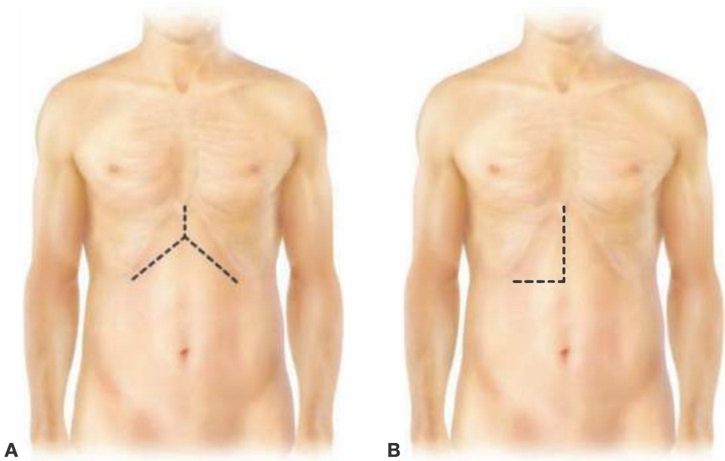

FIG 3 ● Incisions for left trisectionectomy include **(A)** bilateral subcostal incision and **(B)** long midline incision with rightward extension.

INSPECTION OF THE HILUM, CHOLECYSTECTOMY

- The hilar structures are palpated in order to define any anatomic variations (e.g., a posterior pulsation indicates a replaced/accessory right hepatic artery originating from the superior mesenteric artery).
- The cystic duct and cystic artery are identified and ligated, and a cholecystectomy is performed (**FIG 4**).

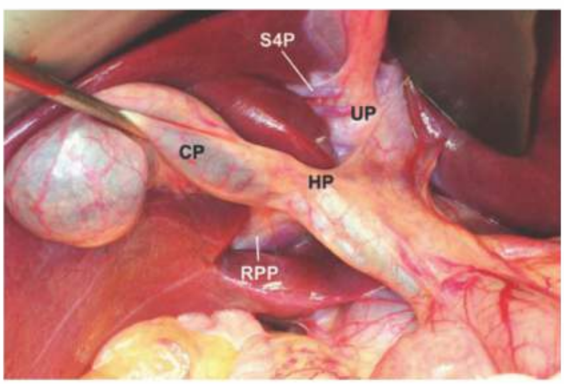

FIG 4 ● Surface anatomy of the plate system showing the cystic plate (CP) covered by the gallbladder, the hilar plate (HP), and the umbilical plate (UP). S4P, segment 4 pedicle; RPP, right posterior pedicle. (From Fischer JF, ed. *Mastery of Surgery*. 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2012.)

MOBILIZATION OF THE LIVER

- The round ligament is ligated and divided, and the falciform, left triangular and coronary ligaments are divided to the level of the hepatic veins. The right coronary and triangular ligaments are transected, exposing the bare area of the liver.
- Intraoperative ultrasound is used at this point to identify the right hepatic vein to plan the line of transection and ensure resectability of the tumor as well as rule out any disease in the future liver remnant.
- After palpation, to identify a potential replaced or accessory left hepatic artery, the gastrohepatic ligament is divided. An aberrant left hepatic artery may be ligated at this time, as segments 2, 3, and 4 will be resected.
- Mobilization of the right liver is also required in order to facilitate parenchymal dissection along the right hepatic vein. Short hepatic veins are ligated and divided off of IVC. The hepatocaval ligament is then ligated or divided with a vascular stapler.

HILAR DISSECTION

- The hepatoduodenal ligament is opened and the common bile duct, proper hepatic artery, and portal vein are visualized after lymphatic and nerve tissues are cleared (**FIG 5**).
- A Rummel tourniquet is placed around the porta hepatis prior to further dissection to facilitate the Pringle maneuver, if needed.
- The left hemiliver is lifted and retracted toward the right to expose the left hilar branches of the portal triad. A vessel loop is placed around the left portal vein, left hepatic

FIG 5 ● Dissection of the hilum and left pedicle. The hepatoduodenal ligament is opened **(A)**, followed by identification of the left hepatic artery **(B)**. Clamping of the artery with a bulldog clamp allows for assessment of blood flow to the right liver. The left hepatic artery and vein are ligated **(C)**, either with suture ligation or with vascular staplers.

artery, and left hepatic duct to isolate them for ligation. Dissection may be aided by using the caudal stump of Arantius' ligament as an anatomic guide toward the left portal vein.

- Ligation of the structures may be performed from an anterior to posterior or posterior to anterior approach; we prefer to begin ligation with the posterior structures. The left portal vein is ligated and divided first, leaving a distance of at least 5 mm to prevent stenosis of the right portal vein. Next, the left hepatic artery and left hepatic duct are ligated and divided. If the caudate lobe will be resected as well, then the left hilar structures should be ligated as close as possible to their origin.
- Next, the right anterior pedicle is identified with careful dissection in the right portal sheath. Identification of this pedicle can be aided by use of ultrasound, which can determine the location and depth (typically 1 to 2 cm from the inferior surface) of the pedicles. There are three options that the surgeon may use to approach this structure, depending on the ease of dissection, the extent of tumor involvement of the right portal sheath, and surgeon preference: extrahepatic, intrahepatic, or delayed dissection and ligation. If the anatomy is clear and the tumor does not impair dissection, then the right anterior pedicle may be dissected in the right portal sheath and individual structures of right anterior pedicle selectively ligated (extrahepatic) or right anterior pedicle is transected en bloc with a vascular stapler (intrahepatic pedicle ligation) while the right posterior pedicle is preserved. If the tumor involves the portal sheath, then the pedicle may be ligated during tissue transection instead (delayed) (**FIG 6**).
- Machado et al.[4] describe an intrahepatic approach to isolating and ligating this structure. A small anterior

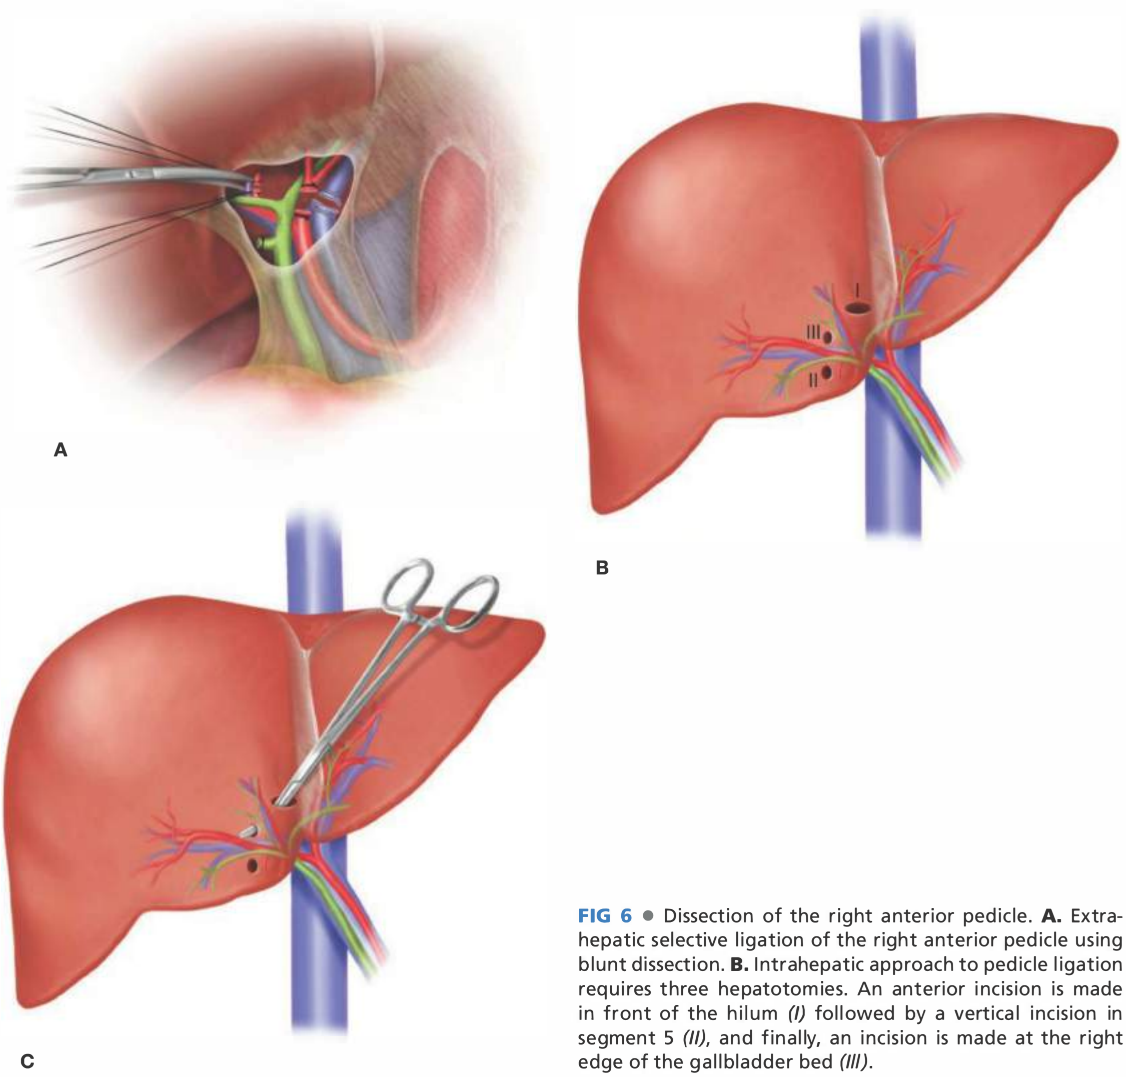

FIG 6 ● Dissection of the right anterior pedicle. **A.** Extrahepatic selective ligation of the right anterior pedicle using blunt dissection. **B.** Intrahepatic approach to pedicle ligation requires three hepatotomies. An anterior incision is made in front of the hilum *(I)* followed by a vertical incision in segment 5 *(II)*, and finally, an incision is made at the right edge of the gallbladder bed *(III)*.

incision is made in front of the hilum, and the parenchyma is bluntly dissected until the anterior aspect of the pedicle is identified. Another small incision is made perpendicular to the hilum at the junction of segments 1 and 5. The right main sheath is then isolated with the use of a large curved clamp inserted between these two incisions, and a vessel loop is placed. A third incision is made on the right side of the gallbladder fossa and a curved clamp used to dissect between this and the first incision, thus isolating the right anterior pedicle.[4]

- It is important to note that the blood supply to segment 7 may come from the right anterior pedicle, and so this must be kept in mind prior to transection in order to ensure adequate blood supply to the remnant liver. Clamping the pedicle prior to transection enables assessment of this relationship if it is not clear on preoperative imaging.
- We ligate these structures using Endo GIA staplers with a vascular load, but if the vessel is too short for this technique, then suture ligation followed by oversewing the distal stump with a continuous 6-0 Prolene may be performed. Our practice is to delay ligation of the right anterior hepatic duct until parenchymal dissection due to the possibility of anatomic variation.
- After ligation of the vessels feeding the left and anterior right liver, the area that will be resected will become demarcated by cyanosis.

DISSECTION OF THE MIDDLE AND LEFT HEPATIC VEINS

- The anterior aspect of the left and middle hepatic veins is exposed by dissection of the falciform left triangular and coronary ligaments as described earlier. The junction of the veins is dissected apart with a blunt right angle and the left phrenic vein is identified, ligated, and divided at its insertion in the left hepatic vein (**FIG 7**).
- With the left lateral section retracted upward, the lesser omentum is divided up to the diaphragm. Arantius' ligament (ligamentum venosum), which runs from the left branch of the portal vein to the left hepatic vein, is then ligated and divided.
- The cephalad stump of Arantius' ligament is grasped and used to guide dissection toward the IVC. The ligament will broaden close to the IVC, at which point dissection is stopped and the ligament is retracted cephalad and leftward to create tension that will enable visualization of an avascular plane between the left and middle hepatic veins.[5]
- A vessel loop is then placed around the confluence of the middle and left hepatic veins. The hepatic veins may be ligated at this time if the confluence of the middle and left hepatic vein is already isolated. However, if vascular control cannot be achieved because of tumor proximity, our practice is to first divide the parenchyma and then ligate these vessels. Premature attempts to ligate these vessels may be dangerous as there are posterior tributaries that are difficult to control prior to transection of the parenchyma.
- If the caudate lobe will be resected, then the low hepatic veins that drain the caudate should be ligated and divided prior to transection of the parenchyma.

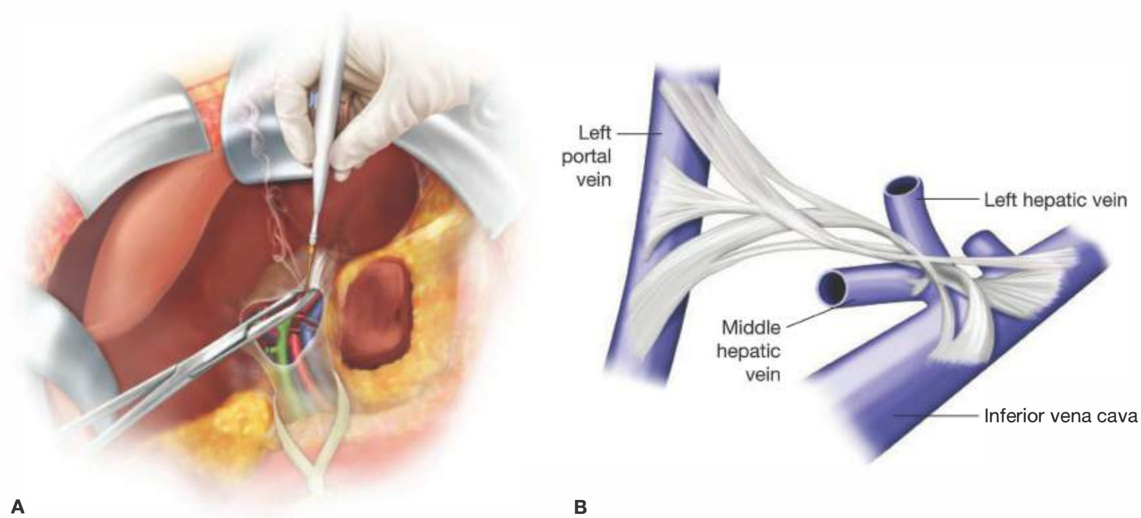

FIG 7 ● Dissection of the left and middle hepatic veins. **A.** Dissection of Arantius' ligament to expose the left and middle hepatic veins. **B.** Arantius' ligament inserts onto the left and middle hepatic veins as demonstrated in this schematic. *(continued)*

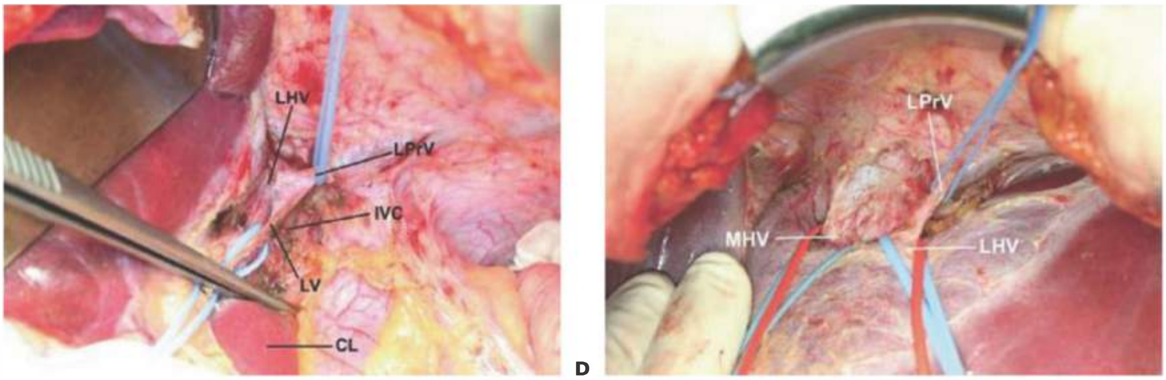
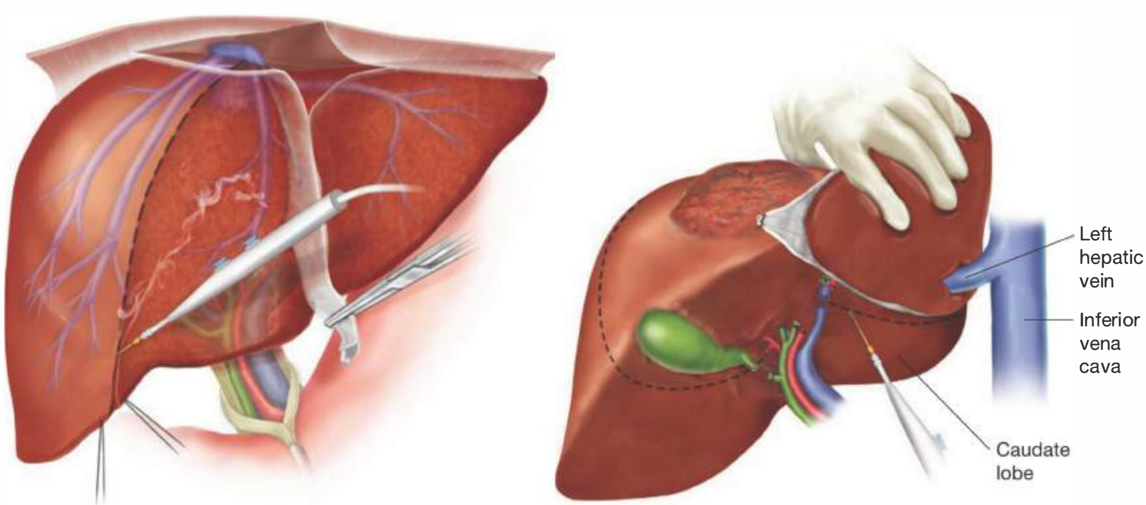


C D

FIG 7 ● *(continued)* **C.** Isolation of ligamentum venosum (LV) at its junction with the left hepatic vein (LHV). **D.** Operative photo showing extrahepatic isolation of the left and middle hepatic veins together with their common trunk. Division of the left phrenic vein allows an extra length of the left hepatic vein to be isolated. LPrV, left phrenic vein; IVC, inferior vena cava; CL, caudate lobe; MHV, middle hepatic vein; LHV, left hepatic vein.

TRANSECTION OF THE LIVER PARENCHYMA

- 2-0 chromic stay sutures are placed at the inferior margin of the liver, one on the ischemic left side and one on the normally perfused right side.
- The surgeon should communicate with the anesthesia team at the beginning of the case to ensure a low central venous pressure (CVP) (<3 mmHg).
- The transection line is scored on the liver capsule following the ischemic demarcation. Resection of the entire specimen can be accomplished en bloc, but if the right anterior pedicle dissection is difficult, then resection of the left lobe initially may facilitate dissection of the right anterior pedicle (**FIG 8**).
- The liver is then divided from the inferior margin following the line of ischemic demarcation. Ultrasound can be used prior to this to ensure that the course of the right hepatic vein is known throughout the liver. Various techniques may be used to transect the liver including stapling, electrosurgery, fragmentation, ultrasonic dissection, radiofrequency energy device dissection, and water-jet dissection (**FIG 9**).



A B

FIG 8 ● Anterior (**A**) and posterior (**B**) lines of transection.

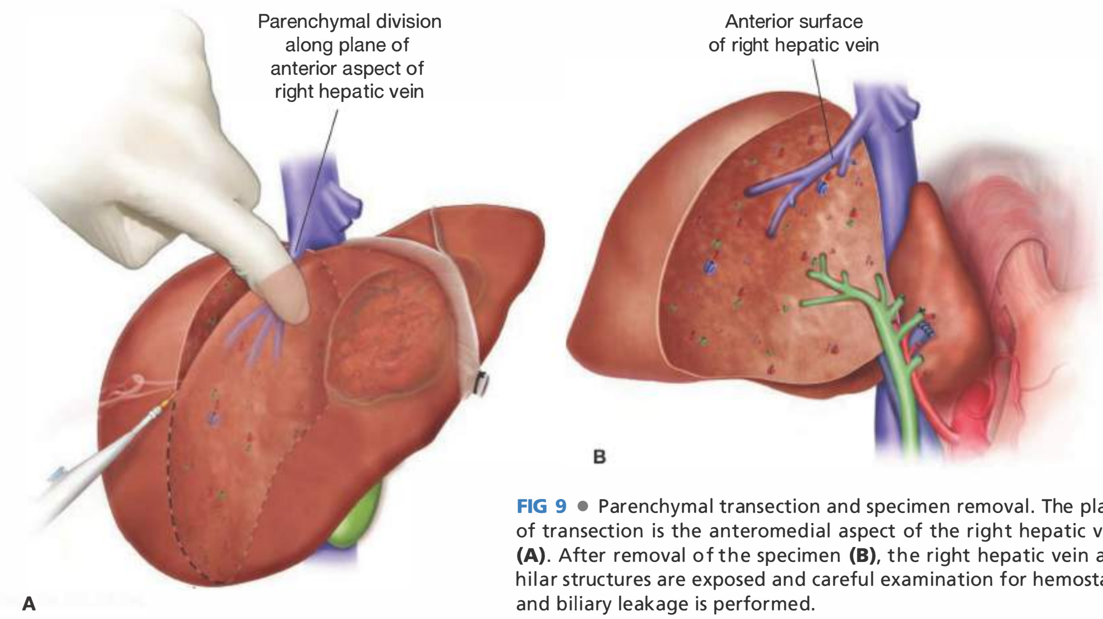


FIG 9 ● Parenchymal transection and specimen removal. The plane of transection is the anteromedial aspect of the right hepatic vein **(A)**. After removal of the specimen **(B)**, the right hepatic vein and hilar structures are exposed and careful examination for hemostasis and biliary leakage is performed.

- If the right anterior pedicle cannot be ligated prior to transection of the parenchyma, then the line of transection should be marked 1 cm to the left of the course of the right hepatic vein.
- When transection is complete, the left and middle hepatic veins are ligated and divided and the specimen is removed from the operative field.
- The remnant liver is examined for hemostasis, which is controlled with argon beam coagulation and placement of Surgicel, and biliary leakage, which is controlled with clips or suture ligation.

CLOSURE

- Placement of a drain is optional and largely dependent on the clinical scenario. We place drains if there is evidence of biliary leakage or if any biliary reconstruction was performed.
- The incision is then closed in the standard fashion with absorbable suture, and the skin is closed with staples or subcuticular sutures.

PEARLS AND PITFALLS

Operative indications	■ Tumor involving the left liver and right anterior section (segments 5 and 8) ■ No evidence of peritoneal spread or other metastatic disease
Preoperative assessment	■ Ensure normal liver function prior to considering operation. ■ Assess the volume of future liver remnant preoperatively to decrease the likelihood of postoperative liver failure.
Isolation of the right anterior pedicle	■ Ultrasound may be used to help identify structures. ■ Dissection may be either intrahepatic, extrahepatic, or delayed until transection. ■ If tumor involves the hilum, then dissection and ligation of the right anterior pedicle should be performed during parenchymal transection. ■ Ensure that the blood supply to segment 7 is not compromised prior to dividing the right anterior pedicle.

POSTOPERATIVE CARE

- Initial postoperative care may occur on a monitored surgical floor or surgical intensive care unit, depending on the course of the operation and the patient's comorbidities.
- Careful attention is paid to hemodynamic parameters, urine output, respiratory status, body temperature, and signs of postoperative liver failure.
- Postoperative resuscitation with colloid (e.g., albumin) instead of crystalloid fluids is preferred in order to maintain a lower CVP, as an elevated CVP and fluid overload cause congestion of the liver remnant and may impair its function.
- Hepatic function and coagulation labs should be followed in addition to blood count and electrolyte panels. Special attention should be placed on monitoring postoperative phosphorus levels. Coagulopathy and anemia should be corrected per institutional protocol.
- Diet is advanced as tolerated and depending on the need for respiratory support. Early ambulation should be encouraged.

OUTCOMES

- Left hepatic trisectionectomy is an extensive procedure and it is rarely performed. There is no large series of outcomes describing the morbidity or mortality of this procedure. In carefully selected patients in expert hands, however, this procedure can be performed safely and with good oncologic results.

COMPLICATIONS

- Postoperative liver failure
- Hemorrhage—perioperative or postoperative
- Bile leak
- Intraabdominal abscess
- Respiratory failure or pneumonia

Chapter 32

Endoscopic Ultrasonography of the Pancreas

Anand R. Gupte   Disaya Chavalitdhamrong   Mihir S. Wagh

DEFINITION

- Endoscopic ultrasonography (EUS or echoendoscopy or endosonography) is an endoscopic procedure using a high-frequency ultrasound transducer integrated into an endoscope.
- The echoendoscope is an oblique-viewing endoscope. It has an ultrasound transducer located at its tip, which emits high-frequency acoustic waves to the surrounding tissues. This action permits the acquisition of unique views of the gut wall, the surrounding organs, and blood vessels.

BACKGROUND

- EUS was first introduced by Dr. Eugene DiMagno in the 1980s. Initial echoendoscopes were radial, which scan perpendicular to the axis of the endoscope and provide 360-degree images similar to computed tomography (CT). In 1991, a convex linear-array echoendoscope was introduced. These linear echoendoscopes scan parallel to the longitudinal axis of the endoscope and enable fine needle aspiration (FNA) and various therapeutic interventions.
- Over the past two decades, EUS has evolved to become an indispensible tool for the evaluation of the pancreas. EUS is useful for the detection, diagnosis, staging, and treatment of multiple pancreatic disorders including solid pancreatic masses, pancreatic cystic lesions, and acute and chronic pancreatitis.
- Currently, two types of echoendoscopes are available: radial sector and linear-array transducers. Radial and linear EUS provides high-resolution images of the gut lumen, the adjacent organs, the lymph nodes, and the vascular structures. They are also equipped with color Doppler, which allows for accurate identification of vascular structures and aids in vascular staging of pancreatic tumors.
- EUS is a safe procedure. Complications are rare and typically related to therapeutic efforts. EUS-FNA complications include bleeding (0% to 1.3%), perforation (0% to 0.4%), infection (0.3%), and pancreatitis (1% to 2%).[1,2] The risk of bacteremia is low, and prophylactic antibiotics are not recommended except prior to EUS-guided FNA of pancreatic cystic lesions. The risk of tumor seeding is significantly lower as compared to percutaneous approaches with only four case reports so far.[2]

PANCREATIC DISORDERS AND ENDOSCOPIC ULTRASONOGRAPHY FINDINGS

- Pancreatic tumors typically appear as irregularly shaped hypoechoic or heterogeneous areas within the normal echo texture of the pancreas. In cases of pancreatic cancer, tumor extension into the adjacent vasculature (portal; splenic and superior mesenteric veins; and celiac, splenic, and superior mesenteric arteries), the common bile duct, and the duodenum can be identified. Additionally, ascites, celiac and peripancreatic lymph nodes, and metastatic disease to the liver can be seen.
- Pancreatic cysts are divided into nonneoplastic and neoplastic cysts. EUS findings should be interpreted in the context of the clinical impression, morphologic EUS criteria, and results of the cystic fluid analysis to determine the origin of the cyst and guidance of further management. Morphologic features associated with an increased risk for malignancy are an irregular or thickened cyst wall, the presence of mural nodules or a solid mass within the cyst, a cyst size over 3 cm, or an increase in cyst size during follow-up.
- EUS can help identify causes of pancreatitis, including gallbladder and bile duct stones and sludge (microlithiasis), pancreatic duct stones, pancreatic cysts (pseudocysts and cystic neoplasms), ampullary neoplasms, pancreas divisum, changes of chronic pancreatitis, and pancreatic masses.
- EUS is sensitive to subtle changes associated with chronic pancreatitis. It shows fine parenchymal details such as early fibrosis, calcifications, and pancreatic ductal changes. The diagnosis of chronic pancreatitis by EUS depends on the presence or absence of multiple EUS criteria of chronic pancreatitis (Rosemont classification),[3] which includes parenchymal features of echogenic foci, focal regions of increased echogenicity (strands), lobularity, cyst formation, and ductal EUS features (increased echogenicity of the main pancreatic duct wall, main pancreatic duct calculi, irregular contour of the main pancreatic duct, dilation of the main pancreatic duct, and side branch dilation).

OTHER DIAGNOSTIC STUDIES

- In the 1980s, EUS was developed to overcome the limitations of transabdominal ultrasonography (US) and CT scan imaging of the pancreas.
- EUS provides high-resolution images of the pancreatic duct, as well as the parenchyma, and complements the ductal images seen in endoscopic retrograde cholangiopancreatography (ERCP).
- EUS is considered one of the most sensitive imaging modalities to detect pancreatic tumors and has the additional advantage of acquiring tissue samples by FNA with linear endosonography. The sensitivity of EUS ranges from 93% to 100%, whereas for CT, it ranges from 53% to 92%.[4]
- Compared to US- or CT-guided FNA, EUS-FNA has been proven to be the safest technique with comparable accuracy (76% of EUS vs. 81% of US/CT).[5] The sensitivity of EUS-FNA for diagnosing pancreatic cancer is greater than 90% with a specificity of greater than 95%.[4]

MANAGEMENT

Preoperative Planning

- A recent complete blood count, basic electrolytes, and coagulation studies are indicated prior to EUS. The patient should hold anticoagulants and antiplatelet agents or use bridge therapy with heparin before EUS-guided FNA.

- Patients are normally instructed to fast after midnight, the night before the procedure.
- Prophylactic antibiotics are recommended only for EUS-guided FNA of cystic lesions.[6]
- The procedure is generally performed under conscious sedation or monitored anesthesia care based on presence of associated medical comorbidities.

Positioning

- EUS of the pancreas is usually performed with the patient in the left lateral decubitus position, similar to that for performing an esophagogastroduodenoscopy (EGD).
- If drainage of pancreatic fluid collections is planned, a prone position is preferred to facilitate better fluoroscopic visualization without interference from bony structures; this positioning also fosters the concomitant performance of ERCP if indicated.

ESOPHAGEAL INTUBATION

- The echoendoscope has an oblique endoscopic view, and therefore, pharyngeal intubation is typically blind or with partial views. The echoendoscope is inserted into the pharynx with downward deflection of the tip, which is then straightened using the up-down wheel once the pharynx is reached. The esophagus is intubated with a slight clockwise torque. Care needs to be taken so as not to forcefully intubate the esophagus because of the risk of perforation if any anatomic variant is present.

STOMACH STATION

- This is the station for examination of the body and tail of the pancreas.
- The echoendoscope is positioned distal to the gastroesophageal (GE) junction, and the aorta is located.
  - Radial echoendoscopy: The aorta is seen as a circular anechoic structure with a positive Doppler signal. The balloon is inflated and keeping the aorta at the 6 o'clock position, and the echoendoscope is passively advanced. The diaphragmatic crura are seen as hypoechoic structures that wrap around the aorta. With further advancement, the crura disappear and the celiac trunk emerges from the aorta at 12 o'clock position and soon bifurcates into the hepatic and splenic arteries, which looks like a "whale's tail." Advancement of the echoendoscope from this position leads to the pancreas body with its characteristic salt-and-pepper appearance. Deep to the pancreas is the classic anechoic Doppler-positive club head (golf club sign), which signifies the splenoportal confluence (**FIG 1**). Clockwise torque and gradual withdrawal of the scope is performed to image the body up to the tail of the pancreas. Initially, the left kidney is seen below the pancreas as an oval structure with a hypoechoic cortex and a hyperechoic medulla. Next, the spleen is seen as a hypoechoic structure to the right of the screen, and the splenic artery and vein are seen entering the hilum of the spleen. This completes the exam up to the tail of the pancreas (**FIG 2**). From this region, the maneuvers are reversed and counterclockwise torque and gradual advancement of the scope is performed to image the pancreas up to the neck.
  - Linear echoendoscopy: The approach is similar to that described earlier with the radial echoendoscope. The echoendoscope is positioned at the GE junction and the scope is rotated in a clockwise manner to locate the aorta, which is a linear structure that slopes downward from the right to the left of the screen. The diaphragmatic crura are again noted and the celiac artery is seen arising from the

FIG 1 ● Radial EUS view of pancreatic body (splenoportal vein confluence is highlighted by the *white arrow*; "golf club sign").

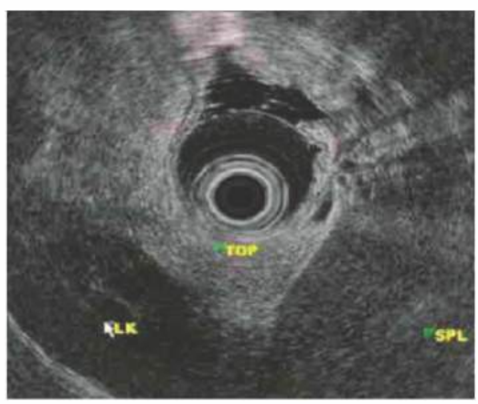

FIG 2 ● Radial EUS view of pancreatic tail. *TOP*, tail of pancreas; *SPL*, spleen; *LK*, left kidney.

aorta as soon as the crura disappear (FIG 3). The celiac artery is traced until it splits into the hepatic and splenic artery. The superior mesenteric artery is seen emerging from the aorta distal to the takeoff of the celiac artery. Advancement of the scope beyond the celiac bifurcation with a gentle down on the up-down wheel (tip up of the echoendoscope) leads to the pancreas. The pancreas is then traced to the tail and the splenic hilum by gentle clockwise rotation and withdrawal. The maneuvers are then reversed to trace the pancreas up to the neck. Unlike the radial endoscope where advancement and withdrawal is mostly passive, constant slow clockwise and counterclockwise torque is essential when examining with a linear endosonoscope.

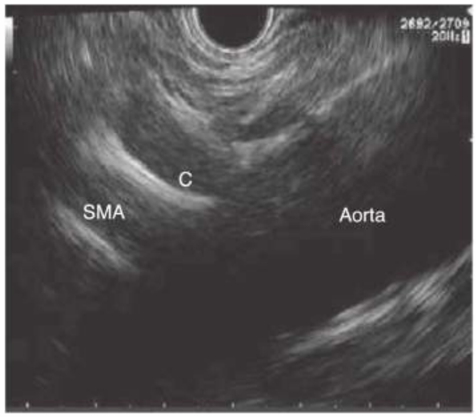

FIG 3 ● Linear EUS imaging of aorta at the level of the celiac artery takeoff. The vessels appear dark given their efficient transmission of ultrasonic waves. *C*, celiac artery; *SMA*, superior mesenteric artery.

DUODENUM STATION (BULB, AMPULLA, AND DISTAL DUODENUM)

- The head of the pancreas is examined from the bulb, the ampullary region, and from the duodenum distal to the ampulla (FIG 4).
  - Radial echoendoscopy: The scope is gently advanced through the stomach and the pylorus is visualized endoscopically. The scope is then advanced through the pylorus with the tip up, that is, big wheel pushed toward the endoscopist ("setting sun sign"). The balloon on the echoendoscope is inflated in the duodenal bulb and endosonographic visualization is commenced. The liver is positioned at 11 o'clock, which places the pancreas at 6 o'clock position. The portal vein is seen as a large tubular structure coursing downward from the top left to the bottom right of the screen. The duodenal falloff represents the muscularis propria of the duodenum and is a hypoechoic line coursing down from the transducer. The bile duct is a tubular anechoic structure coursing from the liver to the duodenal falloff and is located between the portal vein and the transducer. The scope is pushed in with a clockwise torque to trace the bile duct to the ampulla. Counterclockwise torque and withdrawal of the scope enables visualization of the bile duct up to the hilum (bifurcation). The pancreatic duct may or may not be seen in the same plane as the portal vein, bile duct, and the duodenal falloff and gentle upward or downward deflection may be needed to achieve adequate imaging of the pancreatic duct. The next position for visualization of the head of the pancreas is at the level of the ampulla. The echoendoscope is passed into the second part of the duodenum and then is withdrawn into a short position akin to when performing an ERCP. The major papilla is visualized and the balloon is inflated. The major papilla is positioned such that upward deflection of the scope should bring the scope near the papilla. The pancreas appears crescent-shaped in this position. As the transducer is moved back and forth, the bile and pancreatic duct appear to course through the duodenal wall with the bile duct appearing in a cross-sectional configuration above the pancreatic duct. Duodenal motility can be reduced with intravenous administration of glucagon and water infused into the duodenal lumen, if detailed views of the ampulla are required. The uncinate process is next visualized by advancing the scope just distal to the papilla (FIG 5). The big wheel is pushed toward the endoscopist with the tip thus maximally up and the right-left wheel locked in the right position. Gentle counterclockwise torque and withdrawal brings the aorta in

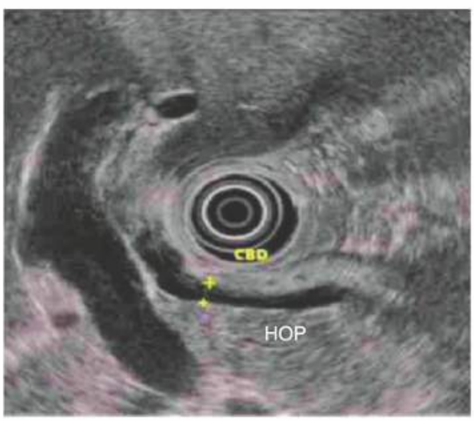

FIG 4 ● Radial EUS view of pancreatic head. *CBD*, common bile duct; *HOP*, head of pancreas.

FIG 5 ● Radial EUS view of the uncinate process. The superior mesenteric artery (SMA) is not easily visualized by EUS.

view. This may appear in a longitudinal configuration, becoming oval and finally round. The inferior vena cava may be seen superior to the aorta or may be compressed by the transducer. The pancreas is visualized to the right of the aorta.

- Linear echoendoscope: Apical imaging for the linear scope follows the same pattern as the radial scope. The scope is advanced through the stomach into the duodenal bulb. The apex of the bulb is identified with a gentle downward deflection of the tip of the scope. With the scope at the apex of the duodenal bulb, slight counterclockwise torque and upward deflection brings the portal vein in view. The bile duct is seen coursing between the transducer and the portal vein and can be traced by torquing the scope in both the directions. The pancreatic duct is also seen coursing below the bile duct and may need upward or downward deflection of the tip of the scope or torquing of the scope to visualize completely. Balloon inflation is not as necessary with a linear scope as it is with a radial scope. Visualization of the ampulla follows the same principles as the radial scope. The papilla is visualized endoscopically, the scope is kept perpendicular to the papilla and imaging is commenced. The papilla is oriented at 6 o'clock position and the bile and pancreatic ducts are visualized in their linear configuration. Gentle torquing and slow withdrawal is performed till the portal confluence is seen. Next, the uncinate process of the pancreas is seen by passing the echoendoscope distal to the ampulla and shortening to achieve a straight position. The aorta is located by gentle torquing of the scope. Once the aorta is localized, the scope is torqued clockwise to locate the pancreas and then withdrawn with gentle torquing in both directions till the portal confluence is again visualized.

ENDOSCOPIC ULTRASONOGRAPHY–GUIDED FINE NEEDLE ASPIRATION

- EUS-guided FNA uses a linear-array echoendoscope, which provides real-time ultrasound imaging of the needle in the target area. The needle device consists of the needle, its sheath, a stylet within the needle, and the handle of the device. Needles are available in various sizes: typically, 19 gauge, 22 gauge, and 25 gauge. A 22-gauge or 25-gauge needle is preferred when accessing lesions from within the duodenum as acute angulation and looping of the scope may make it technically challenging to advance the larger 19-gauge needle out of the scope. An aspiration syringe is typically used along with the needle device and is usually provided in the same package.
    - The lesion of interest is imaged by the linear echoendoscope. The distance between the echoendoscope and the lesion should be minimized with the aid of the up/down and sometimes the left-right wheels of the echoendoscope.
    - Color Doppler imaging is performed to ensure that (1) the lesion of interest is not vascular and (2) there are no intervening vessels in the path of the FNA needle.
    - The needle device is passed through the channel of the echoendoscope and the handle is then Luer-locked. The sheath is slowly advanced out of the scope and the position is confirmed endoscopically.
    - It is helpful to measure the distance from the sheath tip to the middle of the lesion using the on-screen calipers to give an idea about the approximate depth of needle insertion.
    - The needle is then advanced under real-time ultrasound guidance to the middle of the lesion. Once the needle is in the lesion, the stylet is removed from the system. The aspiration syringe is attached to the needle device and suction is applied.
    - If a cystic lesion is being aspirated, the suction syringe is removed and the needle is withdrawn into the sheath at the end of the aspiration of cyst contents. The entire system is then removed and the fluid analyzed. For practical purposes and ease of availability, cyst fluid is typically analyzed for cytology, carcinoembryonic antigen (CEA), and amylase levels.
- If a solid mass is being aspirated, quick and forceful to-and-fro movements are performed with or without suction, and the needle path is fanned inside the lesion to maximize the yield for cytology. After a few strokes, suction is stopped, the needle is withdrawn into the sheath, and the entire system is removed. The material within the needle device is then sent for cytologic evaluation. Presence of a cytologist during the procedure is recommended to get an on-site, immediate cytologic evaluation and thereby limit the number of passes of the FNA needle and maximize the diagnostic yield of FNA.

ENDOSCOPIC ULTRASONOGRAPHY IN THE EVALUATION OF BENIGN PANCREATIC DISEASES

- The normal pancreas has a homogenous, diffusely speckled pattern with a smooth contour. The pancreatic duct located within the pancreatic parenchyma is typically thin, smooth, anechoic, and does not have a positive Doppler signal. It decreases in size from the head to the tail. A normal duct measures 3, 2, and 1 mm in the head, body, and tail of pancreas, respectively. EUS exam for evaluation of benign pancreatic diseases is performed as described earlier.

Acute Pancreatitis

- Findings seen in chronic pancreatitis, with the exception of calcifications, can be seen in acute pancreatitis (cysts, ductal irregularity and dilation, stranding, etc.). Therefore, it is recommended to wait for 4 to 6 weeks before performing EUS of the pancreas after an acute attack of pancreatitis.
  - The pancreas may appear normal or diffusely enlarged with a normal or diffusely low echo pattern in edematous pancreatitis. In some circumstances, it may be possible to differentiate edematous pancreatitis from necrotizing pancreatitis, which may appear as a focal hypoechoic mass with or without echogenic strands.[7]

Chronic Pancreatitis

- EUS features of chronic pancreatitis are divided into major and minor criteria for parenchymal and ductal features based on the Rosemont criteria.[3] Major criteria include hyperchoic foci with shadowing, lobularity with honeycombing, and main pancreatic duct calculi. Minor criteria include cysts, nonshadowing foci, lobularity with noncontiguous lobules, dilated main duct or side branches, irregular duct contour, hyperechoic duct walls, or echogenic strands.

Autoimmune Pancreatitis

- The pancreas in autoimmune disease may appear either normal or enlarged and sausage-shaped. Occasionally, a hypoechoic mass may be seen and may be difficult to differentiate from adenocarcinoma. Hyperechoic strands or lobularity can also be seen,[8] and as such, core biopsy or FNA of pancreatic parenchyma or biopsy of the ampulla may be needed for a definitive diagnosis.

ENDOSCOPIC ULTRASONOGRAPHY IN THE EVALUATION OF PANCREATIC CYSTIC LESIONS

Cystic Neoplasms of the Pancreas

- Cystic neoplasms of the pancreas (FIG 6A–C) can be divided into neoplastic (serous and mucinous cysts, intraductal papillary mucinous neoplasms [IPMN], or solid pseudopapillary neoplasms with cystic degeneration) or nonneoplastic pancreatic cysts (true cysts, retentions cysts, pseudocysts, or lymphoepithelial cysts). Differentiation between the two is essential because nonneoplastic cysts can be safely monitored and treated only if they become symptomatic. Neoplastic cysts, especially those with higher malignant potential, should be considered for resection. EUS can help in examination of the cyst with regard to size, shape, morphologic features, communication with pancreatic duct, and invasion into adjacent structures. It can help evaluate the cyst wall (nodule, thickness) as well as intracystic structures such as debris or septations. The technique for EUS-guided FNA is as described earlier. If a cyst has multiple components, the largest component is targeted first. If there is an intramural nodule (cyst with higher malignant potential), needle aspiration of cyst fluid as well as sampling the nodule are targeted separately. CEA level of more than 192 ng/mL is thought to be a useful but less sensitive marker of a mucinous lesion.[9]

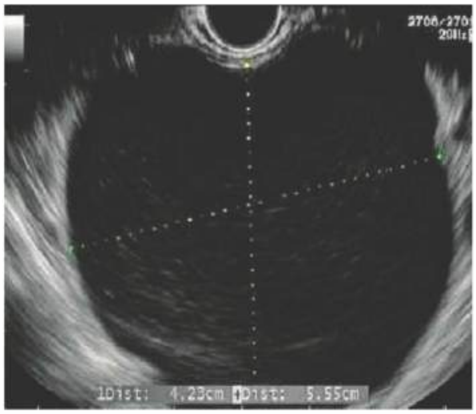

FIG 6 ● *(continued).*

ENDOSCOPIC ULTRASONOGRAPHY IN THE EVALUATION OF PANCREATIC MASSES

- EUS is useful in evaluation of pancreatic masses (**FIG 7**) by providing cytologic confirmation as well as staging of disease. Pancreatic mass lesions can be differentiated into those that are malignant (adenocarcinoma, lymphoma, other rare neoplasm) or those that are benign (chronic pancreatitis or autoimmune pancreatitis). Differentiation between the malignant and the benign mass lesions can be difficult, and occasionally, surgical resection may be the only definitive modality for diagnosis and treatment. FNA of mass lesions of the pancreas is performed as mentioned earlier (**FIG 8**). The number of passes to obtain a cytologic diagnosis is controversial, but about seven passes is considered an optimal number of passes for mass lesions of the pancreas.[10] Having an on-site cytologist is essential. The trajectory of the needle path during FNA should be altered with each stroke so as to fan the lesion and maximize yield. Suction can be used during FNA to hold the tissue against the needle during passes. However, a previous study by Wallace[11] found that suction actually makes the specimen bloodier and does not improve diagnostic accuracy, although this study was primarily done to evaluate aspiration techniques in malignant lymphadenopathy. Although evaluating a mass in the pancreas, attention should be focused on the location of the lesion, the size of the lesion, and its proximity to nearby vascular structures. If abnormal lymph nodes are seen, these should be targeted first. It is helpful to use different needle systems for FNA of pancreatic masses and suspected metastatic lesions to decrease the risk of seeding.

INTERVENTIONAL ENDOSCOPIC ULTRASONOGRAPHY IN PANCREATIC DISORDERS

Fine Needle Injection Therapy for Locally Advanced Pancreatic Tumors

- Endoscopic ultrasonography–guided fine needle injection (EUS-FNI) therapy of antitumor agents has been previously documented.[12,13] Recently, TNFerade, when delivered by EUS-FNI, has shown promise for locally advanced pancreatic cancer.[14] Delivery of TNFerade did not interfere with subsequent surgical resection. The technique for performing EUS-FNI is same as for an FNA.[15]
  - The tumor is localized by the linear echoendoscope, and a 22-gauge needle is advanced through the tumor using Doppler to ensure that blood vessels are not punctured.
  - The needle is slowly withdrawn and the drug is simultaneously injected, slowly, into the tumor.
  - Without complete withdrawal of the needle from the tumor, the needle is then redirected at a different angle and the process repeated, thereby spreading the injectate in a fanned manner. Typically, the volume of TNFerade injectant is 2 mL.[14]

Pancreatic Duct Drainage

- ERCP is usually the first-line therapy for relief of an obstructed pancreatic duct, but when ERCP is unsuccessful, surgery is often indicated. Recently, EUS-guided pancreatic duct drainage has been advocated when ERCP is not feasible.
  - EUS-guided drainage can be performed either via the translumenal approach (stomach or duodenum) or via a transpapillary approach.
  - The pancreatic duct is identified from either the stomach or the duodenal bulb and a 19-gauge needle is used to puncture it. Contrast is injected to delineate the duct.
  - A guidewire is advanced into the pancreatic duct in an antegrade fashion and allowed to coil into the duodenum via the papillary orifice.
  - The transmural tract is then dilated initially with an ERCP cannula or balloon or graduated dilator.
  - A 5- to 7-Fr stent with a length long enough to extend from the stomach or duodenum into the main pancreatic duct and then via the papilla into the duodenum is deployed.
  - In cases where a transpapillary rendezvous approach is undertaken, the guidewire is advanced into the duodenum as mentioned earlier and the echoendoscope is exchanged for a duodenoscope. Cannulation of the pancreatic duct is performed either alongside the guidewire or the guidewire is withdrawn into the endoscope and accessories passed over the guidewire to aid in cannulation and performing the endoscopic retrograde pancreatography (ERP).

Celiac Plexus Block and Neurolysis

- Pain in chronic pancreatitis or pancreatic carcinoma is typically mediated by sympathetic visceral afferent fibers that relay via the celiac plexus to the splanchnic nerves and enter the spinal cord from T5–T9.[16] The celiac plexus is composed of ganglia located anterolateral to the aorta at the level of the celiac trunk. Celiac plexus neurolysis (CPN) is the ablation of the celiac plexus with alcohol, whereas celiac plexus block (CPB) refers to the temporary inhibition of pain impulses through the celiac plexus with the aid of steroids and an anesthetic such as bupivacaine. The technique for CPN and CPB is the same.
  - Procedure is performed with the patient sedated in the left lateral position.
  - Intravenous saline may be administered intra- or postprocedurally to decrease the risk of hypotension.
  - Broad-spectrum antibiotics such as ciprofloxacin are recommended, especially if steroids are injected, as there have been case reports of peripancreatic abscesses after CPB.[17]
  - Using the linear echoendoscope, the aorta is localized at the GE junction and followed to the origin of the celiac artery and the bifurcation of the splenic and hepatic artery with counterclockwise rotation. The celiac ganglia are identified as small hypoechoic structures located just anterior to and above the celiac artery origin.
  - A 22-gauge or a 19-gauge needle or a dedicated 20-gauge spray needle (EUS-20-CPN, Cook Endoscopy, Winston Salem, NC) with multiple holes can be used. The CPN needle allows solutions to be dispersed over a wider area with less force. The stylet is withdrawn and the needle is flushed with saline to remove air and the gastric wall is punctured with the tip of the needle slightly anterior and above the origin of the celiac artery. Aspiration is performed to ensure that a blood vessel has not been punctured.
  - A 0.25% (5 mL) bupivacaine is injected first, followed by 20 mL of absolute alcohol if CPN is performed or 0.25% (20 mL) bupivacaine followed by 80-mg (4 mL) triamcinolone if CPB is performed.[18] The needle is then flushed with 3 mL of saline to ensure complete drug delivery.
  - Patient is observed for 2 to 4 hours for hypotension, fever, or abdominal pain, which usually is transient and treated with supportive measures.

Fiducial Placements

- Fiducials are inert radiologic markers that are implanted into the target lesion for localizing or tracking during radiation therapy of pancreatic cancers. A minimum of 1 or 2 fiducials are required. These can be placed either within the lesion or within 1 cm of the lesion of interest. Fiducials can be delivered with 19-gauge or 22-gauge needle.[19]
- Standard fiducials are cylindrical gold seeds, measuring 3 to 5 mm in length and 0.8 to 1.2 mm in diameter. Sterile bone wax can be used to hold and separate preloaded

gold fiducials within the 19-gauge needle. The new smaller, longer fiducial markers are 10 mm in length and 0.35 mm in diameter. They are preloaded on a needle carrier delivery device for use with a 22-gauge needle, which allows for optimal placement.[20] The process for fiducial implantation is similar to performing FNA. Our group has recently reported early data on EUS-guided fiducial placement with a new multifiducial delivery needle.[21]

- The lesion of interest is located by the linear scope.
- The needle device is advanced through the channel of the echoendoscope and locked in place. The needle is then advanced into the area of interest, ensuring lack of vascular structures in the path of the needle. The stylet of the needle is advanced to maximal insertion, thus pushing the fiducial out of the needle and into the area of interest.

PEARLS AND PITFALLS

ADEQUATE TRAINING AND TECHNICAL EXPERTISE BEFORE PERFORMING ENDOSONOGRAPHY CANNOT BE OVEREMPHASIZED.	
EUS of pancreas (general principles)	▪ A station-based approach is important because complete imaging of the pancreas can only be obtained from specific stations: stomach, duodenal bulb, opposite the ampulla, and distal to the ampulla. ▪ If endosonographic orientation is lost during the exam or if usual landmarks are difficult to find, one could either return to the starting point for that station or examine other stations and then come back to the difficult station. ▪ Gentle clockwise and counterclockwise torque is needed to achieve complete imaging with the linear scope.
EUS with FNA	▪ Passage of needle is easier when the scope is in a straight position and with minimal use of the elevator. ▪ The needle should be placed in the center of the cyst during aspiration. If fluid is not obtained, the needle should be repositioned inside the cyst without complete withdrawal or replaced with a larger diameter needle to allow aspiration of thick cyst contents. ▪ If there is a mass associated with a cyst, samples from both the solid and cystic components should be obtained. ▪ A fanning technique during FNA of solid lesions is preferred to maximize cytologic yield. ▪ If the aspirated specimen is less than desired, suction can be applied during aspiration. Alternatively, if the aspirate is bloody, suction should be avoided.
Celiac plexus interventions	▪ If ganglia are not clearly seen: The entire solution can be injected just above and anterior to the celiac trunk. ▪ If no resistance is encountered during injection: The needle may still be in stomach or a vascular puncture should be considered.
Pancreatic duct drainage	▪ The duct should be sufficiently dilated to allow EUS-guided needle puncture and intervention.

POSTOPERATIVE CARE

- After the EUS procedure is completed, the patient is monitored in the recovery room until sedative medications have worn off (about 30 to 45 minutes) and discharge criteria are met.
- The patient should not drive a vehicle or operate heavy machinery after receiving sedative medication. Therefore, a responsible person is needed to drive the patient home after the exam.
- Antibiotics are usually prescribed for 3 to 5 days after EUS-guided FNA of cystic lesions.[6]

COMPLICATIONS

- Patients undergoing EUS by experienced endosonographers are not at an increased risk for perforation compared with standard endoscopy.
- Most complications of EUS are associated with performing FNA and therapeutic interventions. Patients undergoing EUS-FNA of the pancreas have a 1% to 2% risk of pancreatitis. Clinically significant bleeding and bile peritonitis are rare complications of EUS-FNA.

Chapter 33

Pancreaticoduodenectomy: Resection

George VanBuren, II William E. Fisher

DEFINITION

- Pancreaticoduodenectomy (Whipple procedure) is defined as resection of the pancreatic head, uncinate process, gallbladder, distal bile duct, duodenum, and gastric antrum.
- Pylorus-preserving pancreaticoduodenectomy (pylorus-preserving Whipple procedure) is the same operation with preservation of the gastric antrum, pylorus, and a cuff of proximal duodenum.
- Complete excision of pancreatic head tumors with negative margins maximizes local-regional control and is the standard of care for malignancies of the pancreatic head, ampulla of Vater, duodenum, or distal bile duct.

DIFFERENTIAL DIAGNOSIS

- Pancreatic ductal adenocarcinoma
- Pancreatic neuroendocrine tumor
- Pancreatic cystic neoplasm
- Cancer of the ampulla of Vater
- Distal cholangiocarcinoma
- Duodenal adenocarcinoma
- Biliary stricture
- Chronic pancreatitis

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history and physical exam should be performed prior to treatment.
- Critical history: weight loss greater than 10%, new-onset diabetes, jaundice, vague abdominal pain in mid-epigastrium, pain penetrating to the back (indicates possible celiac involvement), diarrhea (indicating exocrine insufficiency)
- History related to biliary obstruction: jaundice, fever, chills, pruritus, acholic stools, dark urine
- Risk factors for pancreatic cancer: smoking, chronic pancreatitis, diabetes, age 65 years or older, African American race, obesity, male gender, family history of pancreatic cancer, family history of other malignancy (i.e., BRCA2 malignancies)[1]
- Physical exam: scleral icterus, jaundice, signs of malnutrition, cachexia, temporal wasting
- Ominous signs: A palpable abdominal tumor or ascites may indicate metastatic disease. Left supraclavicular lymphadenopathy (Virchow's lymph node) is indicative of metastatic disease.
- In addition to a history and physical relating to pancreatic cancer, an overall assessment of the patient's functional status should be performed to assure the patient is a candidate for major surgery.
  - If the patient's performance status is poor (Eastern Conference Oncology Group [ECOG] score greater than 2 or Karnofsky score of less than 60), he or she should be considered physiologically borderline resectable.[2]
  - The patient's cardiopulmonary status should also be assessed with an assessment of their exercise tolerance and activity level.
  - Physical exam should look for other sources of chronic disease including carotid bruit, jugular venous distension, rales, wheezing, heart murmur, or clubbing of fingers.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- "Pancreatic protocol" computed tomography (CT) scan of the chest, abdomen, and pelvis is required for all patients. Pancreatic protocol is a triphasic thin (≤5 mm), multislice CT scan with an arterial, venous, and delayed phase in conjunction with sagittal and coronal views. Water is used to opacify the stomach. A properly performed CT scan is perhaps the most critical portion of the preoperative assessment to determine if the patient is a candidate for surgery. The purpose of the CT scan is to detect any metastatic disease and to assess the relationship of the low-density tumor to the surrounding vasculature. Particular attention is paid to the relationship of the tumor to the portal vein (PV), superior mesenteric vein (SMV), superior mesenteric artery (SMA), hepatic artery, and celiac axis. In addition, a CT will aid in identification of aberrant anatomy of the hepatic artery, which is present in 20% of cases and must be noted prior to surgery.
- CT scan of chest is done to evaluate for pulmonary metastasis.
- Based on imaging, there are well-defined consensus criteria from the American Hepato-Pancreato-Biliary Association for resectable, borderline resectable, locally advanced, and metastatic diseases. These criteria have been adopted by the National Comprehensive Cancer Network (NCCN).[3]
  - Resectable tumors demonstrate the following:
    - No distant metastases; no radiographic evidence of SMV and PV abutment, distortion, tumor thrombus, or venous encasement; clear fat planes around the celiac axis, hepatic artery, and SMA (**FIG 1**)

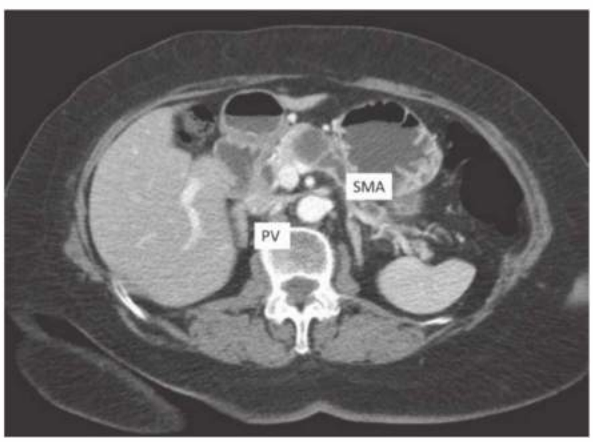

FIG 1 ● CT of a resectable pancreatic cancer. *PV*, portal vein; *SMA*, superior mesenteric artery.

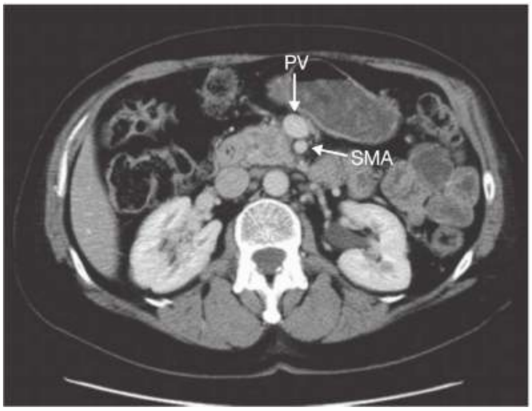

FIG 2 ● CT of a borderline resectable pancreatic cancer. There is a loss of the "fat plane" between the SMV/PV confluence. *PV*, portal vein; *SMA*, superior mesenteric artery.

- Borderline resectable tumors demonstrate the following:
  - No distant metastases; venous involvement of the SMV/PV demonstrating tumor abutment with or without impingement and narrowing of the lumen, encasement of the SMV/PV but without encasement of the nearby arteries, or short segment venous occlusion resulting from either tumor thrombus or encasement but with suitable vessel proximal and distal to the area of vessel involvement, allowing for safe resection and reconstruction; gastroduodenal artery (GDA) encasement up to the hepatic artery with either short segment encasement or direct abutment of the hepatic artery, without extension to the celiac axis; tumor abutment of the SMA not to exceed 180 degrees of the circumference of the vessel wall (**FIG 2**)
- Locally advanced tumors demonstrate the following:
  - No distant metastases; unreconstructable SMV/ PV occlusion; greater than 180 degree encasement of SMA, celiac axis, or aortic invasion; metastasis to lymph nodes beyond the field of resection (**FIG 3**)
- Endoscopic ultrasound (EUS). This is an important step in the assessment of many, but not all, pancreatic masses and cystic lesions. EUS is performed to obtain a tissue diagnosis of a solid mass, which will be required if neoadjuvant chemotherapy is planned. Cystic lesions may be characterized by EUS and the fluid may be aspirated and sent for cytology including a mucin stain, carcinoembryonic antigen (CEA) and amylase concentration, and perhaps, genetic analysis. Furthermore, EUS may be used as an adjunct to the CT scan to further evaluate venous involvement and can be more sensitive than CT in detecting a small mass. If enlarged celiac lymph nodes are seen, they may be biopsied. EUS and CT can be compromised by the presence of a bile duct stent so ideally, these tests are performed prior to endoscopic retrograde cholangiopancreatography.

FIG 3 ● CT of an unresectable/locally advanced pancreatic cancer. The lesion has encircled the SMA. *PV*, portal vein.

- Endoscopic retrograde cholangiopancreatography (ERCP). ERCP may be used to provide biliary decompression. In cholangiocarcinomas, it is necessary to evaluate the entirety of the biliary tree and see the proximal extent of the stricture. This may require a percutaneous transhepatic cholangiogram. In ampullary carcinomas, the mass can be directly visualized and biopsied. A biliary stent should be placed if neoadjuvant therapy is planned, to allow time for referral to a high-volume pancreas surgery center, and in cases where the serum bilirubin is particularly elevated (>10 mg/dL).[4] Although stent placement has been shown to increase infectious complications, prolonged biliary obstruction causing liver insufficiency and coagulopathy adversely affects surgical outcomes.
- Duplex ultrasound of the neck is performed selectively in patients who may need to undergo PV resection to evaluate the patency of the internal jugular veins. It may also evaluate the carotids in patients at high risk for atherosclerotic disease.
- Octreotide scan. Octreotide scan is a radionuclide scan used for localization of primary and metastatic neuroendocrine tumors. Radioactive octreotide attaches to tumor cells that have receptors for somatostatin. Somatostatin receptor scintigraphy and three-dimensional single-photon emission computed tomography (SPECT) images are taken at 4 hours and 24 hours. The tracer is visible in the thyroid, liver, gallbladder, kidneys, spleen, and urinary bladder; the physiologic uptake by these organs is diffuse. Carcinoid tumors may be seen at 24 hours more clearly than at 4 hours by virtue of reduction in background activity.
- Tumor markers. Serum carbohydrate antigen 19-9 (CA 19-9) is shown to be predictive of outcomes in pancreatic adenocarcinoma. However, CA 19-9 can be falsely elevated in the setting of obstructive jaundice. If it is more than 1,000 U/mL in the absence of jaundice, there should be a high suspicion for metastatic disease.[5] In patients who receive neoadjuvant therapy, CA 19-9 may be used as a marker to assess response. A drop in CA 19-9 of greater than 50% may be predictive of improved survival.[2] A low value is not predictive of favorable biology. Serum chromogranin A should be performed in patients with pancreatic neuroendocrine tumors. Elevated chromogranin A may be followed as a marker; a low value is not predictive of favorable biology.
- Liver function test and coagulation profile: Bile salts are required for absorption of vitamins A, D, E, and K. Patients with biliary obstruction may require vitamin K (10 mg administered intramuscularly three times every day) if the prothrombin time/international normalized ratio (PT/INR) is prolonged. A serum albumin level of less than 3 may indicate the need for preoperative nutritional supplementation.
- Cardiopulmonary clearance and risk assessment by a cardiologist or appropriate internist may aid in perioperative optimization.

SURGICAL MANAGEMENT

Preoperative Planning

- Presentation of the case at a multidisciplinary tumor board with radiology, gastroenterology, medical oncology, radiation oncology, and surgical teams in attendance is optimal in the evaluation of all pancreatic lesions. This allows the case to be reviewed in an objective manner, facilitates enrollment in clinical trials, and allows the development of institutional guidelines of care among all specialties.

- All patients with pancreatic adenocarcinoma, whether resectable, locally advanced, or metastatic, should be offered access to a clinical trial.
- A pancreaticoduodenectomy should be performed at a high-volume center (approximately more than 16 pancreatic resections per year). Resections performed at institutions below that volume have higher perioperative morbidity and mortality rates and worse oncologic outcomes.[6,7]
- Be prepared to alter the sequence of the dissection; anatomic relationships of the tumor drive this up to the point of commitment for resection—unaffected planes should be addressed before embarking on those at risk.

Positioning

- Supine position with both arms out to the side. Tuck the sheet tight under the bed to ensure bed rails are accessible for retractor placement.
- Turn the head to the right with neck extended to expose the left internal jugular vein.

TECHNIQUES

DIAGNOSTIC LAPAROSCOPY

- Diagnostic laparoscopy. The value of staging laparoscopy has decreased as the accuracy of CT scanning has improved.[3] Laparoscopy should be performed as a prelude to potential surgical resection in selected patients who have pancreatic adenocarcinoma. We advocate selective laparoscopy on the same day as the planned resection in high-risk patients with potentially advanced disease, large (>4 cm) or borderline resectable tumors after neoadjuvant therapy, liver lesions too small to characterize or percutaneously biopsy, any ascites fluid, marked weight loss, hypoalbuminemia, and high (>1,000 U/mL) CA 19-9 levels.
- The peritoneum, omentum, and surface of the liver are inspected for evidence of metastasis. A multiport technique with mobilization of the tissues and use of a laparoscopic ultrasound probe is required for a thorough examination.

INCISION

- Pancreaticoduodenectomy can be performed through a midline incision from xiphoid to umbilicus or through a bilateral subcostal incision. A bilateral subcostal incision may be superior in patients with a shorter body habitus or significant obesity. A bilateral subcostal incision can be inferior in patients with a narrow costal angle and may limit exposure to the pelvis in patients with adhesions from previous pelvic surgery.
- The falciform ligament is ligated, keeping it long to place over the stump of the GDA at the end of the case.
- Surgical retractor of choice (Bookwalter or Thompson) is placed.

INITIAL ASSESSMENT OF RESECTABILITY

- The initial portion of the procedure is an assessment of resectability.
- The liver and visceral and parietal peritoneal surfaces are thoroughly assessed via a systematic four-quadrant exploration including bimanual palpation of the liver and running the small bowel from the ligament of Treitz to the cecum and palpation of the colon.
- The gastrohepatic omentum is opened, and the region of the celiac axis is examined for enlarged lymph nodes. The base of the transverse mesocolon to the right of the middle colic vessels is examined for tumor involvement.
- Additional information regarding the extent of the malignancy with respect to the PV, SMA, and so forth will be gleaned as the dissection progresses.

CATTELL-BRAASCH AND KOCHER MANEUVERS

- The ascending colon and hepatic flexure of the colon are freed of their lateral and superior attachments using an energy device. The colonic mesentery is completely mobilized and reflected medially to expose the second and third portions of the duodenum and the head of the pancreas (**FIG 4**). An avascular plane between these structures will develop over the third portion of the duodenum and extend up to the inferior border of the neck of the pancreas (**FIG 5**). A Kocher maneuver is performed by incising the peritoneum along the lateral edge of duodenum. This incision should be extended cephalad into the foramen of Winslow. Incise the avascular ligament that tethers the third portion of the duodenum inferiorly, allowing further dissection behind the head of the pancreas, thus elevating the duodenum and pancreas from the vena cava and aorta. The duodenum is mobilized medially until the left renal vein is seen crossing over aorta. This will usually also result in fully exposing and dividing the ligament of Treitz from the right side of the patient.

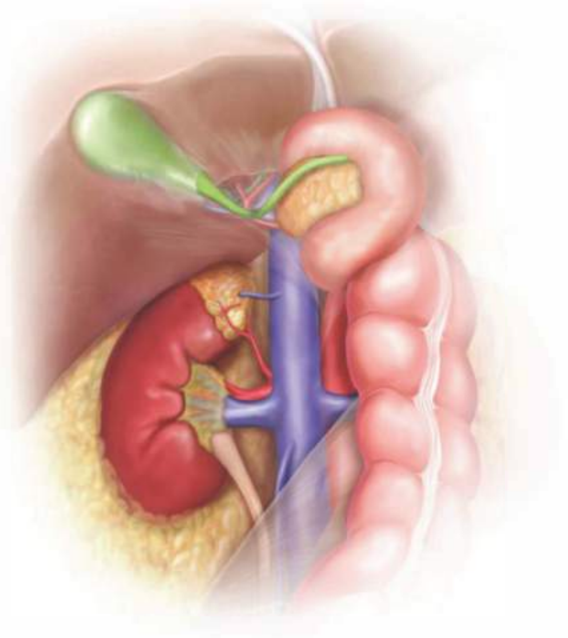

FIG 4 ● Artist's renditions of the Cattell-Braasch maneuver and subsequent wide Kocher maneuver.

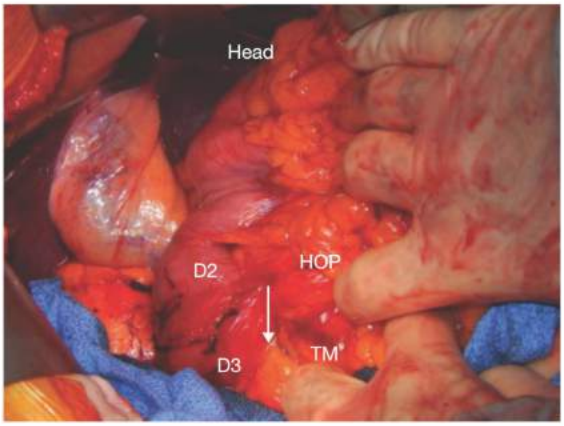

FIG 5 ● Operative photograph taken during performance of a Cattell-Braasch maneuver exposing the duodenum and pancreatic head. The *white arrow* points to the avascular plane between the transverse mesocolon and the head of the pancreas, which in this view has yet to be dissected from the mesentery and omentum. *TM,* transverse mesocolon; *D2,* second portion of duodenum; *D3, third* portion of duodenum; *HOP*, head of pancreas.

EXPOSURE OF THE INFRAPANCREATIC SUPERIOR MESENTERIC VEIN

- The gastrocolic omentum is divided, opening the lesser sac and exposing the body and tail of the pancreas. As the gastrocolic ligament is divided, the dissection is kept outside of the gastroepiploic vessels to preserve the gastric vasculature and blood supply to the duodenal cuff. Dissection proceeds from the patient's left to right with the goal of defining the avascular fusion plane between the omentum, the right gastroepiploic vascular pedicle, and the transverse mesocolon. This plane is fully mobilized to expose the pancreatic head. Congenital adhesions of the antrum to the anterior pancreas are then taken along the inferior border of the pancreas working toward the gastroepiploic vein (**FIG 6**).
- Dissect the anterior aspect of the middle colic vein(s) and circumferentially dissect the gastroepiploic vein as it inserts into the anterior surface of the SMV at the inferior border of the neck of the pancreas. They may enter as a common trunk (gastrocolic trunk) or separately. There is often a tributary vein inserting into the cephalad (unvisualized) aspect of the gastroepiploic vein. Although contraintuitive, the safest place to get around the vein is at the level of the SMV—not a little bit away from it. Once isolated, the gastroepiploic vein is ligated and divided (**FIG 7**). All efforts should focus on preservation of the middle colic vein; however, in rare circumstances, it is prudently divided based on anatomy to prevent traction injury or tearing of the vessels later in the dissection.

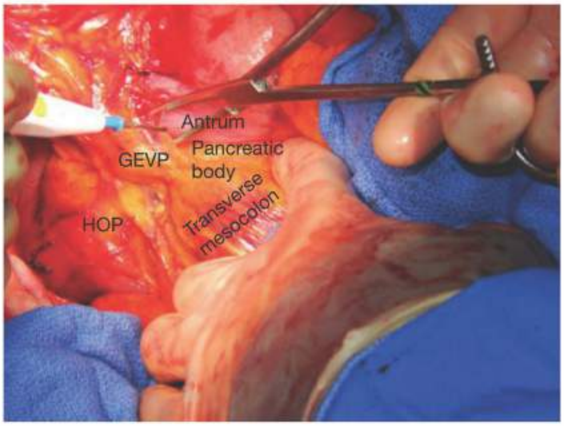

FIG 6 ● Take down the congenital attachments of the posterior stomach to the anterior aspect of the pancreatic body. After division of the gastrocolic omentum, dissect along the inferior border of the pancreas, working from the patient's right to left up to the gastroepiploic vascular pedicle (GEVP). The head of the pancreas (HOP) is visualized on the left.

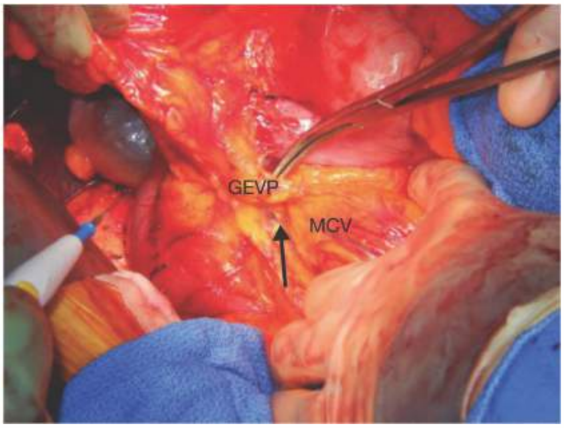
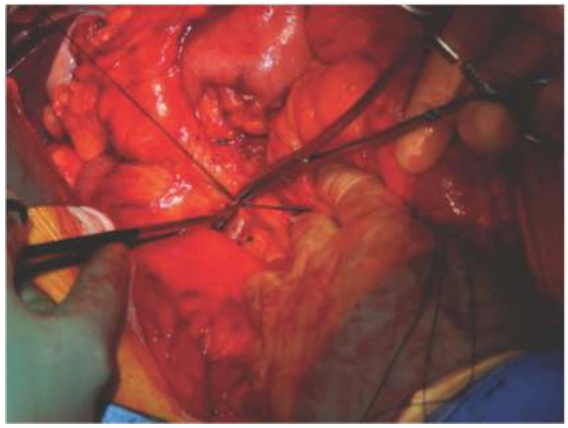
- Dissection is continued to further mobilize inferior border of the pancreas to identify and expose the anterior surface of the SMV (**FIG 8**).
- At this point, the anterior aspect of the pancreas is fully exposed and the inferior aspect of the neck and body has



A



B

FIG 7 ● **A.** The gastroepiploic vein is circumferentially dissected (*black arrow* marks the course of the SMV) and **(B)** ligated between ligatures and divided. *GEVP*, gastroepiploic vascular pedicle; *MCV*, middle colic vein.

been dissected, including the anterior aspect of the SMV (**FIG 9**).

- The plane anterior to the SMV as it courses behind the pancreatic neck is now initially assessed. Completion of this retropancreatic tunnel should be deferred until the PV is exposed cephalad to the pancreatic neck in subsequent steps. The authors recommend the use of a blunt-tipped instrument such as a Kelly clamp to perform this exposure. Care must be taken to carefully assess potential involvement of this plane by tumor or inflammation during this step. Inadvertent injury to the SMV at this point will result in catastrophic hemorrhage that can be very difficult to control given the limited exposure.
- The relation of the tumor to the SMV and artery can now be relatively well assessed by palpation; however, palpation is not completely reliable, as posterior or lateral extension of the lesion that compromises these margins cannot be completely determined until later in the operation when the neck of the pancreas is divided and the surgeon is committed to resection.

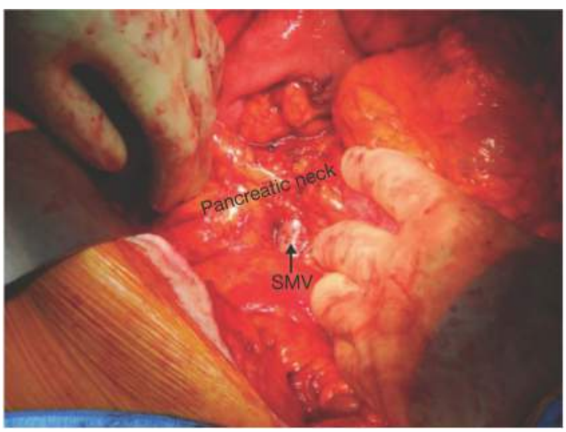


FIG 8 ● Once the gastroepiploic vein has been divided, the anterior aspect of the SMV is exposed. This dissection of the SMV is continued inferiorly to the caudad aspect of the third portion of the duodenum.

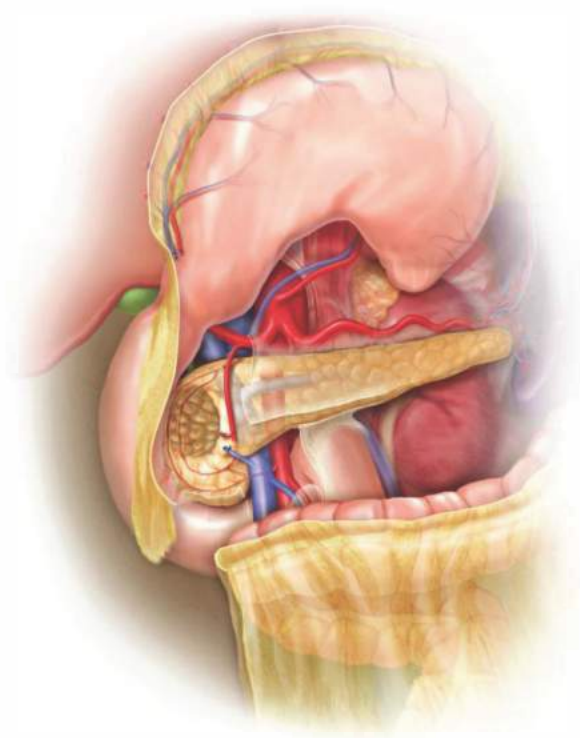

FIG 9 ● Schematic representation of exposure of the pancreatic head, neck, and body including the anterior aspect of the SMV.

DISSECTION OF THE PORTA HEPATIS

- The porta hepatis is palpated by placing a finger through the foramen of Winslow. Enlarged or firm lymph nodes that can be swept down toward the head of the pancreas with the specimen do not preclude resection.
- The presence of an aberrant right hepatic artery or other anomalies should be identified during review of the preoperative CT scan. Regardless, prior to initiating the dissection of the porta hepatis, it is important to assess for aberrant hepatic arterial anatomy, which is present in approximately 20% of patients, by palpation of the porta hepatis. The aberrant artery commonly arises from the SMA posterior to the pancreas and ascends parallel in a lateral and posterior location to the common bile duct and PV. Possible alterations in this anatomy are reviewed in Part 3, Chapter 15.
- The proximal hepatic artery is identified usually by removing a lymph node that lies anterior to the artery.
- The hepatic artery is dissected and traced toward the porta hepatis. Small vessels in this area can be ligated with silk ligatures or bipolar electrocautery to prevent bothersome hemorrhage that makes subsequent dissection more tedious.
- Inferior retraction of the pylorus will expose a band of tension from the hepatic artery—this is the right gastric artery and this is ligated and divided. The GDA is identified posterior to the right gastric artery coming directly off the caudad aspect of the hepatic artery (**FIG 10**).

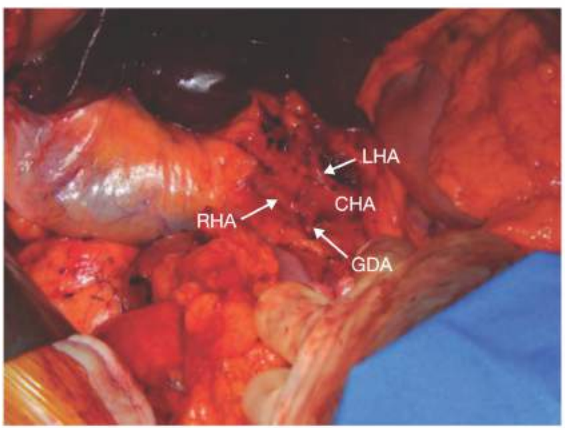

FIG 10 ● Operative exposure of the common hepatic artery (CHA) and its named branches. The demonstrated anatomy is not classic in that the bifurcation of the right and left hepatic artery (RHA and LHA) occurs prior to the origin of the GDA. The GDA arises from the RHA. The right gastric artery has been ligated and divided in this photograph.

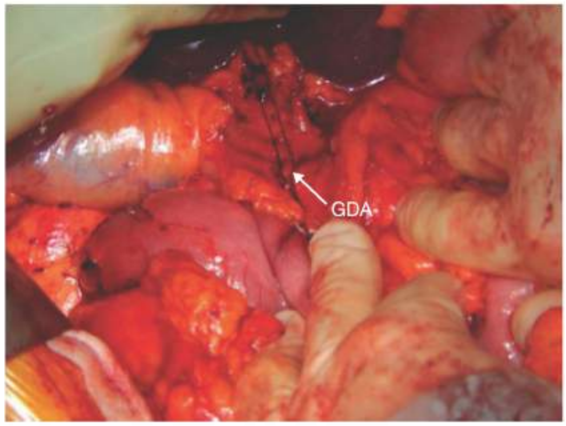

FIG 11 ● The GDA is ligated and divided. The authors recommend additional suture ligation or oversewing the GDA stump and marking it with a surgical clip.

- Once the GDA is identified (**FIG 11**), it is circumferentially dissected and test clamped to ensure that a strong pulse remains in the proper hepatic artery. This test rules out a hemodynamically significant celiac stenosis leading to hepatic blood flow depending on collateral circulation through the pancreatic head. If this clinical scenario is present, proceeding with resection is contraindicated.
- The GDA is doubly ligated and a surgical clip applied.
- Once the GDA is divided, the hepatic artery is retracted medially and the common bile duct is retracted laterally to reveal the anterior surface of the PV (**FIG 12**).

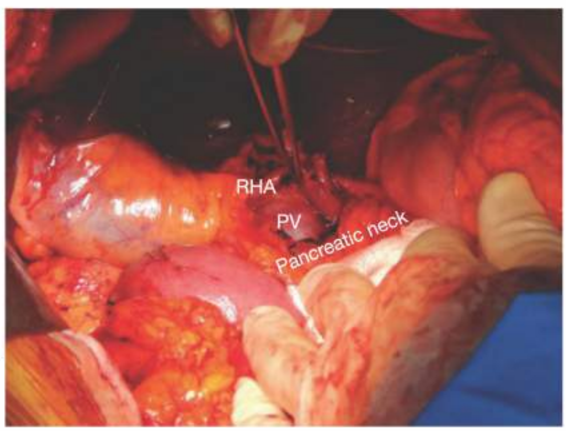

FIG 12 ● Division of the GDA facilitates medial and cephalad retraction of the hepatic artery and its branches (RHA), exposing the PV cephalad to the pancreatic neck.

CREATION OF A TUNNEL BETWEEN THE PANCREATIC NECK AND PORTAL VEIN

- The authors prefer to complete this step prior to dissection of the bile duct as findings may impact the decision to proceed.
- Dissection is performed only on the anterior surface of the vein.
- Dissect the PV superior to the neck of the pancreas. If there is no tumor involvement, the neck of the pancreas will separate from the vein easily. A large, blunt-tipped clamp is a safe instrument to use for this dissection.
- The tunnel under the neck of the pancreas can then be completed mostly under direct vision as one progresses from both the inferior and superior aspects of the pancreas (**FIG 13**).
- A vessel loop or umbilical tape is then placed under the neck of the pancreas.
- The common bile duct or hepatic duct (depending on the need for margin) is circumferentially dissected and a vessel loop is placed around the duct (**FIG 14**).

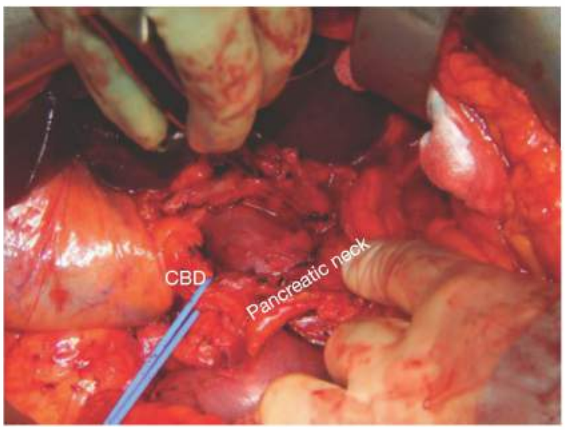

FIG 13 ● To circumferentially dissect the common bile duct (CBD), continue working anterior to posterior along the lateral margin of the PV establishing a plane between the PV and the CBD. The lateral lymphatic tissues are also dissected so they remain with the specimen. The encircled CBD can be controlled with a vessel loop. If a replaced hepatic artery is present, use care to ensure you establish a plane between the bile duct and the artery.

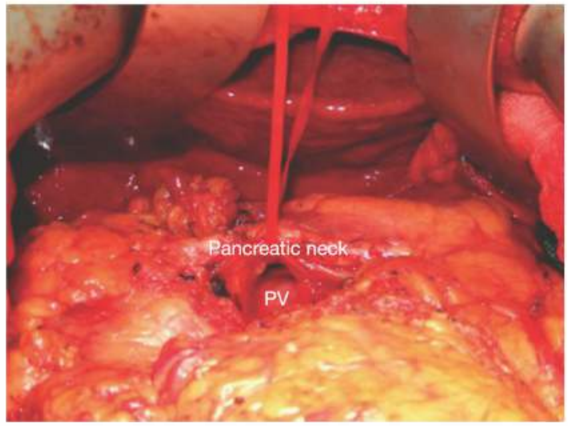

FIG 14 ● Complete the dissection of the anterior aspect of the PV from the neck of the pancreas. An umbilical tape can be placed to facilitate subsequent parenchymal transection.

- The cystic duct and artery are dissected, ligated, and divided (**FIG 15**). A cholecystectomy is performed. Alternatively, it is safer to perform a retrograde dissection of the gallbladder if inflammation is present.
- At this point (**FIG 16**), one must commit to resection or abort.

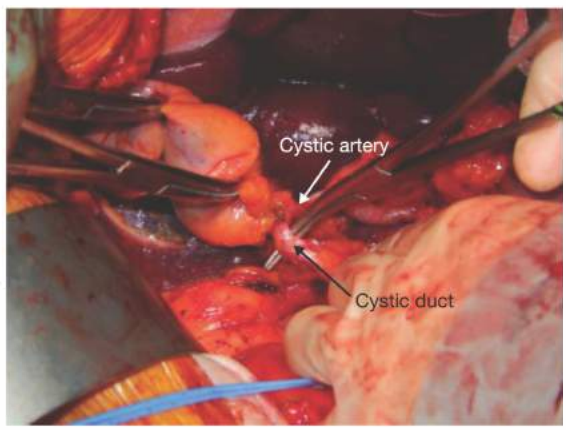

FIG 15 ● Cholecystectomy is performed. The cystic duct and artery are dissected, controlled with ligatures, and divided.

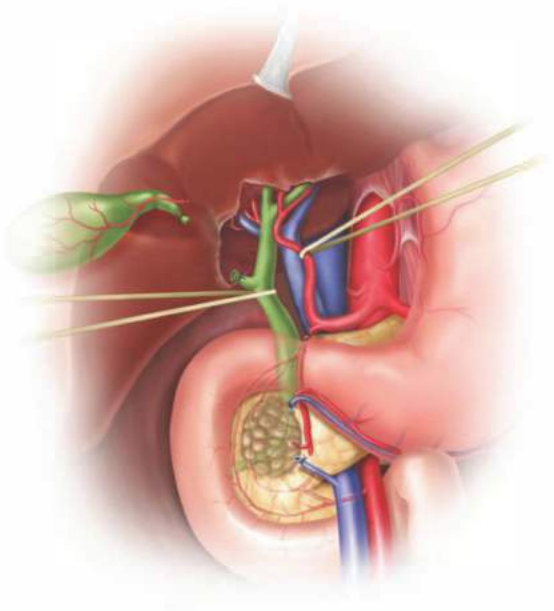

FIG 16 ● Schematic drawing of the dissection at the point of decision to proceed or abort. The next step commits to resection.

DIVISION OF THE DUODENUM

- If the operative plan is for pyloric preservation, the stomach and proximal duodenum are mobilized off the pancreas, preserving the gastroepiploic vessels down to the pylorus.
- Either the duodenum is divided 1.5 to 2 cm distal to the pylorus-preserving pancreaticoduodenectomy (PPPD) or, alternatively, the antrum is divided (**FIG 17**).
- Antrum division is performed at the division of the vagus nerves of Latarjet ("crow's feet") usually at the third or fourth transverse vein on the lesser curvature and at the confluence of gastroepiploic veins on the greater curvature.
- If the pylorus is preserved, the authors typically digitally dilate the pylorus prior to reconstruction just prior to the duodenojejunal anastomosis.

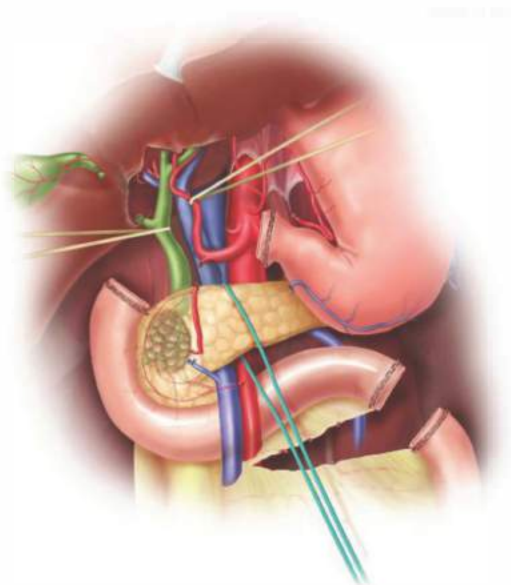

FIG 17 ● Division of the duodenum and the jejunum with a GIA stapler. The point of duodenal transaction should be at least 2 cm distal to the pylorus. Alternatively and in line with the classic performance of the operation, the antrum is divided. The jejunum is divided distal to the LT. The point of transaction is based on the vascular arcade and mesenteric length. The distal limb must reach the right upper quadrant without tension. The mesentery of the proximal limb is controlled and divided adjacent to the bowel wall to minimize risk of injury to the superior mesenteric vessels.

TAKEDOWN OF THE LIGAMENT OF TREITZ

- The jejunum is divided approximately 10 cm beyond the ligament of Treitz (LT). Careful attention is made to avoid injury to the inferior mesenteric vein just to the left of the LT.
- The mesentery of jejunum is ligated until the jejunum can be delivered posterior to the superior mesenteric vessels from left to right.
- The authors recommend performing the majority of this dissection from the left side of the patient and mobilizing as much as possible from this same side of the base of the mesentery. Dissection is continued proximally to divide and control the mesentery of the fourth and third portion of the duodenum. The visualization is maximized in this manner and this avoids moving the specimen back and forth and repositioning of retractors.
- The mesentery can be taken with ties; however, many surgeons have found that energy devices may speed this portion. Care must be taken as the dissection approaches the mesenteric vessels—the plane of dissection is the bowel wall.

DIVISION OF BILE DUCT

- The common hepatic bile duct is then sharply divided, usually above the entrance of the cystic duct.
- If present, the biliary stent is removed and passed from the operative field as a contaminated object. Of note, metallic stents do not impact division of the bile duct and can be extracted with minimal resistance.
- Some surgeons obtain cultures of the bile and continue directed, postoperative antibiotic therapy.
- A bulldog clamp is placed on the bile duct to prevent bile from contaminating the field (**FIG 18**). The distal bile duct is oversewn and the ends of the suture left elongated to orient the pathologist to this important margin.
- The distal bile duct and associated lymphatic tissue is then further dissected down along the anterior plane of the PV.

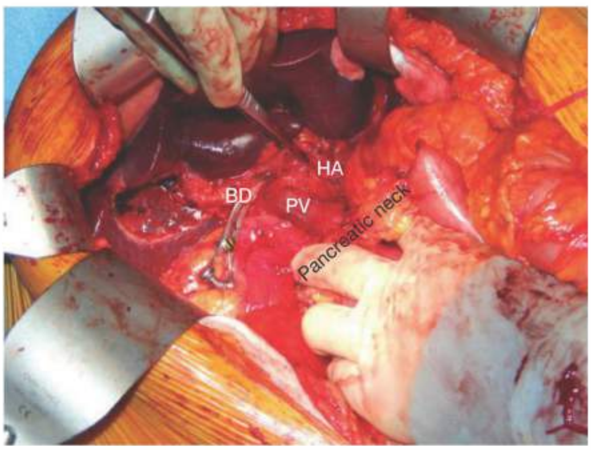

FIG 18 ● Division of the bile duct. A bulldog clamp is placed proximally to prevent ongoing contamination of the operative field with bile and maintain hemostasis. The bile duct is sharply divided. If present and easily retrievable, the biliary stent is removed and passed off the field. It should be cataloged as removed by the pathologist. The distal bile duct is sutured closed. The ends of this suture are left long to orient the pathologist. *BD*, bile duct; *HA*, hepatic artery; *PV*, portal vein.

DIVISION OF THE PANCREAS

- Hemostatic traction sutures are placed on the inferior and superior borders of the pancreas around the transverse pancreaticoduodenal vessels prior to division. These sutures should be placed to intentionally ligate the longitudinal arteries within the pancreas; however, care must be taken to ensure they do not entrap the pancreatic duct (**FIG 19**).
- The pancreatic neck is divided anterior to the PV (**FIG 20**). The authors would divide the pancreas with electrocautery on the superior and inferior ends and with the scalpel through the midsection of the pancreas to prevent cautery injury and assist in identification of pancreatic duct. Division is performed just anterior to the PV with a large blunt-tipped clamp being placed behind the pancreas to protect the vein.

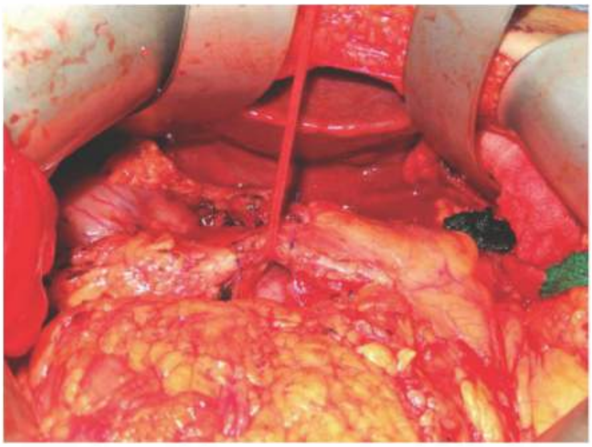

FIG 19 ● Place sutures at the proximal and distal margins of the pancreatic neck to control the longitudinal arteries and provide retraction.

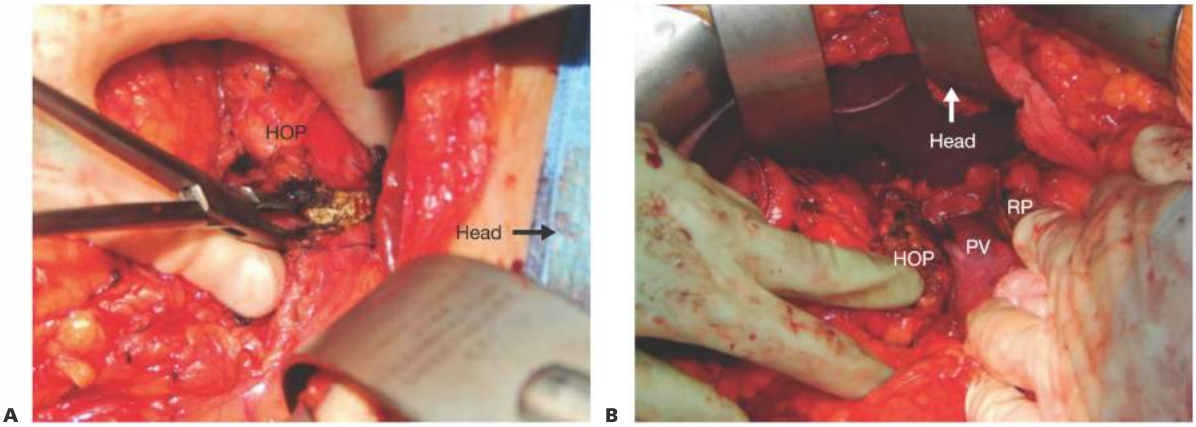

FIG 20 ● Divide the pancreatic neck. **A.** This is ideally performed sharply with judicious use of cautery to control hemorrhage to facilitate pathologic assessment of the margin. **B.** Once completed, the anterior aspect of the PV is fully exposed. *RP*, remnant pancreas; *HOP*, head of pancreas specimen; *PV*, portal vein.

DISSECTION OFF THE LATERAL ASPECT OF THE SUPERIOR MESENTERIC-PORTAL VEIN CONFLUENCE

- The pancreatic head and uncinate process are then dissected off of the right lateral aspect of the SMV, ligating the fragile branches draining the head and uncinate process into the PV (FIG 21).
- Superiorly, as the pancreatic head is being retracted inferiorly and laterally, the small venous tributaries from the PV and SMV to the pancreatic head including the superior pancreaticoduodenal vein (vein of Belcher), which inserts at the superior lateral surface of the PV, are ligated.
- Inferiorly, as the pancreatic head is retracted superiorly and laterally, the first jejunal branch will be encountered. The authors suggest ligating the first jejunal branch as it comes off of the SMV. If this is not ligated close to the SMV, it may be injured during the dissection and retract behind the SMA. Efforts to control bleeding once the vessel has retracted may result in injury to the SMA. If the tumor is inferior in location, this ligation is critical. In cases where the tumor is away from the first jejunal branch of the SMV, it can be preserved.
- The SMV is then fully mobilized off of the uncinate process to reveal the SMV/PV groove. The vein must be entirely mobilized away from the head of the pancreas to allow for maximal retroperitoneal margin resection (FIG 22).

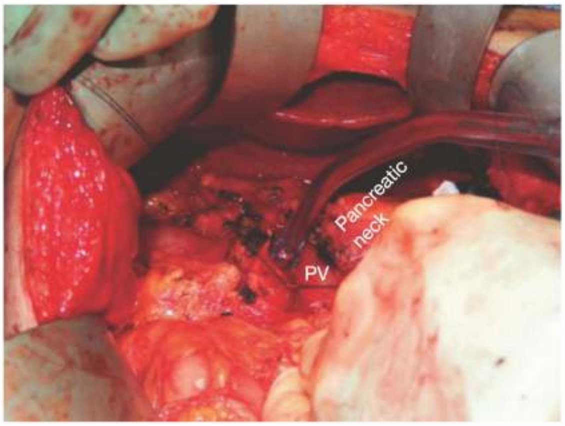

FIG 21 ● Ligate and divide the lateral venous branches of the pancreas inserting into the SMV/PV. Beware the first jejunal branch of the SMV. It inserts into the SMV posteriorly and receives a branch from the uncinate process. *PV*, portal vein.

- If the lesion is adhered to the SMV, PV, or confluence of these vessels, obtain vascular control by circumferentially dissecting the SMV. Mobilize the body of the pancreas off the splenoportal confluence and off the proximal splenic vein. Encircle the splenic vein with a vessel loop as well, and encircle the PV superiorly with a vessel loop. Once venous vascular control is achieved, the dissection then proceeds medial to the SMV directly anterior down onto the SMA and is continued around the right lateral aspect of the SMA, retracting the specimen laterally and mobilizing the specimen up so that it is then only attached by the venous involvement and is otherwise completely free. Part 3, Chapter 39 discusses PV resection and reconstruction.

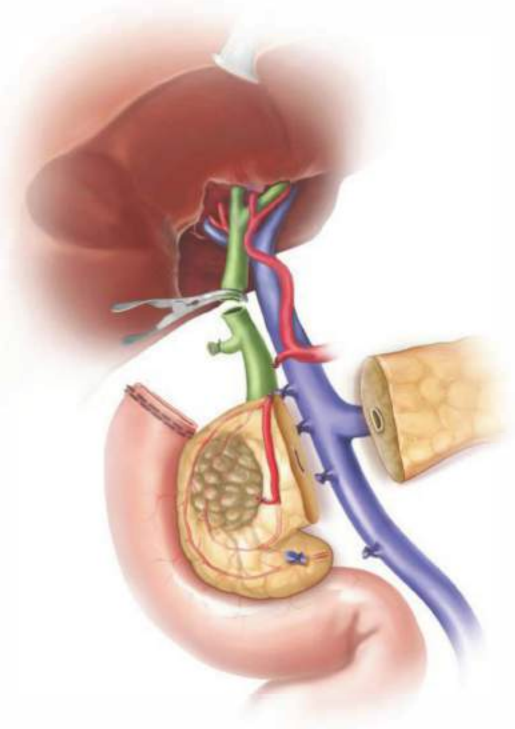

FIG 22 ● Dissect the anterior and lateral surface of the SMA. The splanchnic nerves and lymphatics in this region can make identification of the inferior pancreaticoduodenal artery or arteries challenging. Avoid the impulse to divide these structures with an energy device alone—pseudoaneurysm in the setting of pancreatic fistula from this site is universally life threatening.

COMPLETION OF THE RETROPERITONEAL AND SUPERIOR MESENTERIC ARTERY DISSECTION

- In cases without vein involvement, the superior mesenteric-portal vein (SMPV) confluence is retracted medially with a peanut or vein retractor to allow exposure of the retroperitoneal attachments to the SMA.
- The uncinate process is then dissected off of the posterior and right lateral aspect of the SMA, removing all associated autonomic nerve tissue so that the dissection plane is along the adventitia of the SMA. This can be the most tedious portion of the operation, but thoroughly clearing all tissue from the mesenteric vessels minimizes the risk of a margin-positive resection.
- The authors recommend taking the retroperitoneal margin in a controlled fashion with small bites separating out the tissue and division with either suture ties or energy device. They prefer ligation of the inferior pancreaticoduodenal artery and any lesser, unnamed nutrient arteries arising from the SMA (**FIG 23**). The authors think that use of a stapler for this portion of the procedure leaves tissue behind on the SMA and will increase the incidence of R1 resections.
- If an energy device is used on this portion, caution must be taken to avoid lateral spread to the SMA which can result in a catastrophic, postoperative SMA pseudoaneurysm.
- Once the pancreatic specimen is out (**FIG 24**), the remaining pancreatic neck should be fully mobilized approximately 2 to 3 cm off of the splenic artery and vein to facilitate the reconstruction.

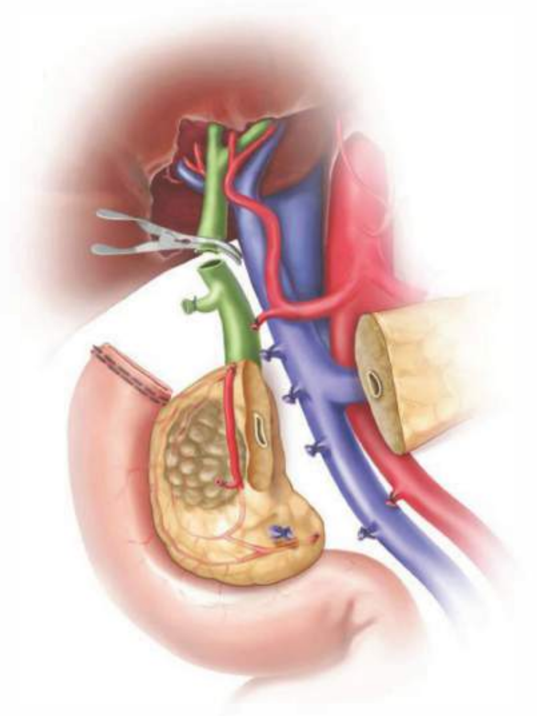

FIG 23 ● Operative image of the completed dissection. *PV,* portal vein; *SMV,* superior mesenteric vein; *CBD,* common bile duct.

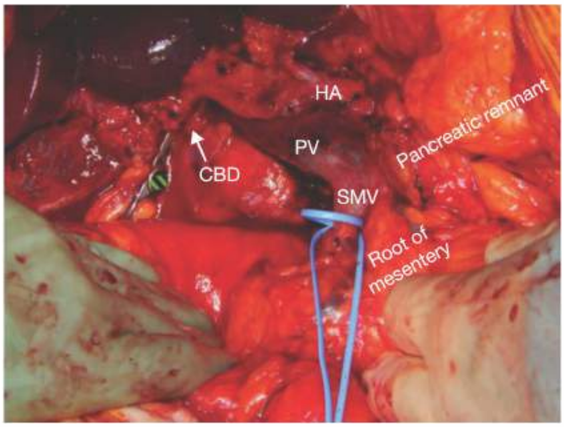

FIG 24 ● Operative image of the completed dissection.

ORIENTING THE SPECIMEN FOR PATHOLOGIC ANALYSIS

- Before the specimen is sent to pathology, it is critical that the specimen be labeled by the surgeon in a standardized fashion to facilitate communication with the pathologist. We place sutures on the bile duct, pancreatic neck, and retroperitoneal/SMA margin. The SMA margin cannot be marked retrospectively. Furthermore, if any portion of the SMV or PV was resected, the vein should be marked and sent for frozen section.
- Positive resection margins of the pancreatic neck or bile duct may warrant further resection, but recently forwarded data would suggest that this maneuver does not impact outcome.
- If there is a positive margin on the SMA margin, no further tissue can be taken and gold fiducial markers can be left in place for postoperative radiation therapy.

PEARLS AND PITFALLS

Preoperative assessment	■ Not adequately identifying a replaced hepatic artery can result in injury leading to an ischemic injury to the liver and possibly subsequent liver failure.
Opening of the lesser sac	■ Ligate the gastroepiploic and sometimes middle colic veins early. This provides improved exposure of the SMV and prevents a traction injury to the vein.
Dissection of the SMV/PV confluence	■ First jejunal branch not being properly ligated can result in division or injury to the vein with it retracting behind the SMA. Attempts to control this bleeding may result in iatrogenic injury to the SMA.
Retroperitoneal dissection	■ Complete removal of uncinate process and the mesenteric soft tissue from the SMA decreases the chance of an R1 resection.

Vein involvement	▪ If the tumor is adhered to SMPV confluence, we obtain vascular control of the PV, SMV, and splenic vein and dissect medial to the PV/SMV and perform an artery-first dissection. Completing this dissection first decreases clamp time once the vein is divided.
Pancreatic neck	▪ Mobilization of the pancreatic neck off of the splenic artery and vein facilitates a secure reconstruction and anastomosis.
Pylorus preservation	▪ If the pylorus is preserved, the authors typically digitally dilate the pylorus prior to reconstruction once the staple line is removed. The authors think this reduces postoperative gastroparesis.

POSTOPERATIVE CARE

- Patients should be monitored in the intensive care unit for hemodynamic changes, urine output, or changes in drain characteristics.
- Monitoring of drains: The authors would check postoperative drain amylase on postoperative days 1 and 3. If a pancreatic leak exists, the drain should be left in place. In addition, the drain fluid should be monitored for change in character to bilious or sanguineous. If no pancreatic or biliary leak exists, the drains should be removed on postoperative day 3.
- A low amylase level in the drain does not ensure the absence of a leak. Tachycardia and leukocytosis should drive concern and may warrant CT evaluation.
- Patients should be placed on perioperative antibiotics. If the bile cultures come back positive, the authors continue culture-directed antibiotics for 7 days.

OUTCOMES

- At high-volume institutions, 30-day mortality rates are less than 1.5% and 90-day mortality rates are 4%.
- The overall 1-year survival rate of people with pancreatic cancer is 26%, and the 5-year survival rate is approximately 6%. If the cancer is detected at an early stage when surgical removal of the tumor is possible, the 5-year survival rate is about 22%.

COMPLICATIONS

- Pancreatic fistula
- Delayed gastric emptying
- Biliary fistula
- Fistula-associated pseudoaneurysm—uncommon. Often, a herald bleed presents as an episode of hypotension accompanied by hematemesis and blood from the intraabdominal drain. These should be treated emergently with angiography
- Wound infection
- Abdominal abscess

Chapter 34

Pancreaticoduodenectomy: Minimally Invasive Resection

Song Cheol Kim   Ki Byung Song

DEFINITION

- Pancreaticoduodenectomy (PD) is defined as the resection of the pancreatic head, duodenum, bile duct, and gallbladder, with or without the distal stomach (pylorus preserving), for benign or malignant periampullary diseases.
- Gagner and Pomp first introduced laparoscopic pyrolus preserving pancreatoduodenectomy (LPPPD) in an advanced laparoscopic surgical trial in 1994. Subsequently, there has been technical progress in laparoscopic pancreatoduodenectomy (LPD) that includes hand-assisted LPD as well as laparoscopic-assisted and robot-assisted PD.

DIFFERENTIAL DIAGNOSIS

- Pancreatic cancer
- Distal bile duct cancer
- Ampullary cancer
- Duodenal cancer
- Pancreatic neuroendocrine neoplasms
- Others

PATIENT HISTORY AND PHYSICAL FINDINGS

- Not all patients are suitable candidates for LPD. Table 1 shows the currently accepted contraindications for LPD. LPD with portal vein (PV) resections and reconstructions has been reported. With increasing experience, LPD can be attempted in obese patients.
- A history of extensive, previous abdominal surgery or pancreatitis may preclude successful completion of LPD. Hence, a detailed patient history and medical record review is vital to minimize the rate of conversion.
- A high body mass index (BMI) should be considered a significant factor for morbidity, especially during the learning period. Patients with a high BMI usually have a large amount of parietal and visceral fat, which makes identification of the detailed structures of the inner abdominal organ challenging. Exposure of the third and fourth portions of the duodenum is particularly challenging in the obese patient. Furthermore, the fragile nature of a fatty pancreas leads to difficulties in manipulating or suturing the organ during anastomosis.

Table 1: Current Contraindications for Laparoscopic Pancreaticoduodenectomy

Locally advanced disease
Obesity (BMI >35)
Extensive adhesions from previous operations or inflammation
Cardiopulmonary disease that will not tolerate prolonged insufflation of the abdomen
Aberrant anatomy

BMI, body mass index.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Patients require abdominal or abdominopelvic computed tomography (CT) or magnetic resonance imaging for diagnosis and surgical planning. Multidetector CT (MDCT) is a useful diagnostic tool for detecting the vascular involvement of the tumor, including the PV, the superior mesenteric vein (SMV) or artery, and the celiac axis. MDCT has been reported to have a sensitivity of 85% to 95% and a specificity of 95% for pancreatic cancer.
- The advent of MDCT has eliminated the need for routine magnetic resonance imaging. Heavily weighted T2 imaging sequences in magnetic resonance cholangiopancreatography can depict the pancreatic duct, biliary tree, liver, and vascular structures. Magnetic resonance cholangiopancreatography can replace endoscopic retrograde cholangiopancreatography for imaging of pancreatic and biliary lesions, thereby avoiding endoscopic retrograde cholangiopancreatography-related complications such as bleeding, perforation, and pancreatitis.
- Endoscopic ultrasound (EUS) with a high-frequency probe produces a high-resolution image of the pancreas and its surrounding structures; a small pancreatic mass or cancer can be detected with a sensitivity of 91% to 99% and a specificity of 100%. EUS fine needle aspiration (EUS-FNA) is useful for the diagnosis of an indeterminate pancreatic cystic lesion or when a clinical diagnosis prior to operation is clinically indicated. However, EUS-FNA is not mandatory in operable patients who have been diagnosed with a resectable surgical pancreatic mass by conventional CT and who have clinical signs compatible with a malignant diagnosis. Surgeons should also be mindful of possible risk factors and complications that are associated with an extended surgical time, a possibility that may arise during LPD. (See the guidelines of the Society of American Gastrointestinal Endoscopic Surgeons.)

SURGICAL MANAGEMENT

Preoperative Planning

- Preoperative palliation of obstructive jaundice may be appropriate for jaundiced patients but such procedures are associated with an increased risk of operative complications.
- In the case of colon or mesocolon invasion, a bowel prep should be considered before the operation.
- Prophylactic antibiotics and chemical and mechanical venous thromboembolism prophylaxis are warranted.

POSITIONING

- The patient is placed in the supine position with pads underneath the right side of the back to elevate the right side of the abdomen. Alternatively, a split-leg positioning can be used for LPPPD. In this position, the operator stands between the legs of the patient and the assistants stand on either side of the patient.
- A nasogastric tube and Foley catheter are inserted to decompress the stomach and bladder, respectively.
- Reverse Trendelenburg (10 degrees to 30 degrees) position is used to expose the operative field.
- Two monitors are placed at the sides of the operator and first assistant. The primary surgeon and second assistant, who holds the laparoscope, stand to the right of the patient, and the first assistant and the scrub nurse are positioned to the left of the patient. Intravenous patient-controlled analgesia systems are used to control the pain after the operation.

TROCAR PLACEMENT

- Open technique is used to establish the pneumoperitoneum through a 12-mm trocar on the umbilicus.
- Thirty-degree angled vision scope is used for visualization of the deep portion. The trocar locations are shown in **FIG 1**.
- An additional three or four trocars are placed under direct vision. Two or three 5-mm trocars (one on the right flank for the left hand of the surgeon and one or two on the left flank for surgical assistance, if necessary) and two 12-mm trocars (one for the laparoscope and one on the umbilicus for the right hand of the surgeon) are employed.
- Abdominal pressure is maintained at 12 mmHg using carbon dioxide (CO_2) gas insufflation. Keeping the abdominal inflation pressure low, not more than 12 mmHg, is important to minimize accumulation of CO_2 gas; the LPD procedure can routinely take more than 6 hours.

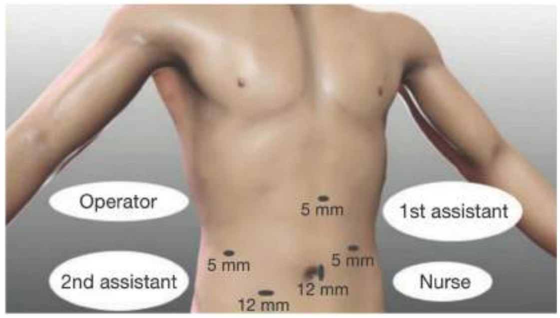

FIG 1 ● Location of trocar placement for laparoscopic pylorus-preserving PD. Two or three 5-mm trocars (one on the right flank for the left hand of the surgeon and one or two on the left flank for surgical assistance) and two 12-mm trocars (one for the laparoscope and one on the umbilicus for the right hand of the surgeon) are employed.

IDENTIFICATION OF THE PORTAL VEIN AND DIVISION OF THE DUODENUM OR STOMACH

- The entire abdomen is examined for any abnormalities or metastasis. The entire hepatic and peritoneal surfaces should be inspected. Intraoperative ultrasound may be used for further examination.
- The gastrocolic omentum is dissected to allow entry into the lesser sac (**FIG 2**).
- The PV is identified at the inferior border of the pancreas by distally following the gastroepiploic vein (GEV) to its insertion into the SMV. The GEV is clipped and divided as it inserts into the SMV (**FIG 3**). The GEV often drains into the middle colic vein, and in this circumstance, efforts should be made to preserve the middle colic vein.
- The anterior aspect of the retropancreatic segment of the PV/SMV is dissected, creating a tunnel, and potential invasion of tumor into the PV is assessed (**FIG 4**).
- The gastrohepatic omentum is opened to expose the hepatic artery coursing cephalad to the pancreas. The right

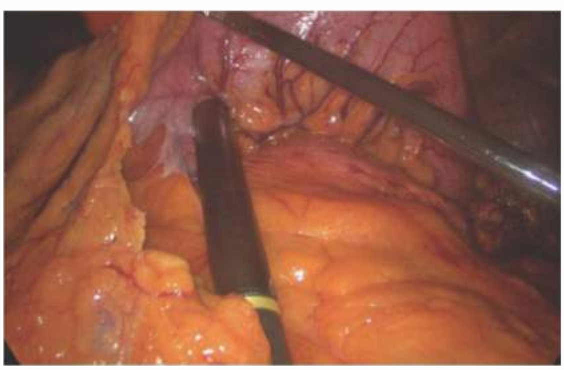

FIG 2 ● Laparoscopic ultrasound. Laparoscopic intraoperative ultrasound probe is inserted into the 12-mm trocar, and ultrasonography is performed for identifying the location of the lesion.

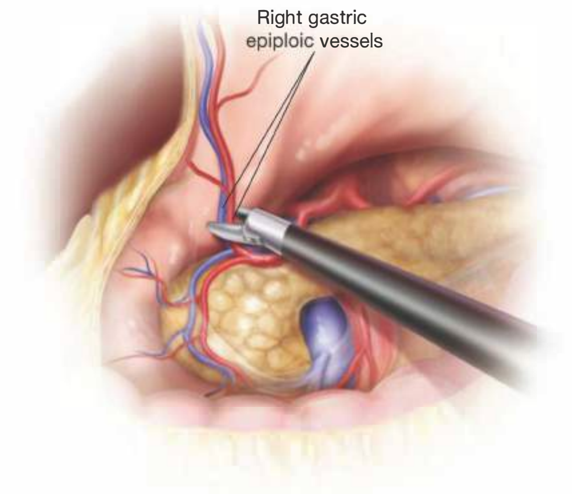

FIG 3 ● Right gastric epiploic vessels are transected and divided.

gastric artery is ligated using a metal clip or Harmonic scalpel. After dividing the branches of the right gastroepiploic vessels along the duodenum, the duodenum is divided 2 cm distal to the pylorus using an endoscopic linear stapler (**FIG 5**). Alternatively, resection of the gastric antrum can be performed according to surgeon preference or when there is concern for obtaining an adequate margin. The stomach is placed in the upper region of the abdominal cavity.

- The upper border of the pancreas is dissected to establish "Kim's triangle," formed by the common hepatic artery, upper border of the pancreas neck, and gastroduodenal artery (GDA) (**FIG 6**). The GDA is ligated at its origin and

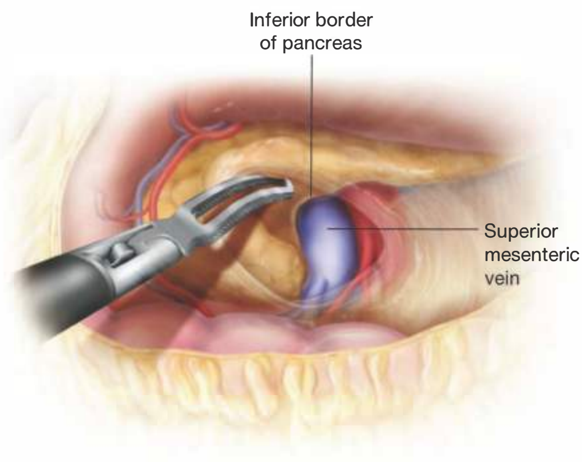

FIG 4 ● Identification of PV and SMV. The SMV is identified at the inferior border of the pancreas and dissected up to the retropancreatic PV.

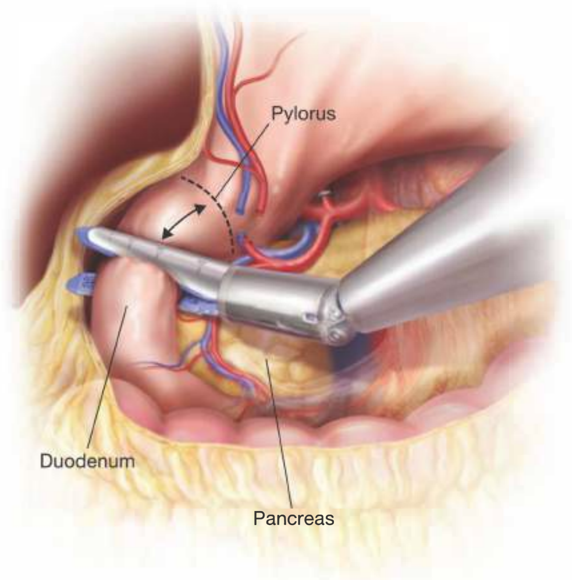

FIG 5 ● The duodenum is divided approximately 2 cm distal to the pylorus *(dotted line)* using an endoscopic linear stapler. We prefer early division of the duodenum to facilitate the subsequent dissection.

then divided with a vascular staple load. The author recommends marking this vessel as well using a clip.

- The PV tunnel is completed and gentle upward traction of the isolated pancreas is applied using an umbilical tape in preparation for division of the pancreas.

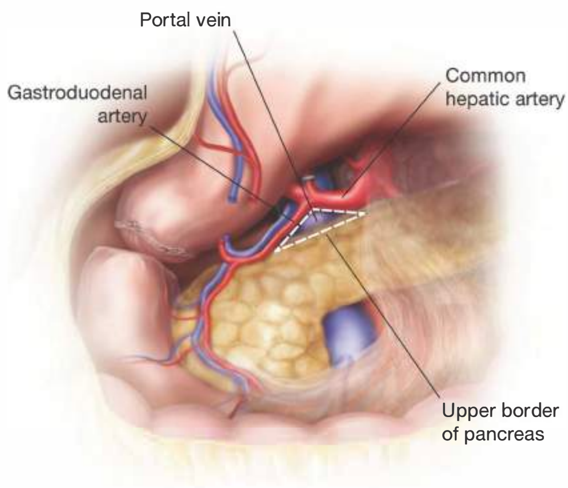

FIG 6 ● Kim's triangle. The outline of common hepatic artery, upper border of the pancreatic neck, and GDA forms a triangle for the tunneling behind the neck of the pancreas. The triangular space is dissected to isolate the pancreas from the PV (tunneling) and gentle upward traction of the isolated pancreas is applied using cotton tape ("lasso technique") in preparation for division of the pancreas.

MOBILIZATION OF THE RIGHT COLON AND DUODENUM AND IDENTIFICATION OF THE SUPERIOR MESENTERIC VEIN

- The peritoneum of the hepatic flexure of the right colon is incised. The right colon is mobilized downward and to the left side of the patient to fully expose the second and third portions of the duodenum. The dissection between the mesocolon and the duodenum/pancreatic head proceeds along the avascular surgical plane and is facilitated by the first assistant pulling the mesentery of the right colon toward the patient's left lower quadrant (**FIG 7**). Any remaining branches of right gastroepiploic vessels are divided (**FIG 8**).
- Mobilization of the third and fourth portions of the duodenum (Kocher maneuver), including division of the ligament of Treitz, is performed (**FIG 9**). Careful traction of the duodenum should be applied to prevent perforation. Dissection is continued to the left of the aorta and up to the origin of the superior mesenteric artery (SMA). The ligament of Treitz can be successfully taken down from this exposure in the majority of patients, but occasionally, there are additional peritoneal attachments to the first portion of the duodenum that will need to be divided with exposure beneath the transverse mesocolon. The third and fourth portions of the duodenum must be fully exposed prior to initiating the division of the mesentery to the duodenum.

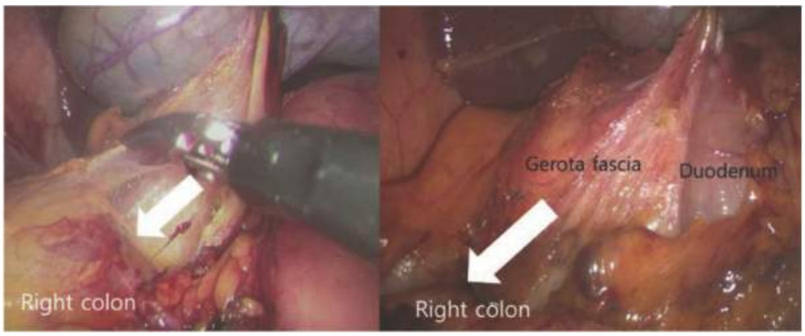

FIG 7 ● Dissection of coloduodenal avascular plane. The coloduodenal plane is bluntly dissected along the avascular surgical plane. This step is a crucial to avoid colonic ischemia due to injury of the mesocolic vessels near the colon.

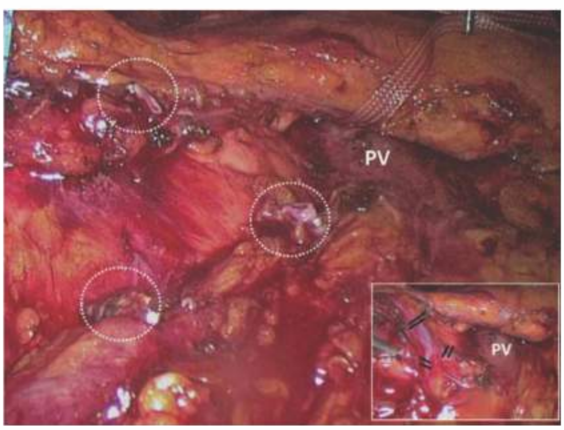

FIG 8 ● Division of branches of right GEV. *Black line*, division line of branches of right GEV; *dotted white circle*, ligated branches of right GEV.

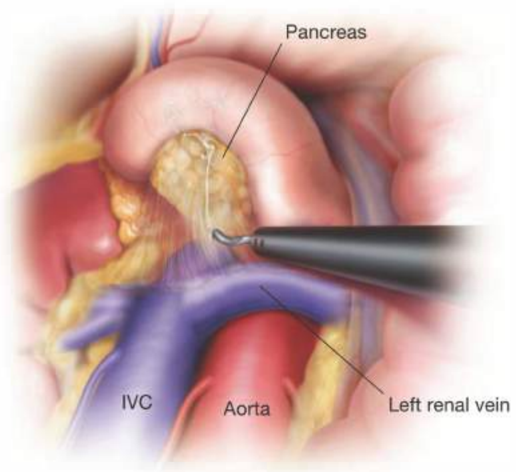

FIG 9 ● Mobilization of the retroperitoneal duodenum. Kocher maneuver is performed to the left renal vein and aorta. Careful traction of the duodenum should be performed to prevent perforation of the duodenum. A full mobilization of the retroperitoneal duodenum facilitates the separation of duodenum from the root of the mesentery.

DISSECTION OF THE PORTA HEPATIS

- Cholecystectomy is performed.
- The lymphatic dissection proceeds distally from divided origin of the GDA up to the bifurcation of the proper hepatic artery.
- Careful dissection of the bile duct should be performed to avoid injury to the accessory or replaced hepatic artery from the SMA traveling posterior to the common bile duct or the low-lying right hepatic artery travelling anterior to the bile duct (**FIG 10**). Preoperative review of the CT scan and careful inspection before division of the bile duct are crucial to avoid unexpected injury to the hepatic artery because palpation of the porta hepatis is impossible in laparoscopic surgery.
- Division of the common bile duct is executed 2 to 3 cm proximal to the duodenum. The proximal duct is controlled with a bulldog clamp. The distal duct is oversewn to prevent contamination and to provide hemostasis. The PV can now be fully exposed by dissecting the soft tissues and lymphatics using ultrasonic shears or bipolar electrocautery.

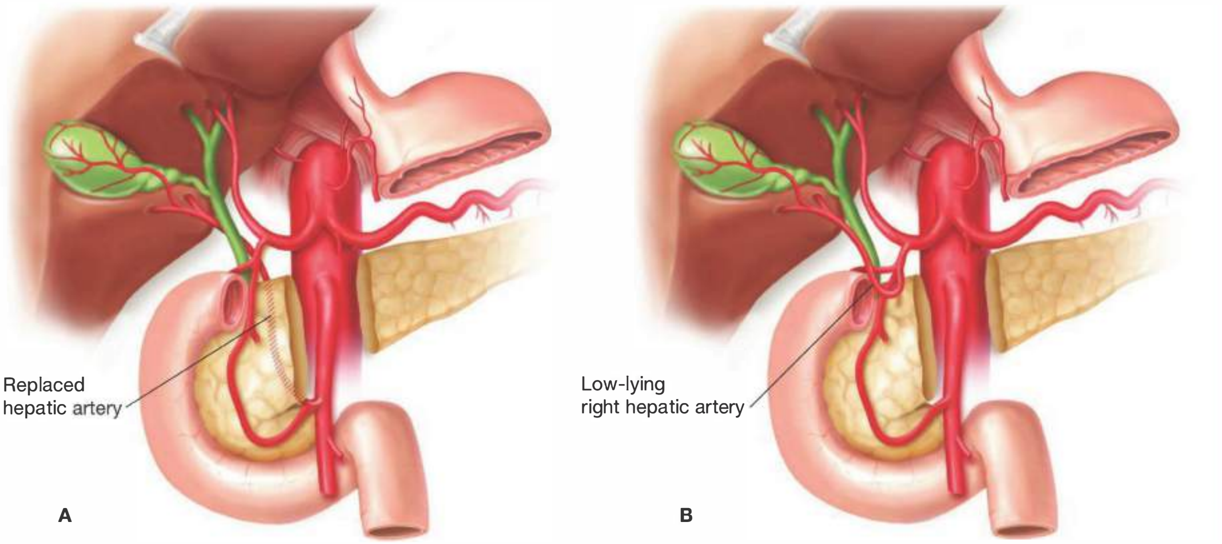

FIG 10 ● Replaced hepatic artery **(A)** and low-lying right hepatic artery **(B)**. Careful dissection of the bile duct should be performed to avoid injury to the accessory or replaced hepatic artery from the SMA travelling posterior to the common bile duct or the low-lying right hepatic artery travelling anterior to the bile duct.

DIVISION OF THE NECK OF THE PANCREAS

- Suture ligation of the longitudinal arteries coursing within the parenchyma along the superior and inferior border of the neck of the pancreas can help control bleeding from the cut surface during transection of the pancreas. We prefer to use ultrasonic shears to divide the pancreas to minimize bleeding (**FIG 11**).
- Retraction of the pancreas parenchyma using cotton tape to separate the PV/SMV helps prevent injury to

FIG 11 ● Division of pancreas using ultrasonic shears. Electrocautery can be used depending on the surgeon's preference. We prefer to use ultrasonic shears to divide the pancreas with minimal bleeding.

the PV. Meticulous control of bleeding from the cut pancreatic surface is necessary to prevent postoperative bleeding and failure of the pancreaticoenteric anastomosis. The pancreatic duct is identified (**FIG 12**). A frozen tissue section can be obtained from the margin of the pancreas.

- The SMV and PV are further dissected, identifying, controlling, and dividing the few venous tributaries arising from the head of the pancreas and uncinate process. The authors recommend the use of clips to control these vessels.
- The remaining pancreatic stump is further dissected to provide the 1 to 2 cm of mobility necessary to invaginate the pancreas into the jejunum for the pancreaticojejunostomy (**FIG 13**).

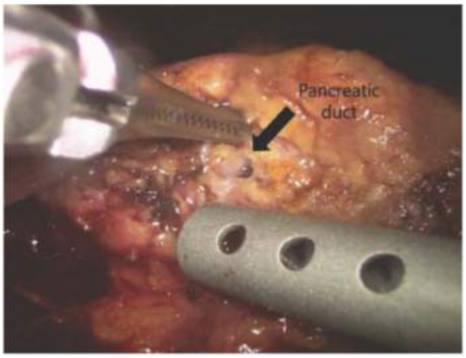

FIG 12 ● Identification of pancreatic duct.

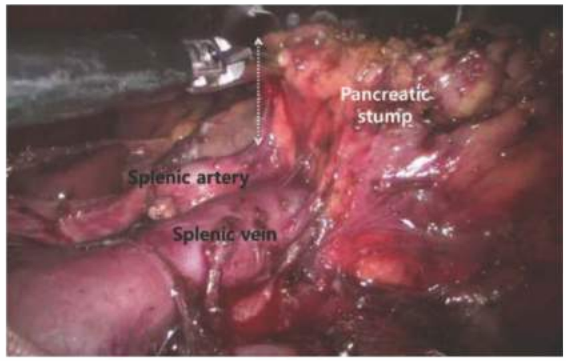

FIG 13 ● Mobilizing the pancreatic remnant. The remaining pancreatic stump is mobilized by 1 to 2 cm to facilitate invagination of the pancreas into the jejunum for the pancreaticojejunostomy.

TRANSECTION OF THE PROXIMAL JEJUNUM

- The jejunal mesentery, 10 to 15 cm distal to the ligament of Treitz, is divided between vascular arcades and the mesenteric vessels are ligated (**FIG 14**). The jejunum is transected with an endoscopic linear gastrointestinal stapler. This procedure can be performed to the right side of the base of the mesentery after pulling the jejunum through the retromesenteric space. Alternatively, we perform this procedure in its original position (performing the division of the jejunum and mesentery prior to pulling the jejunum into the right side).
- Although the Harmonic scalpel or bipolar electrocautery are useful for dividing the mesentery of the proximal jejunum, it is prudent to clip the mesenteric (remaining) side (**FIG 15**).
- The nutrient vessels of the jejunum and duodenum should be taken at the level of the bowel to minimize risk of injury to the cisterna chyle or mesenteric vessels.

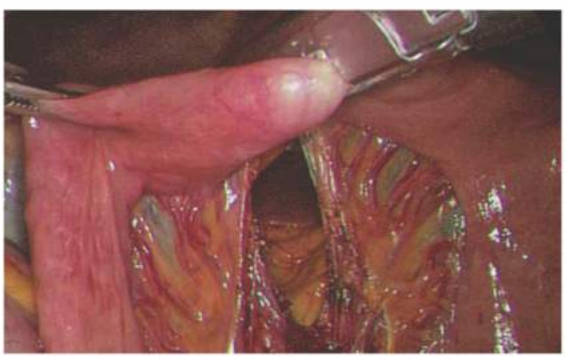

FIG 14 ● Transection of proximal jejunum. The jejunal mesentery 10 to 15 cm distal from the ligament of Treitz is divided along the mesenteric vascular arch and mesenteric vessels are ligated.

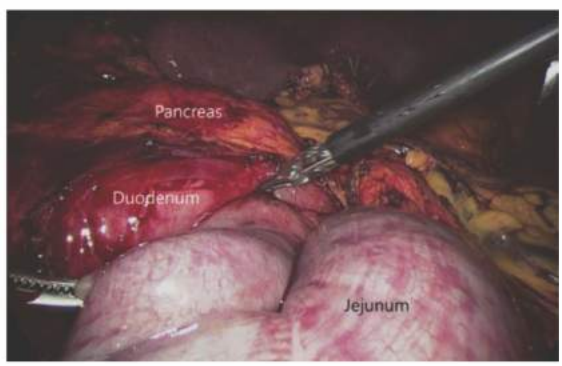

FIG 15 ● Retraction of the jejunum behind the mesenteric vessels without division of the mesenteric vessels can complicate the operation due to the resulting large volume of bowel in a confined space; this is a particularly relevant point for laparoscopic surgery.

DISSECTION OF THE UNCINATE PROCESS FROM THE SUPERIOR MESENTERIC ARTERY

- This step is the most technically difficult part of the procedure, and also, the most critical in terms of obtaining tumor-free margins. Elevation of the specimen reveals detailed features of the remaining attachments, including tributaries of the PV or SMV. The first jejunal vein and its tributaries to the uncinate process of the pancreas can also be identified with this lateral anterior traction of the specimen (**FIG 16**). Importantly, this maneuver rotates the mesentery facilitating visualization of the SMA; however, this change in the anatomic relationship puts the artery to the right of the PV and at risk for injury.
- To aid in the dissection and to control any unexpected bleeding from the PV or SMV, an umbilical cotton tape is applied to the PV and SMV, respectively, just above the splenic vein and the first jejunal vein (**FIG 17**). A hooked retractor is useful for traction of the mesenteric root to the left in order to dissect the plane between the uncinate process and the mesenteric veins. Traction with umbilical tape allows the neurolymphatic soft tissues around the SMA to be clearly visualized.
- Two possible methods can be used to dissect between the SMA and the uncinate process: downward (from the common bile duct side to the mesentery of the jejunum) or upward (from the mesentery of the jejunum to the common bile duct side) (**FIG 18**). We prefer an upward dissection because this exposes the venous branches more effectively than the downward approach.

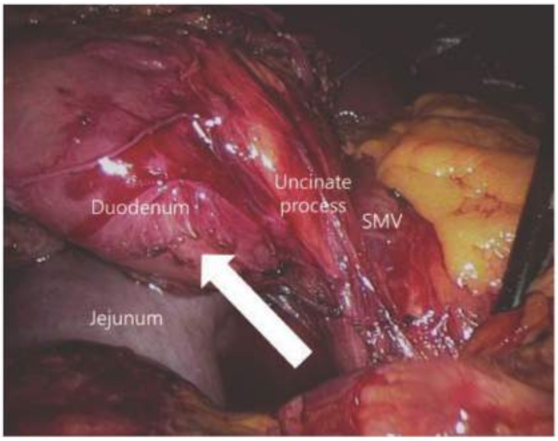

FIG 16 ● Lateral and anterior retraction of the specimen is useful to identify the first jejunal vein and its tributaries to the uncinate process of the pancreas.

FIG 17 ● The application of umbilical cotton tape to the PV and SMV is useful to aid in the dissection and control any unexpected bleeding from the PV or SMV.

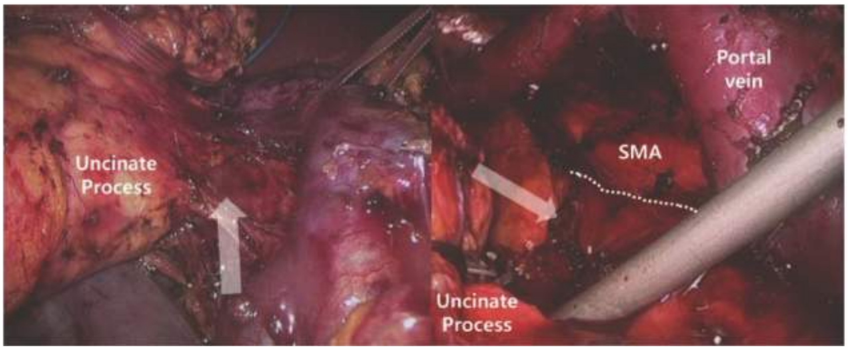

FIG 18 ● Two possible methods to dissect between the SMA and the uncinate process: upward dissection (from the mesentery of the jejunum to the common bile duct side) or downward (from the common bile duct side to the mesentery of the jejunum). We prefer an upward dissection *(arrow)* because this exposes the venous branches more effectively than the downward dissection *(arrow)*.

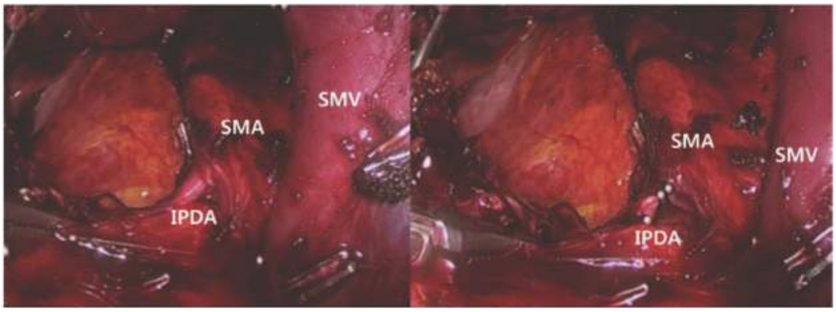

FIG 19 ● Identification of inferior pancreaticoduodenal arteries (IPDA). After dividing the tributaries from the first jejunal branch, the soft tissue near the SMA should be dissected to identify one or two IPDA.

- With upward traction of the SMV using umbilical tape and caudal traction of the specimen, posterior venous tributaries draining from the uncinate process to the first jejunal vein (two or three veins) can be identified and divided with clips and a Harmonic scalpel. After dividing the tributaries from the first jejunal branch, the soft tissue near the SMA should be dissected to identify one or two inferior pancreaticoduodenal arteries (**FIG 19**). A Harmonic scalpel may be used to divide these arteries; however, we prefer to separately clip the remaining pancreaticoduodenal arteries. Occasionally, small branches that cannot be identified may be easily divided using a Harmonic scalpel.
- The remaining dissection of the soft tissue between the SMA and the uncinate should be performed according to the oncologic status of the disease. For diseases other than pancreatic ductal adenocarcinoma, the dissection can be performed near the uncinate process without risk of injury to the SMA. However, for pancreatic ductal adenocarcinoma, a clear dissection of the neurolymphatic soft tissues of the right side of the SMA is needed to obtain a margin-negative specimen.
- Most soft tissues including small mesenteric vessels can be safely sealed with a Harmonic scalpel to transect the pancreas head from the SMA. However, the remaining large superior pancreaticoduodenal vein should be tied or clipped securely.
- The specimen is placed in a specimen bag and retrieved at the end of procedure, either through the 2- to 3-cm extension of the umbilical port or a separate incision (**FIG 20**). The specimen bag containing the gallbladder is removed at the same time.

FIG 20 ● Periumbilical and Pfannenstiel incisions. The specimen is placed in a specimen bag and retrieved at the end of procedure, either through the 2- to 3-cm extension of the umbilical port or a separate Pfannenstiel incision.

PEARLS AND PITFALLS

Indications	■ Surgeons wishing to perform LPPPD should have sufficient experience in both OPD and advanced laparoscopy and laparoscopic suturing techniques. ■ The indications for LPD should be limited initially to patients with low BMI, benign or low-grade malignant disease, or confined malignant disease without vascular involvement.
Preoperative planning	■ Palpation cannot be used to identify aberrant arterial anatomy. Review preoperative imaging specifically to this regard.
Technique	■ Early division of the duodenum facilitates further dissection. ■ Mobilization of the right colon is crucial to clearly expose the operative field. ■ Staple and ligate the GDA—Clips will slip off the specimen side during subsequent manipulation of the specimen. Staple lines are at risk for pseudoaneurysm. Ligate above the staple line. ■ A bulldog clamp on the proximal bile duct prevents contamination and provides hemostasis. ■ Ligation of longitudinal arteries and energy division of the pancreatic neck are essential steps to a hemostatic field. ■ Anterior and lateral retraction of the specimen is essential for visualization of the attachments of the uncinate process to the SMV and SMA. ■ Identification and careful division of the first jejunal vein and its tributaries to the uncinate process of the pancreas is critical to prevent unexpected bleeding. ■ Applying umbilical cotton tape around the PV and SMV just above the splenic vein and first jejunal vein can also help control any unexpected bleeding.

Postoperative care	■ Hemorrhage is managed based on timing and clinical observations.
	  ■ Within 24 hours, return to the operating room.
	  ■ Within the first 5 to 7 postoperative days, consider endoscopy to assess for an anastomotic source.
	  ■ Over 5 to 7 days, CT arteriography and catheter-based control of pseudoaneurysm

POSTOPERATIVE CARE

- In the majority of cases, patients should be transferred to an intensive care unit for monitoring. However, patients may be transferred to a general ward in highly specialized centers.
- The patient should wear antithrombotic stockings and receive prophylactic low-molecular-weight heparin until discharge.
- Intravenous patient-controlled analgesia systems are used to control pain.

OUTCOMES

- When compared to open pancreaticoduodenectomy (OPD), LPD potentially offers the recognized advantages of laparoscopic surgery, including faster postoperative recovery, improved cosmesis, and fewer wound complications.
- Mortality rates of 1% to 8% for LPD have been reported. Our series of 100 cases showed a mortality rate of less than 1%. The postoperative morbidity rate was approximately 30%. The operative time is usually longer than that of conventional pyrolus preserving pancreatoduodenectomy (PPPD). The time between surgery and hospital discharge is the same or less than that of an open procedure. Oncologic outcomes for advanced cancer, such as the number of harvested lymph nodes and the rate of negative margin status, also show similar results to those of open procedures.
- The perioperative outcomes of LPPPD in large series including ours are shown in the Table 2.

COMPLICATIONS

- Morbidity rates of between 20% and 40% have been reported. The most common and fatal complications are pancreatic leakage and hemorrhage. The majority of intraabdominal infections are associated with pancreatic leaks and fistulas.
- Pancreatic fistula
- Hemorrhage

Chapter 35

Pancreaticoduodenectomy: Robotic-Assisted Resection

Brian A. Boone Herbert J. Zeh

DEFINITION

- Pancreaticoduodenectomy entails resection of the head of the pancreas and duodenum, which requires mobilization and transection of the pancreas, stomach, common bile duct, and jejunum. This chapter will focus on the resection and extraction of the specimen using a robotic-assisted technique, with subsequent chapters devoted to reconstruction.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The history and physical exam should focus on identifying evidence of metastatic disease, which would preclude resectability.
- The robotic technique is routinely used for both benign and malignant disease.
- Patients are not excluded from the robotic approach based on age, body mass index (BMI), or comorbidities.
- Relative contraindications to robotic surgery are the anticipation of vascular resection and reconstruction and extensive prior abdominal surgery.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- A primary goal of imaging modalities for pancreatic cancer is to determine resectability by excluding metastatic disease and involvement of the mesenteric vessels.
- Based on consensus guidelines,[1] resectable tumors are those that have no distant metastasis; have no radiographic evidence of abutment or distortion of the superior mesenteric vein (SMV) and portal vein (PV); and have clear fat planes surrounding the celiac axis, hepatic artery, and superior mesenteric artery (SMA) (**FIG 1**). Patients with tumor abutment of the SMV/PV, gastroduodenal artery (GDA) abutment or encasement up to the hepatic artery, or abutment of the SMA less than 180 degrees are considered to be borderline resectable and may benefit from neoadjuvant treatment.[2]
- Computed tomography (CT) scan—A triphasic CT scan of the chest, abdomen, and pelvis with fine cuts through the pancreas is the mainstay of imaging for pancreatic pathology. CT allows for characterization of the pancreatic mass, identifies involvement of the mesenteric vessels, and evaluates for metastatic disease, particularly in the liver or lungs.
- Endoscopic ultrasound (EUS)—This diagnostic modality, although not routinely performed at all institutions, should be considered standard of care in most cases. EUS allows for visualization and biopsy of the mass, particularly if a tissue diagnosis is required for treatment with neoadjuvant or adjuvant chemotherapy. Mesenteric vessel involvement can be evaluated. Additionally, suspicious lymph nodes can be identified and biopsied, which helps to accurately stage the patient.
- Staging laparoscopy—The role of staging laparoscopy in the management of pancreatic cancer remains controversial and is not routinely performed at most institutions.[3] For patients with large tumors, equivocal CT findings, or highly elevated carbohydrate antigen (CA 19-9), staging laparoscopy can be considered.

B

FIG 1 ● A CT scan demonstrating the tumor relationship to the surrounding vasculature is required to determine resectability during the preoperative planning phase. **A.** CT scan of the abdomen with arterial contrast demonstrating clear fat planes around SMA in resectable pancreatic cancer *(white arrow)*. **B.** Venous phase scan demonstrating clear fat planes around SMV *(white arrow)*.

SURGICAL MANAGEMENT

Preoperative Planning

- Determining resectability based on high-quality diagnostic and imaging modalities is the key step in preoperative planning, particularly because the use of the robotic technique precludes the ability of the surgeon to palpate the tumor and readily identify vascular involvement intraoperatively.
- Four units of crossmatched packed red blood cells should be prepared and available.
- Preoperative antibiotics should be administered.

Positioning

- The general setup for the robotic operating room is depicted in **FIG 2**.
- The patient is positioned supine on a split-leg table, which allows space for the assistant surgeon to have access to the abdomen. The right arm is tucked with protective foam padding.
- Prior to the start of the procedure, central and arterial lines are inserted in addition to a nasogastric tube and Foley catheter. A convective warming blanket is used on the upper body.

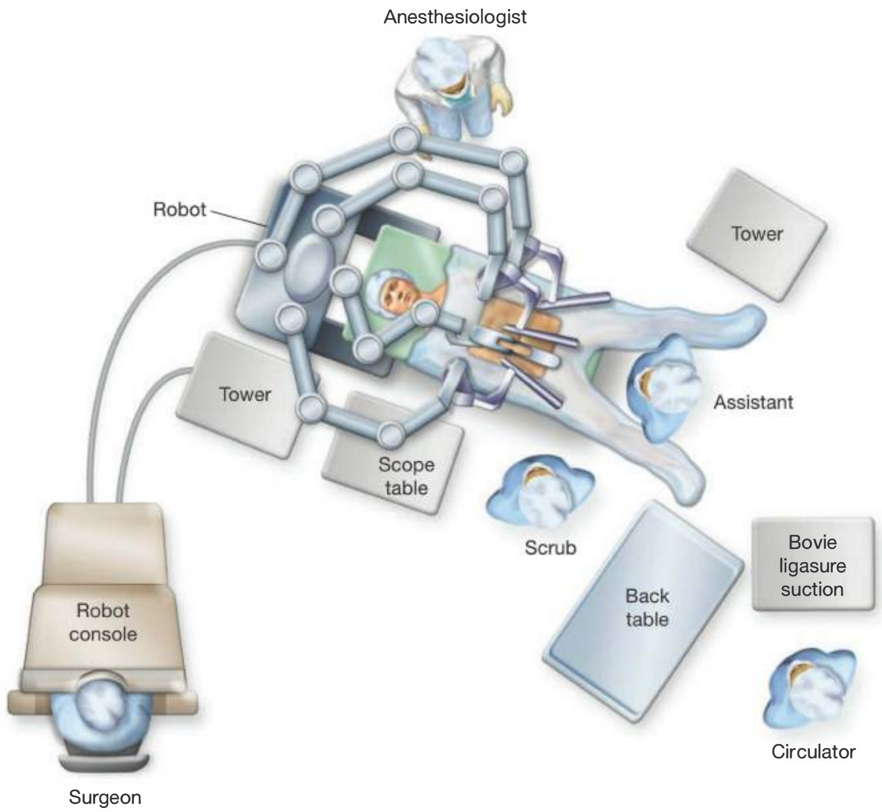

FIG 2 ● Setup of operating room for robotic pancreaticoduodenectomy. The robot is placed above the patient's head. A split-leg table is used to allow the assistant access to the abdomen and robotic arms. The robotic console is placed to the side of the room to allow ample space for the circulator and scrub tech.

PORT PLACEMENT

- Seven ports are used for robotic assistance during pancreaticoduodenectomy. Ports include a 10-mm camera port, three robotic arm ports, two assistant ports, and a 5-mm liver retractor port. Our port location and configuration is displayed in **FIG 3**.
- Access to the abdomen is obtained using a 5-mm optical separator port inserted to the left of the umbilicus in the midclavicular line. This port is eventually upsized to 8 mm and serves as a robotic arm.
- A 4- to 5-cm incision to extract the specimen is placed in the left midclavicular line.

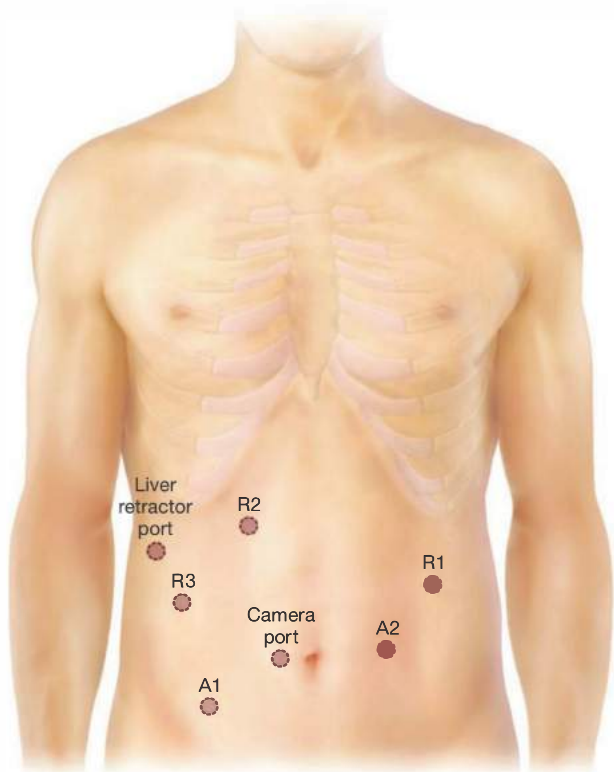

FIG 3 ● Seven ports are used for robotic assistance during pancreaticoduodenectomy, including a 10-mm camera port, three robotic ports, two assistant ports, and a 5-mm liver retractor port.

MOBILIZATION OF THE RIGHT COLON AND DUODENUM

- Standard laparoscopic instruments including an atraumatic grasper and bipolar electrocautery are used to fully mobilize the right colon.
- The duodenum is kocherized with mobilization of the third and fourth portion until the jejunum reaches into the right upper quadrant and the SMV is exposed at the root of the small bowel mesentery (**FIG 4**).
- The jejunum is transected 10 cm distal to the ligament of Treitz using a linear stapler. The proximal jejunum is passed back under the superior mesenteric vessels. The distal jejunum is then marked with a suture at aprproximately 50 cm and secured to the stomach in an antecolic fashion, ensuring it is easily identified for reconstruction of the gastrojejunostomy (**FIG 5**).

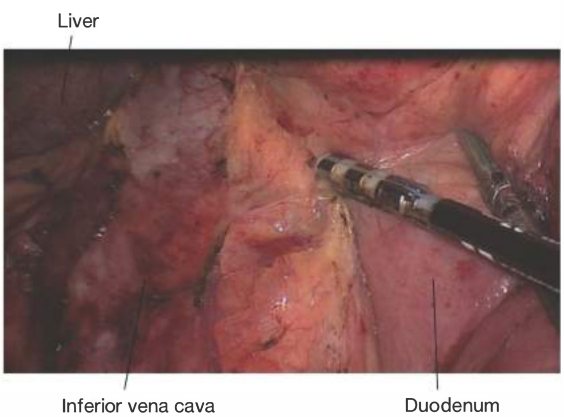

FIG 4 ● Complete kocherization of the duodenum using laparoscopic instruments brings the duodenum into the left upper quadrant. The inferior vena cava is visualized during mobilization of the duodenum.

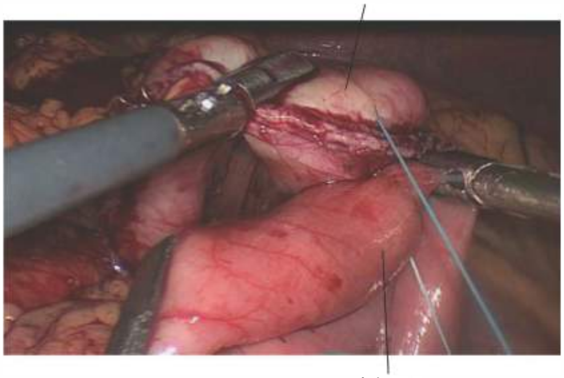

FIG 5 ● Suturing the divided jejunum to the stomach facilitates finding it for the gastrojejunostomy.

MOBILIZATION AND DIVISION OF THE STOMACH

- Continuing laparoscopically, the lesser sac is entered by division of the gastrocolic omentum. The posterior stomach is freed from the anterior pancreas.
- The right gastric and right gastroepiploic arteries are ligated close to the stomach with a bipolar electrocautery device and clips (**FIG 6**).
- The stomach is divided with a linear stapler after removal of the nasogastric tube.

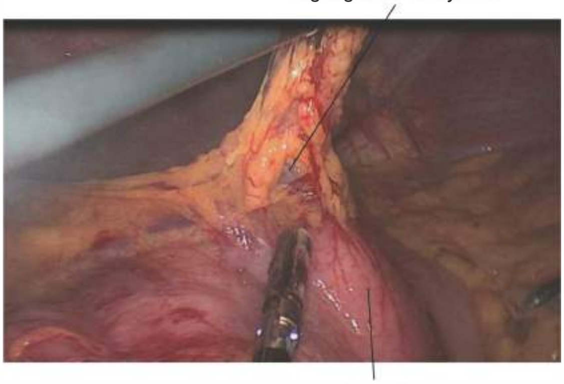

FIG 6 ● The right gastric artery is identified and ligated close to the stomach using bipolar electrocautery.

DISSECTION OF THE PORTA HEPATIS

- At this point in the operation, the robot is docked directly over the head of the table with the patient in steep reverse Trendelenburg position. The operating surgeon moves to the robotics console and the assisting surgeon stands between the legs to exchange instruments, pass needles, and assist with suction and stapling.
- Dissection is continued along the superior border of the pancreas and into the porta hepatis using the robotic hook cautery. The common hepatic artery (CHA) lymph node is identified and removed (**FIG 7**). This allows exposure of the CHA. The CHA is exposed and followed until the right gastric and GDAs are identified (**FIG 8**). A vessel loop is passed around the GDA and it is occluded while flow is checked by color flow and 3-D Doppler

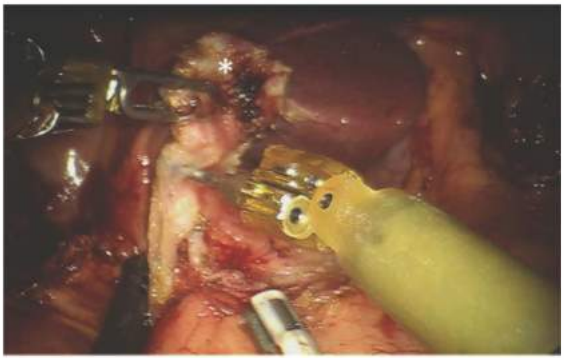

FIG 7 ● The CHA lymph node is identified *(white asterisk)* and removed using hook cautery. This allows exposure of the CHA.

in the CHA. Once flow is confirmed, the GDA is ligated with a vascular load stapler and reinforced with a 10-mm titanium clip.

- Portal lymph nodes are dissected and removed. The PV and common bile duct are then exposed (**FIG 9**).
- Cholecystectomy may be performed in an antegrade fashion at this point or reserved for after the main specimen is removed.
- The common bile duct is dissected and divided with a vascular load of the endostapler.

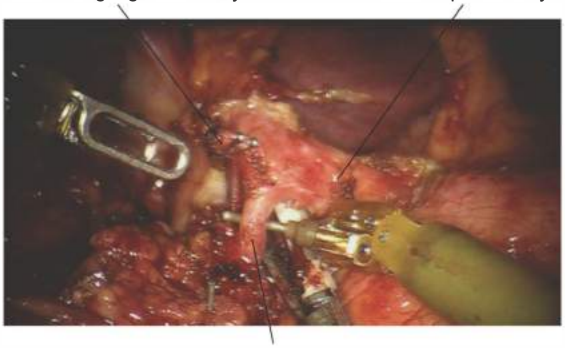

FIG 8 ● The GDA is identified. Flow in the CHA is confirmed with a vessel loop constricting the GDA. The GDA is then ligated with an endostapler with a vascular load.

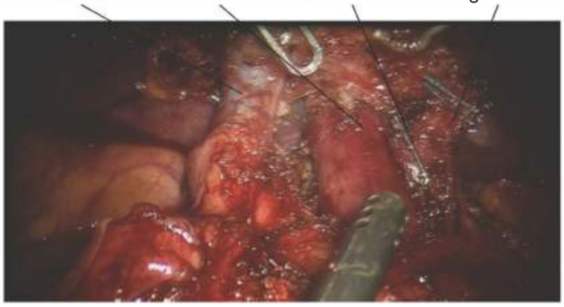

FIG 9 ● The portal dissection continues until the common bile duct and PV are identified and exposed.

MOBILIZATION AND DIVISION OF THE PANCREAS

- The right gastroepiploic vein is followed to its origin to identify the SMV. The SMV is dissected off the inferior border of the pancreas and a tunnel is created between the pancreas and PV. The robotic camera angles allow for excellent visualization of the tunnel (**FIG 10**).
- Once a tunnel is formed, the neck of the pancreas is divided with electrocautery (**FIG 11**). Care is taken to identify the pancreatic duct and leave small extension on it.
- The pancreas is then mobilized, first at the lateral border of the SMV/PV. The first jejunal branch of the SMV is identified as it crosses over the SMA inferiorly. The first jejunal branch of the SMV is preserved by taking several small recurrent branches to the uncinate process over clips or silk ties.
- The SMV/PV is brought medially, exposing the SMA, which is then dissected along the plane of Leriche (**FIG 12**).
- The superior and inferior pancreatico-duodenal artery (PDA) are individually identified and secured with clips, silk ligatures, or LigaSure, depending on size and location (**FIG 13**).
- The superior uncinate branch of the PV is identified and ligated with the vascular load, clips, or silk ligature.
- The specimen is removed in an EndoCatch bag through a 4- to 5-cm extraction incision in the left midclavicular line. Following removal of the specimen, the resection field is prepared for reconstruction (**FIG 14**).

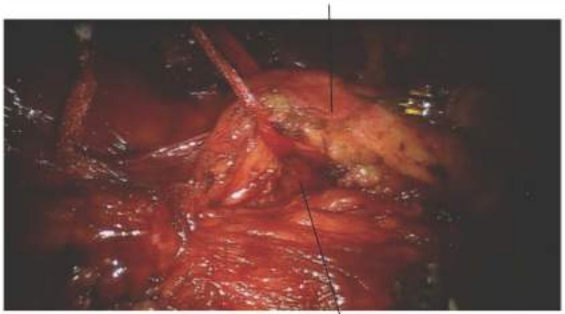

FIG 10 ● Dissection at the inferior border of the pancreas allows the tunnel underneath the pancreas and over top of the mesenteric vessels.

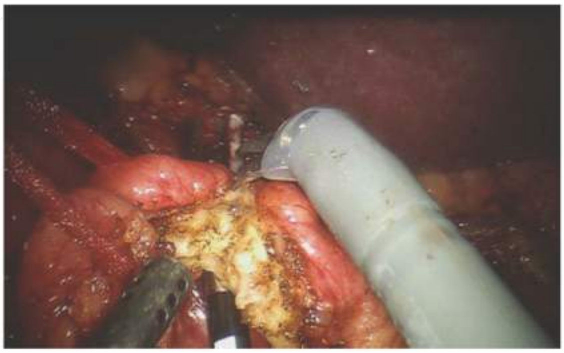

FIG 11 ● The pancreas is divided using cauterized scissors. The enhanced camera angles on the robotic system allow for excellent visualization during the tunnel and subsequent division of the pancreas.

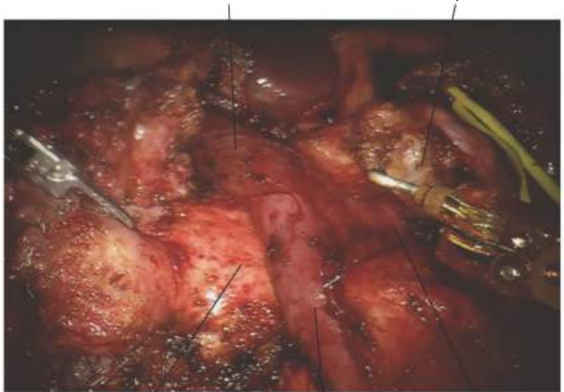

FIG 12 ● The uncinate process is dissected using a combination of hook cautery and fine scissors.

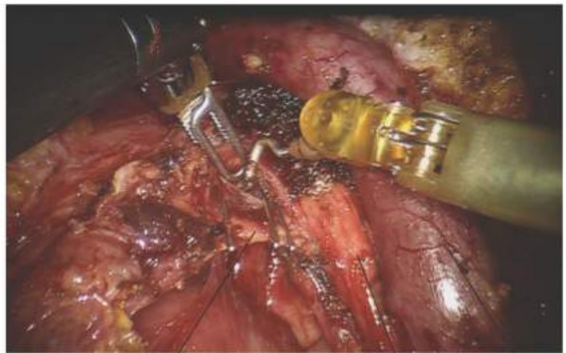

FIG 13 ● Retraction of the SMV medially exposes the SMA to allow for dissection along the plane of Leriche. The inferior pancreaticoduodenal artery is identified and ligated.

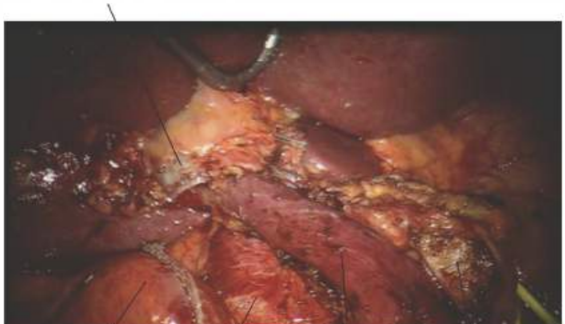

FIG 14 ● The resection bed following removal of the specimen. The field is now prepared for reconstruction.

PEARLS AND PITFALLS

Preoperative planning—determination of resectability	■ Invasion of the tumor into the mesenteric vessels cannot be fully assessed by palpation until after the pancreatic neck is divided and the surgeon is committed to resection; therefore, a high-quality preoperative CT and planning are required to determine resectability.
Port placement	■ If the ports are placed too close together, the robot arms will hit each other. The camera port needs to be superior and lateral to the umbilicus to allow for adequate portal and uncinate dissection exposure.
Securing the divided jejunum to the stomach	■ The suturing of the jejunum to the stomach prior to docking the robot facilitates finding it for reconstruction.
Dissection of the porta hepatis	■ Assess for aberrant vascular anatomy such as a right hepatic artery from the SMA, which occurs in up to 20% of patients.
Hanging technique for uncinate	■ The third robotic arm must rotate the specimen laterally and superiorly to allow for adequate exposure of the SMA.

POSTOPERATIVE CARE

- Following completion of the operation, the patient is extubated and transferred to either the intensive care unit or a monitored floor bed based on individual patient and operative factors. A nasogastric tube is left in the place.
- A drain is left in the pancreatic bed and a drain amylase is checked after postoperative day 3. Drains with normal amylase are removed prior to discharge.

OUTCOMES

- Although no randomized or large case-control series have been published comparing robotic and open pancreaticoduodenectomy, the preliminary experience of several groups suggests that outcomes of robotic pancreaticoduodenectomy are comparable to open surgery.[4–7] Several series have consistently demonstrated a reduction in estimated blood loss with the robotic approach.
- The largest series of robotic pancreaticoduodenectomy from a single institution was recently reported,[8] with outcomes for 132 pancreaticoduodenectomies listed below:
  - Thirty-day and 90-day perioperative mortality was 1.5% and 3.8%, respectively.
  - Clinically significant morbidity (grade 3 or 4 Clavien Dindo) affected 21% of patients.
  - Median operative time was lengthy at 527 minutes; however, significant improvement was noted over the experience.
  - The median estimated blood loss was around 300 mL for the series.
  - Conversion to open was required in 8% of cases.

COMPLICATIONS

- The types of complications following robotic pancreaticoduodenectomy are identical to open. The incidence and severity appears to be similar to open surgery in series detailing preliminary experiences with robotic pancreaticoduodenectomy.[4–8]
  - Pancreatic leak
  - Pseudoaneurysm
  - Delayed gastric emptying
  - Infection (wound, intraabdominal abscess)
  - Biliary leak
  - Gastric leak
  - Gastric outlet obstruction
  - Bowel obstruction

Chapter **36**

Pancreaticoduodenectomy: Pancreaticojejunostomy

Charles M. Vollmer

DEFINITION

- Pancreaticojejunostomy is defined as the anastomosis of a remnant pancreas to the jejunum. This is a necessary step in restoring intestinal tract continuity following pancreaticoduodenectomy (PD).
- Although there are numerous options on how to restore continuity of the pancreas to the enteric tract following PD, central pancreatectomy, or distal pancreatectomy (rarely), pancreaticojejunostomy is the most frequently applied technique worldwide. Furthermore, there are a number of technical variations available for this procedure including "dunking" and "invagination" approaches. This chapter depicts construction of the widely prevalent double-layered, duct-to-mucosa, end-to-side pancreaticojejunostomy.
- This chapter's importance lies in the following: Although the first half of PD hinges on the optimal resection of diseased tissue, which determines long-term (usually oncologic) outcomes, the reconstruction phase sets the tone for the immediate postoperative recovery period through the prevention of complications. Chief among these is pancreatic anastomotic failure, which occurs roughly 15% of the time.

PATIENT HISTORY AND PHYSICAL FINDINGS

- An improved, international consensus definition of this complication has been enthusiastically adopted by most pancreatic surgeons (International Study Group on Pancreatic Fistula [ISGPF]).[1] Subsequently, patient-specific risk factors for clinically relevant leaks have been identified as (1) soft gland texture, (2) small pancreatic duct diameter, (3) pathology exclusive of pancreatic cancer or pancreatitis, and (4) elevated blood loss.[2] These variables are best elucidated at the time of the operation, but preoperative prediction of these important variables is possible, should factor into decision making, and understanding them can influence intra- and postoperative management techniques.[3]

TECHNIQUES

SURGICAL MANAGEMENT

Pancreatic Transection

- A successful anastomosis begins well before the reconstruction phase of the procedure. Limiting blood loss and careful handling of the pancreas during the resection stage should be regular goals.
- Once an appropriate site of transection over the portal vein (PV) canal is chosen, it is helpful to place hemostatic transfixion sutures on each side of the proposed plane. There are reproducible horizontal arterial arcades a few millimeters within the superior and inferior borders of the pancreas. A 2-0 silk, figure-of-eight suture is deeply placed into each border and on each side of the transection plane (total of four). Care must be taken to not place these too deeply in to the parenchyma on the left (stay) side, such that the pancreatic duct is inadvertently occluded. This is not a concern on the right side where the pancreatic head specimen will ultimately be removed. Once tied down, these sutures are not cut but rather maintained long on a snap to aid in leverage of the distal gland during the reconstruction phase (**FIG 1**).
- Transection can occur via a number of techniques including scalpel or staplers. However, Bovie cautery is preferred for its ability to limit blood loss. A needle-tipped cautery provides good precision with focused coagulation. The cut mode is used to transect the capsule and most of the parenchyma, whereas focal use of the coagulation mode is valuable to control distinct blood vessels when encountered. This approach proceeds through the majority of the gland until the area of the duct is anticipated. Sharp transection of this area is preferred to prevent thermal damage to the duct.
- Cautery is then focally applied to dry up any oozing from the cut edge of the pancreas. There is quite often a reproducible arterial vessel on the posterior edge of the gland just beneath where the duct lies.
- The distal pancreatic remnant should be elevated off of the splenic vein beneath it for a distance of at least 2 to

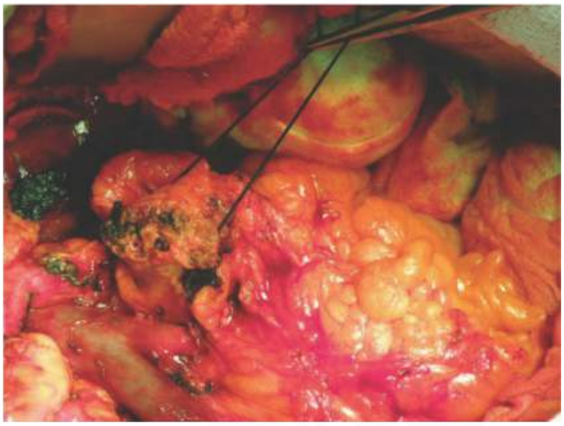

FIG 1 ● En face picture of the transection plane of the pancreatic neck. Two sutures are placed into the parenchyma to control the superior and inferior vascular arcades. These also provide leverage in "lifting" the pancreatic remnant out of the retroperitoneum for the anastomotic construction.

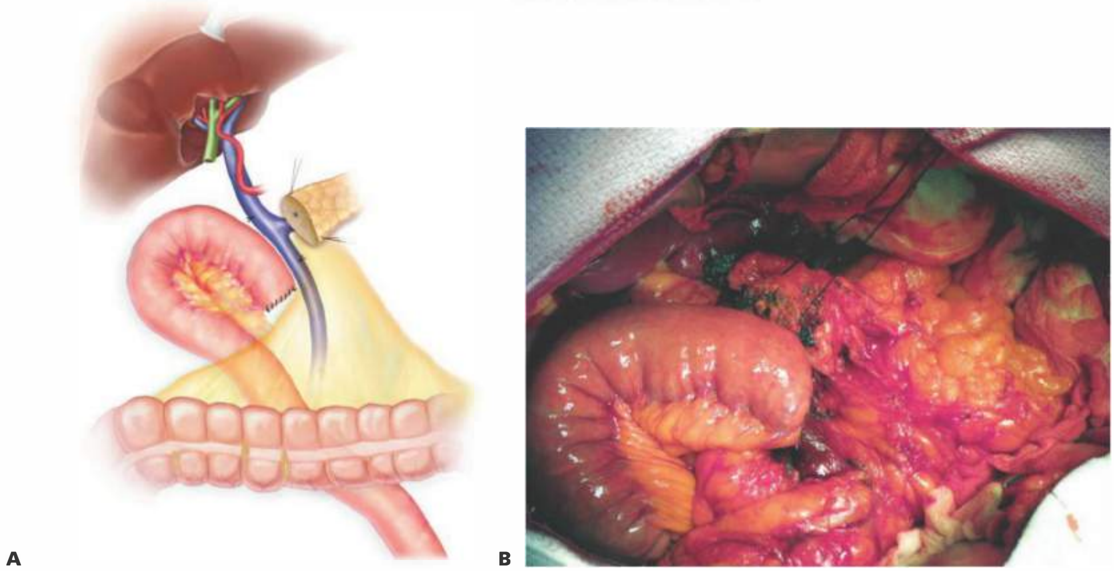

FIG 2 ● **A.** The pancreaticobiliary limb is positioned in the RUQ by bringing it behind the mesenteric stalk through the ligament of Treitz canal. **B.** In effect, this becomes a neoduodenum, as it lays comfortably in apposition with the pancreas and bile duct. Undue tension on this limb can be avoided by resecting at least 20 cm of proximal jejunum initially.

3 cm. This, along with traction on the transfixion sutures, will expose the back side of the gland so that the posterior row of the outer anastomotic layer can eventually be created. This is generally an avascular plane until the point where the splenic vein becomes incorporated by pancreatic parenchyma.

The Setup

- Once hemostasis of the pancreatic transection planes is achieved, the pancreaticobiliary drainage limb is introduced to the right upper quadrant (RUQ). Although many achieve this by placing it through the transverse mesentery in a retrocolic position, the author prefers to lay the limb in a completely retromesenteric fashion. The limb is introduced from the infracolic compartment (left side of midline) through the previous ligament of Treitz canal to the RUQ. Once placed in apposition with the remnant pancreas and the transected bile duct, this, in essence, becomes a "neoduodenum" (**FIG 2**). However, this may also be achieved in the more traditional fashion mentioned earlier, particularly in the cases where the patient has significant central obesity.
- Remember the hallmark surgical dictum that the success of an anastomosis is predicated on the following factors: (1) healthy tissue with a good blood supply, (2) lack of tension, and (3) freedom of distal obstruction. You can assure that the pancreaticobiliary drainage limb has a good pulse by palpating the vascular arcade within the mesentery after it has been placed in the desired position. Meticulous technique during the jejunal resection should assure that there is not a mesenteric hematoma, which might compromise the health of the limb. Do not shortchange the amount of proximal jejunum, which is originally resected, as this will shorten the mesenteric "leash" and therefore place tension on the limb as it reaches to the RUQ.
- Hemostasis of the transection plane of the neck of the pancreas is achieved by judicious use of the needle-tipped Bovie cautery on a low power (15 to 20). Energy near the pancreatic duct is avoided.
- The pancreatic duct diameter is examined and measured with a flexible ruler. An absorptive "Weck-Cel" arrowhead spear is useful in keeping the duct dry both now, and later, when precision is needed during suture placement in the duct (**FIG 3**).
- The duct can be actively dilated by placing the tips of a fine instrument (Gemini or pediatric right angle) within the duct and gently spreading and holding them open, being careful to not disrupt the duct tissue. Finally, the patency of the course of the pancreatic duct should be assured by advancing a 5- or 8-Fr pediatric feeding tube within the duct in a retrograde manner. These are flexible and safer than a rigid probe, which might be advanced inadvertently through the duct wall and even the parenchyma.
- The operative field is then prepared by covering the retraction devices with an arrangement of white towels which, in effect, excludes the retractor from the field and provides a neutral background to better visualize fine, colored monofilament sutures (**FIG 4**).

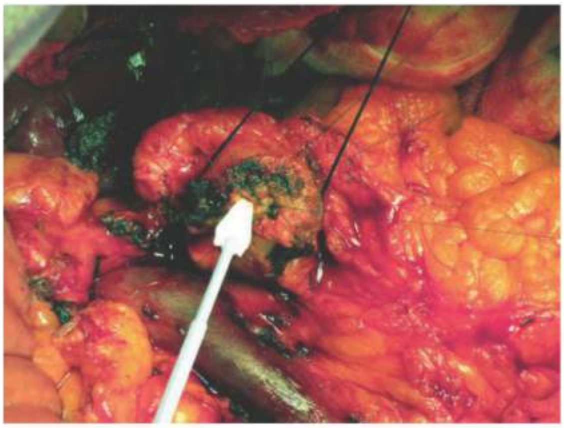

FIG 3 ● An arrowhead Weck-Cel facilitates precise visualization of the pancreatic duct.

FIG 4 ● Placement of four white surgical towels around the periphery of the incision enhances visualization of fine suture and prevents it from tangling on the retractors.

TECHNICAL CONSIDERATIONS

- The inner (duct-to-mucosa) anastomosis is constructed with monofilament absorbable suture. A 6-0 caliber is favored for normal to small ducts, but a 5-0 caliber can be used on larger, dilated ducts (≥8 mm). In select circumstances in *extremely* small diameter ducts (1 to 2 mm), a 7-0 caliber may be necessary. Remember that smaller grade suture has smaller needles, and thus creates smaller puncture holes. Double-armed sutures provide the most flexibility for needle placement, as some sutures are best applied from in to out, whereas others are optimally placed from out to in. This should be determined on a suture-for-suture basis, depending on how the arc of the needle is applied the most effortlessly through the duct.
- Due to the precision required for this step, a Castro Viejo needle driver is recommended rather than a bulky, longer driver controlled in the palm. Finer sized ducts (<3 mm) may benefit from the use of Loupe glasses for magnification.
- The author routinely *avoids* placing a pancreatico-enteric stent across the anastomosis, in light of its inefficiency in preventing pancreatic fistula, particularly in high-risk patients.[4] However, to increase precision of the needle placement in precarious ducts, some surgeons find value in creating the anastomosis with a small pediatric feeding tube temporarily in place during the anastomotic construction.

THE INNER LAYER—FRONT ROW

- The objective of this step is to "open" the duct orifice and further elevate the face of the transection plane into the field. The appearance of the transected duct can be compared to the face of a clock (**FIG 5**).
- Start by placing the 12 o'clock suture. These needles are curved considerably, and thus, the hand motion should allow for perpendicular placement of the needle tip into the parenchyma about 2 mm behind the duct. A curving motion will deliver it about a millimeter into the duct lumen, where it should be retrieved using a smooth "roll out" motion rather than a "tugging" technique.
- The two limbs of the suture are gathered, and the needle from the parenchymal side is removed while the needle attached to the limb emanating from the duct is maintained. A *straight snap* is used to identify that this is an ordinal point (3, 6, 9, and 12 o'clock positions; **FIG 5**) and is placed off the field in a manner that elevates the pancreas out of the incision slightly.

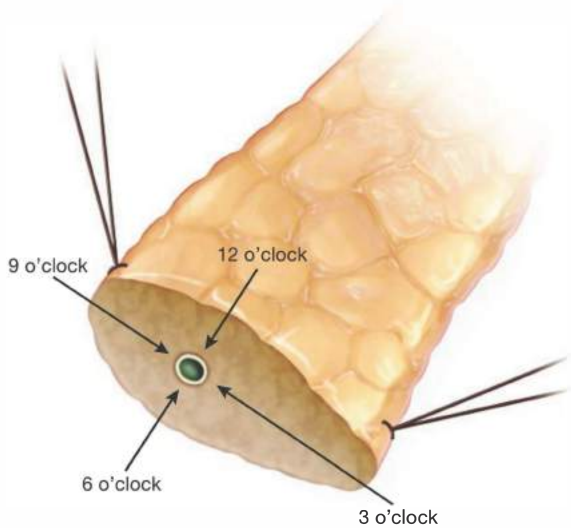

FIG 5 ● Clockface orientation of the pancreatic duct at the transection plane.

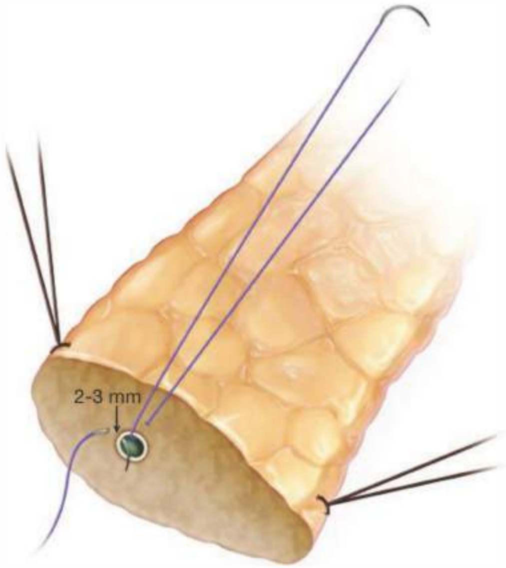
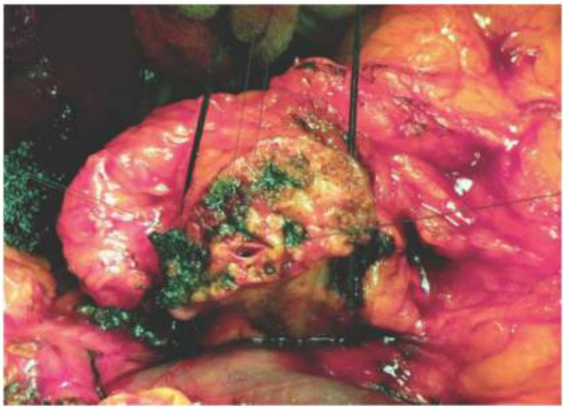


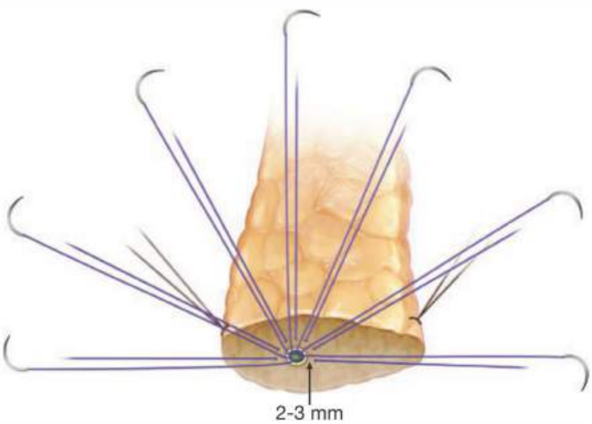
A



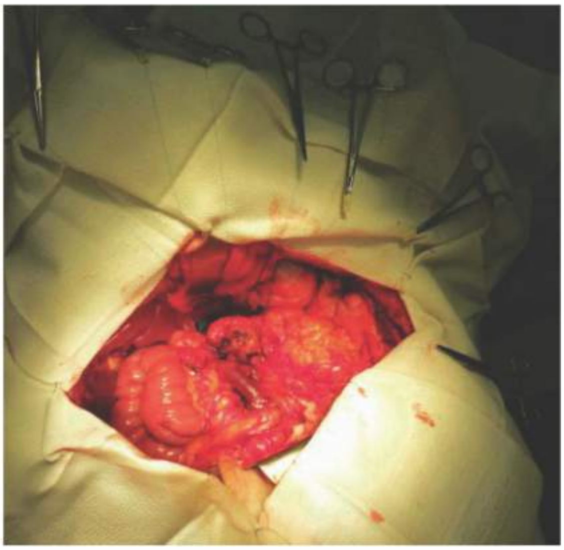
B

FIG 6 ● **A.** Placement of the 9 o'clock stitch from in to out on the pancreatic duct, incorporating a few millimeters of parenchyma around the duct. **B.** Placement of these initial stitches in the front row provides better exposure for subsequent stitch placement.

- The next moves consist of placing the 9 o'clock and 3 o'clock (horizontal plane) sutures which, when under tension, will fully "open up" the lumen of the duct (**FIG 6**). These are also gathered with straight snaps.
- Next, the two limbs can be completed from the horizon to the zenith (3 o'clock to 12 o'clock positions and 9 o'clock to 12 o'clock positions, respectively). A 3-mm duct will usually accommodate two evenly placed sutures in each of these limbs, for a total of seven sutures placed during this sequence (**FIG 7A**). However, there is room for flexibility to add more sutures as necessary (three to four per quadrant) for larger diameter ducts. To keep a semblance of order, these intermediate limb sutures should be gathered with *rubber shods* (**FIG 7B**).



A



B

FIG 7 ● **A.** A 3-mm duct will accommodate seven double-armed sutures on the anterior row. Needles should be maintained on the limbs that exit the duct and cut off on the sides that enter the duct. **B.** To maintain consistency, sutures should be carefully laid out in an array across the external field. Straight snaps are used to gather the corner sutures, whereas rubber shods delineate other positions around the duct circumference.

PREPARATION OF THE ENTEROTOMY

- An appropriate-sized enterotomy is created on the antimesenteric side of the pancreaticobiliary drainage limb, about 5-cm upstream from the oversewn staple line. Care should be taken to match the diameter of this to correspond to the size of the pancreatic duct lumen. Do not make the enterotomy too big; in fact, undersize it if anything, as the opening tends to expand as you are working on it.
- A needle-tipped Bovie cautery works nicely here (**FIG 8**). Use the "cut" mode to precisely open the serosal level. Then, create a pinpoint opening of the mucosa in an atraumatic fashion. Avoid manipulating this fragile tissue with unnecessary instrumentation to minimize bleeding, hematomas, and edema.
- To optimize orientation and control of the mucosal outpouching, place four 6-0 sutures at the ordinal positions (3, 6, 9, and 12 o'clock) (**FIG 9A**). In doing so, the clock faces of the duct and the enterotomy should now mirror themselves (**FIG 9B**). These sutures should be very small bites, which tack the mucosa to the serosa in the four corners (**FIG 9B**, *inset*). Again, the precision of a Castro Viejo instrument is preferred to minimize tissue trauma.

FIG 8 ● The enterotomy is created with excellent precision using a needle-tipped Bovie cautery. The serosal layer is opened about 2 mm for a corresponding 3-mm wide pancreatic duct. Create a pinpoint opening in the mucosa at first.

A

B

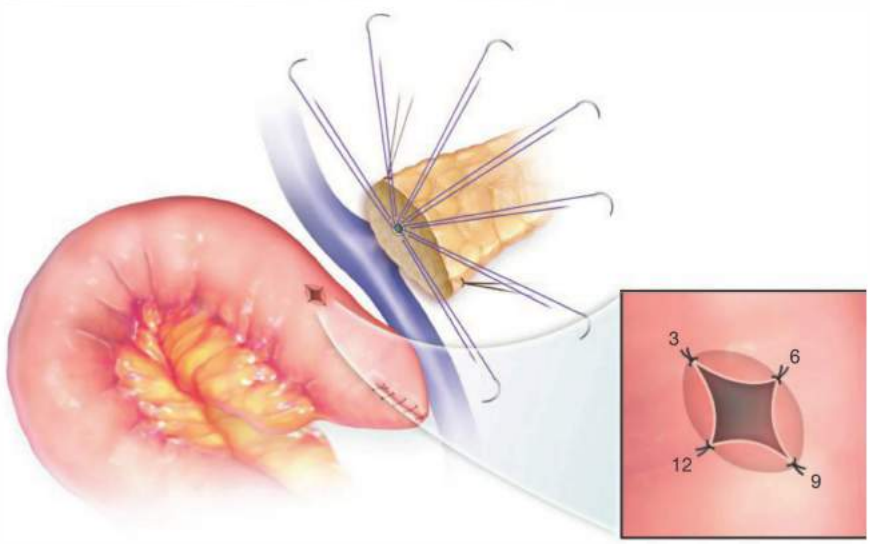


FIG 9 ● **A.** In order to "tidy up" the enterotomy, 6-0 absorbable sutures are applied to each corner by tacking the mucosa to a small (1 mm) bite of serosa. Use care to prevent undue manipulation of the mucosa. **B.** These sutures prevent puckering of the mucosa *(inset)* and again indicate a clockface configuration, which now forms a mirror image of that of the duct.

THE OUTER LAYER—BACK ROW

- This element is best achieved earlier in the process rather than after the inner layer has been completed. It is important to properly size up where the sutures will be placed vis-à-vis the duct and enterotomy. In doing so, you can assure a good apposition of the duct and the enterotomy, which will not be under tension.
- Fewer sutures here mean less opportunity to damage the usually fragile pancreatic parenchyma. Therefore, most of distance of the back row can be approximated with two *horizontally* placed 2-0 or 3-0 silk sutures, limiting the number of holes introduced into the gland.
- The first suture is placed on the lateral posterior surface of the pancreatic capsule and emerges in the midline of the pancreas about 1 cm behind the transection edge (**FIG 10A**). Care is taken to keep this bite rather superficial so as not to incorporate the pancreatic duct beneath yet deep enough to "grip" enough parenchyma so that it does not rip through when being tied down.
- This is then brought across to the bowel, where the direction of the needle travel is now from medial to lateral on a line about 1.5 to 2 cm peripheral from the enterotomy (**FIG 10B**). Assuming the enterotomy is situated at the antimesenteric edge of the bowel circumference, this essentially equates to about a quarter of the way from the interface of the bowel and its mesentery.
- A second posterior suture is placed in an analogous fashion. This time, however, the first move is from lateral to medial on the bowel (**FIG 11A**), and then across to the gland where it is placed in a medial to lateral trajectory (**FIG 11B**). Thus, the knots of each of these sutures are tied down laterally.
- Extra security of the periphery of this row can be achieved by one to two additional silk sutures on each side, tied again on the outside. The bowel now lays in direct apposition with the cut face of the pancreas (**FIG 11C**).

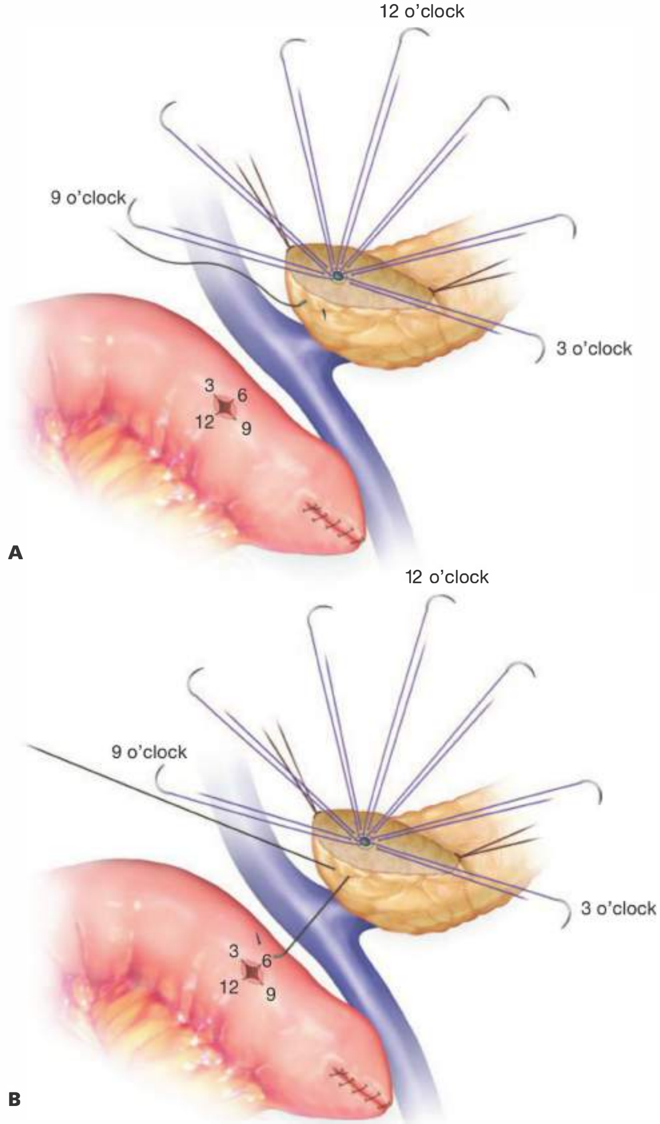

FIG 10 ● **A.** Construction of the back row of the outer layer commences with a horizontally oriented silk suture placed from lateral to medial on the posterior surface of the pancreas. The needle should emerge at the midpoint of the gland but be placed superficially to avoid involving the pancreatic duct behind it. **B.** This suture is then brought across to the bowel and applied in a medial to lateral direction so that the knot can be tied on the periphery of the pancreas.

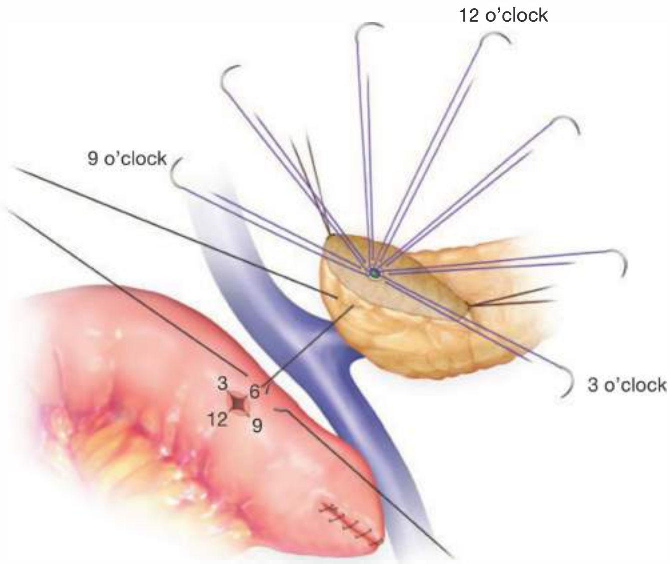
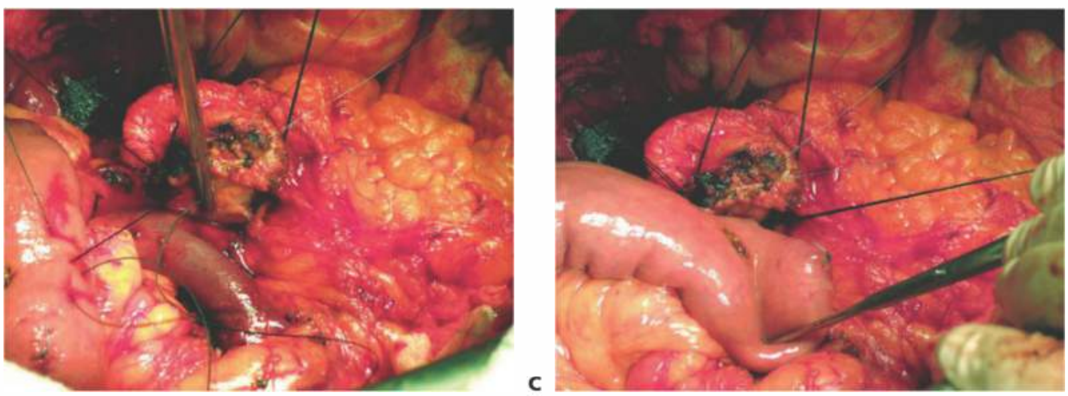
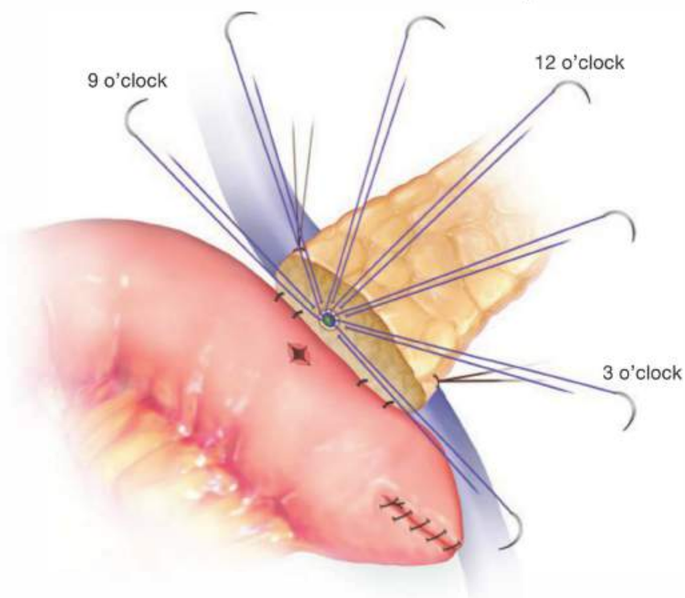


A



B

C



D

FIG 11 ● **A.** The back row is continued in an analogous fashion. First, a silk suture is placed from lateral to medial in the horizontal plane on the bowel to meet the prior stitch. **B.** Then, the suture is applied from the midpoint of the pancreatic parenchyma laterally to the inferior border of the posterior pancreas. **C.** Demonstration of the relative distance of suture placement. Sutures on the posterior pancreatic parenchymal surface should be about 1 to 2 cm behind the transection margin, whereas the position on the bowel usually corresponds to about one-fourth around the circumference from the enterotomy site. **D.** Once the back wall is completed with a few additional sutures on the periphery, the enterotomy will be appropriately positioned across from the orifice of the pancreatic duct.

THE INNER LAYER—BACK ROW

- If the previous step is well performed, the enterotomy site of the bowel should "roll over" to align with the pancreatic duct without any tension. Now, place a single-armed 6-0 monofilament suture at 6 o'clock position within the duct such that it curves out about 2 mm in the transected plane of the parenchyma (**FIG 12A**). Roll this through carefully.
- Then, place it through the bowel serosa about 2 mm away from the edge of the mucosa of the enterotomy (**FIG 12B**). Advance this through the enterotomy at the site of the 6 o'clock marking stitch, being careful to not incorporate the mucosa of the opposite side. Gather the suture, and after the needle is removed, apply a straight clamp to indicate that this is the midpoint of the posterior row.
- Next, using the same technique, place two to three sutures in each lower quadrant of the duct coming from medial to lateral (**FIG 13**). Gather these with rubber shods after the needle is placed through the bowel and removed. The sequence of placement of this row is demonstrated in (**FIG 14**). Again, you can be flexible with how many sutures are needed on each quadrant based on the actual duct diameter.
- Once these have all been placed, tie them down from the middle suture (6 o'clock position) to the periphery. You will notice that the knots of this absorbable suture are all on the inside of the anastomosis.

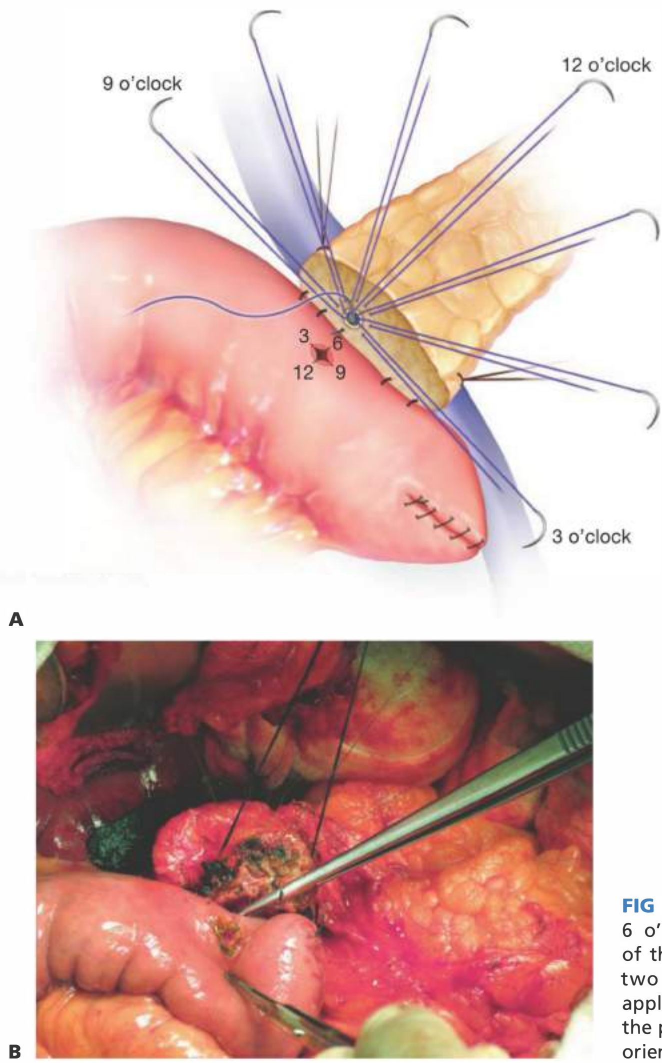


FIG 12 ● **A.** Placement of a suture from in to out at the 6 o'clock position of the duct begins the construction of the back row of the inner layer. Take a millimeter or two of parenchyma with the bite. **B.** This suture is then applied to the bowel and brought through the mucosa at the point corresponding to the previously placed 6 o'clock orientation suture.

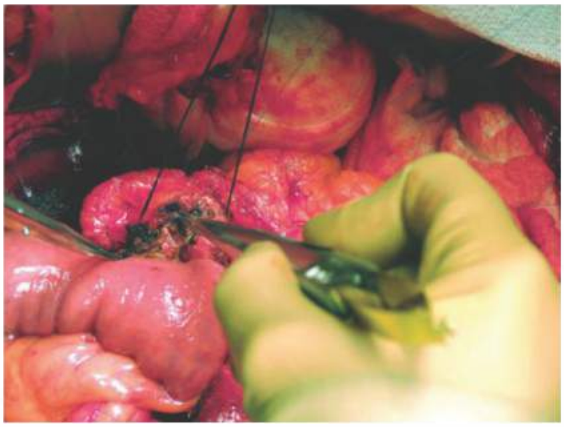

FIG 13 ● Placement of the 7 o'clock stitch from in to out on the duct. This is then continued from out to in at 4 o'clock position on the bowel.

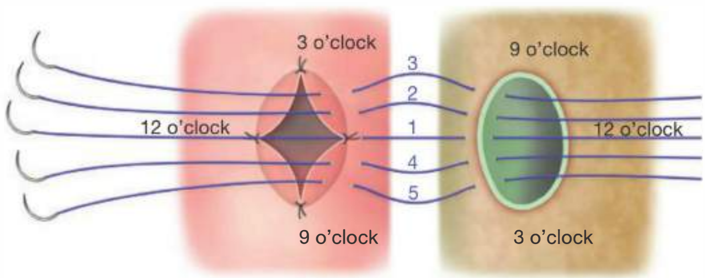

FIG 14 ● Sequence of placement of sutures for the back row of the inner layer. The general theme is to work from medial to lateral for optimal exposure of needle placement.

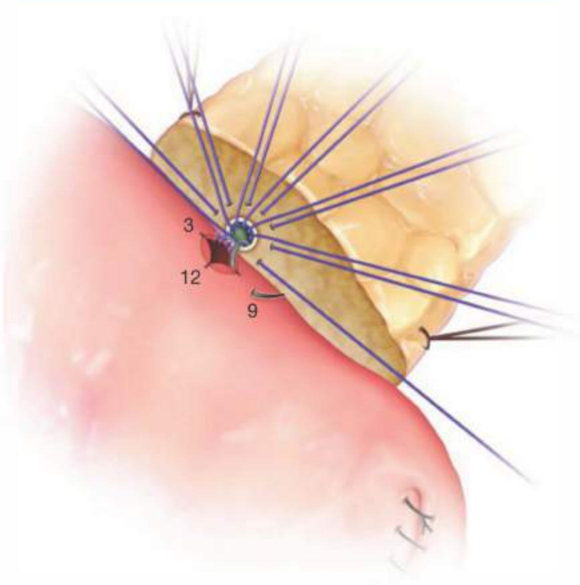
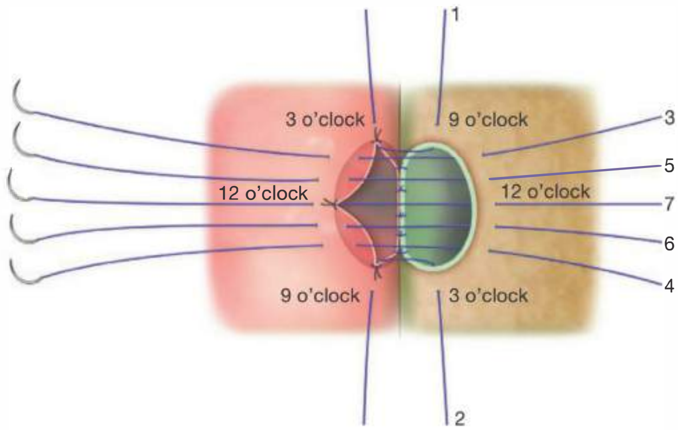
COMPLETION OF THE INNER LAYER—FRONT ROW

- Now it's time to revisit the originally placed sutures from the front row of the inner layer. These are placed serially across to the enterotomy—this time working from the lateral (3 o'clock and 9 o'clock) positions up to the zenith (12 o'clock position) (**FIG 15A**). The sequence of placement is depicted in **FIG 15B**.
- Ensure that the suture limbs are unwound completely before placing across to the enterotomy, as twisted sutures across the anastomosis will lead to a leak. Again, be careful not to incorporate the mucosa of the back wall of the enterotomy. Only once, all the sutures from both limbs are placed across to the bowel should you tie them down. These knots will be external to the anastomosis.



A

FIG 15 ● **A.** Completion of the front row of the inner layer starts by placement of the previously placed corner sutures (either 3 o'clock or 9 o'clock position) from in to out on the enterotomy. *(continued)*



B

FIG 15 ● *(continued)* **B.** The optimal sequence of this placement is depicted, reflecting a general movement from the horizon (3 o'clock and 9 o'clock positions) up to the zenith (12 o'clock position). Place all sutures across to the bowel before any one of them is tied.

THE OUTER LAYER—FRONT ROW

- The pancreaticojejunal reconstruction is completed by securing the front row of the outer layer. The 2-0 silks are placed carefully into the pancreas about half a centimeter behind the cut edge of the parenchymal transection edge (**FIG 16**). Although these need to be substantial particularly in softer glands, take care to stay superficial to the inner anastomosis, particularly, because as you get closer to the center of the gland, the parenchyma becomes shallower.
- Bring these sutures across to the serosa of the bowel limb. Allow for some distance (5 to 10 mm) between the inner anastomosis and the needle placement into the bowel. This allows for enough redundancy such that the bowel will roll over to the face of the transection without placing undue tension to the pancreatic capsule (**FIG 17**).
- The greatest of care is needed when tying these sutures down to avoid "sawing" through the parenchyma. Avoid "bobbing" movements as you are tying these knots, as this will lift the suture out of the field and thus cause a linear tear through the parenchyma.

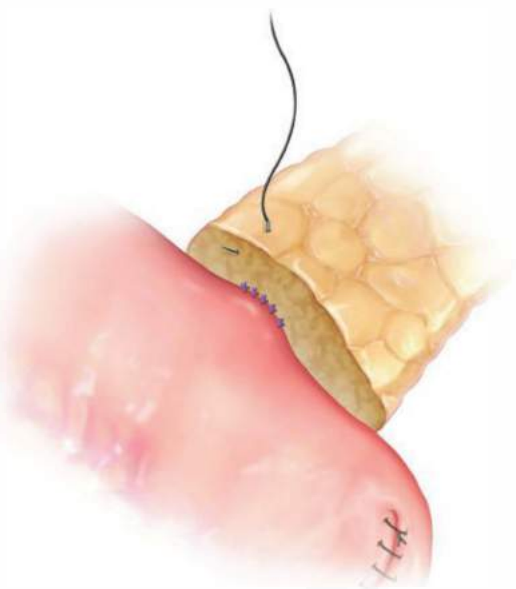


FIG 16 ● The front aspect of the outer layer is completed by placing silk sutures into the pancreatic parenchyma. Once placed across to the bowel, tie these down with the greatest of care because the pancreas capsule is vulnerable to tearing. Again, work from the lateral aspects of the gland sequentially to the midpoint (directly over the inner anastomosis).

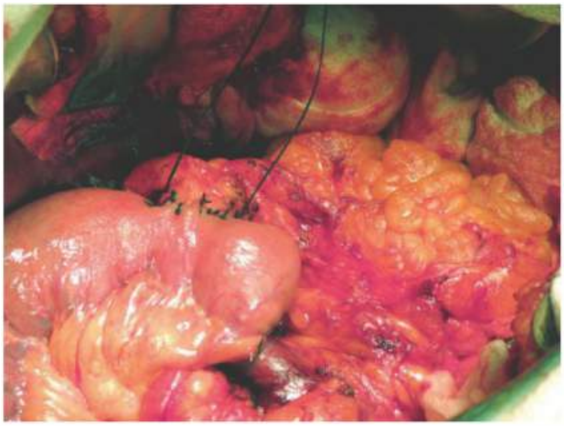

FIG 17 ● Final appearance of the double-layered anastomosis showing the tension-free apposition of the bowel to the pancreatic capsule.

TECHNIQUES

FINAL STEPS

- In select circumstances, some pancreas will have a fibro-fatty layer on their anterior surface. Try to preserve this when initially dissecting and transecting the pancreas, and keep it attached to the pancreatic body. If it is available, it can be applied across to the bowel wall with silk sutures to essentially provide a third layer (hood) for the anterior row.
- You may also be able to attach the redundant bowel near the distal staple line to elements of the transverse mesocolon inferior to the anastomosis in order to help secure the limb against an outright dehiscence.
- Finally, a drain can be placed in the vicinity. I prefer a thin, fluted 19-Fr Blake drain and place it just anterior to the anastomosis. Avoid placing rigid drains directly behind the anastomosis, which necessarily places them between the pancreas and the portal and superior mesenteric veins.

PEARLS AND PITFALLS

Prelude	■ A good pancreaticojejunostomy begins during the resection phase with attention to detail. Minimize unnecessary blood loss and avoid undue tissue trauma to the pancreatic parenchyma. ■ Although finesse is required for the first half (resection phase) of PD, the tone of the reconstruction phase is markedly different, with concentration on detail, and the surgeon should reorient their mindset accordingly at this point of the case.
Setup	■ Assure that the pancreaticobiliary drainage limb is viable, nonedematous, and healthy with good blood flow, and adequate laxity to the RUQ structures. ■ To minimize technical mishaps with fine-caliber sutures, cover the retractor system with a field of white towels. ■ Castro Viejo needle drivers provide the precision necessary for the delicate suturing required.
The inner anastomosis	■ Control the operative field by consistently applying straight clamps to gather ordinal (3, 6, 9, and 12 o'clock positions) sutures. Employ rubber shods for the in-between positions. ■ Use a deliberate, rolling motion in placing the suture through the duct and parenchyma, taking advantage of the natural arc of the needle. Avoid tugging motions when controlling the needle.
The outer anastomosis	■ Take care to keep the bites shallow, yet substantial, so as to avoid the inner layer of the anastomosis or pancreatic duct distal to it. ■ Careless suture tying at this point can lead to tissue fractures of the pancreatic capsule, even in firm glands.

POSTOPERATIVE CARE

- The drain can be assessed for amylase activity once the patient is tolerating a soft diet, which will stimulate vigorous pancreatic secretion (usually around day 5 or 6).
- The drain can be removed if the patient appear clinically well, the drain amylase level is low (generally under 300 International Unit), the volume is reasonable, and the fluid does not appear sinister.[1]
- Drain amylase values between 300 and 1,000 International Unit are indeterminate and require judgment about the individual patient's circumstances. Levels over 1,000 International Unit are highly suggestive of a leak and warrant the continuation of external drainage, and possibly, more intervention (radiology assessment, percutaneous or operative procedures, etc.).
- If a postoperative leak is clinically apparent, general guidelines for management are provided in a review by Callery et al.[5]

OUTCOMES

- This described pancreatic anastomotic technique has resulted in a 3% clinically relevant fistula rate in the author's last 70 cases in patients with an average Fistula Risk Score of 3.70.[3]

Chapter **37**

Pancreaticoduodenectomy: Pancreaticogastrostomy

Laureano Fernández-Cruz

DEFINITION

- Pancreaticogastrostomy (PG) is defined as the anastomosis of the remnant pancreas to the stomach rather than a limb of jejunum. This procedure is necessary following pancreaticoduodenectomy or central pancreatectomy.

DIFFERENTIAL DIAGNOSIS

- PG is a viable option regardless of the indication for pancreatic resection requiring reconstruction.
- PG may be a particularly attractive option for patients with intraductal papillary mucinous neoplasms (IPMN). In these patients, the rationale for surgical intervention is reduction of risk for malignant transformation. Many surgeons advocate partial pancreatectomy for IPMN, trading the risk of progression of disease in the remnant against the brittle diabetes associated with total pancreatectomy. However, this approach mandates surveillance of the pancreatic remnant. PG theoretically provides straightforward access to the remnant duct to facilitate this surveillance, but clinical benefit has not been proven.
- PG should also be considered for reconstruction of the distal, remnant pancreas in the rare situation that central pancreatectomy is performed. PG avoids the need for creation of a Roux limb, and although complications of this component of intestinal reconstructions are rare, they do occur.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Pancreatic fistula has a central role in the development of other intraabdominal complications and occurs with a frequency of 5% to 30%.[1,2] Risk factors for pancreatic fistula include a soft pancreas, a small pancreatic duct, the underlying pathology, reduced regional blood supply, and the surgeon's experience.[3,4] Thus, patient factors impact the risk of pancreatic fistula.

SURGICAL MANAGEMENT

Preoperative Planning

- Efforts to reduce the rate of pancreatic fistula have encompassed the consideration of replacing the pancreaticojejunal (PJ) anastomosis with PG.
- The lack of a uniform technique for performing PG has led to the same debate as that regarding the PJ anastomosis (duct-to-mucosa, invagination, or telescoping the pancreatic remnant into the gastric cavity).
- At present, there is still no consensus on the choice of anastomotic technique (PJ vs. PG). There have been four prospective randomized controlled trials (RCTs) comparing PJ with PG.[3,5–7] Three RCTs[5–7] showed similar pancreatic fistula rates for the two types of pancreatic anastomosis: 12%, 16%, and 13% for PG and 11%, 21%, and 16%, respectively, for PJ. In one recent RCT,[3] the pancreatic fistula rate was significantly lower after PG (4%) compared with that after PJ (18%).
- PG has been gaining favor in recent years. Of historical interest, the clinical introduction of this procedure originated when Waugh and Claggett[8] reported it in 1946.

TECHNIQUES

TELESCOPIC INVAGINATION

- Delcore et al.[2] reported a method of PG in which the pancreatic remnant was telescoped into the gastric lumen (a small gastrotomy is made in the posterior gastric wall) without any stenting of the main pancreatic duct.
- PG is performed either through the transected gastric stump prior to gastrojejunostomy or through an anterior wall gastrotomy (in the case of a pylorus-preserving procedure) (**FIG 1**).
- The most important technical aspect of this anastomosis is establishing adequate mobilization of the remnant pancreatic body and tail. At least 3 cm is required, but greater mobilization is not discouraged provided it does not compromise perfusion.
- A posterior, transverse gastrotomy is created. Attention to the size of the gastrotomy is paramount and should take the elastic nature of the stomach into consideration. The need to dilate the gastrotomy to accommodate the pancreatic remnant is a welcome finding.
- A generous longitudinal, anterior gastrotomy is performed directly opposite of the posterior gastrotomy to provide access to the lumen side of the PG. (Alternatively, the staple line from the antrectomy that will be used for a subsequent gastrojejunostomy is removed.)
- The pancreaticogastric anastomosis is fashioned by taking full-thickness bites of the stomach to the pancreas.
  - Start at the most cranial aspect of the anastomosis. Work caudally, alternating between the posterior and anterior sutures so that the anastomosis

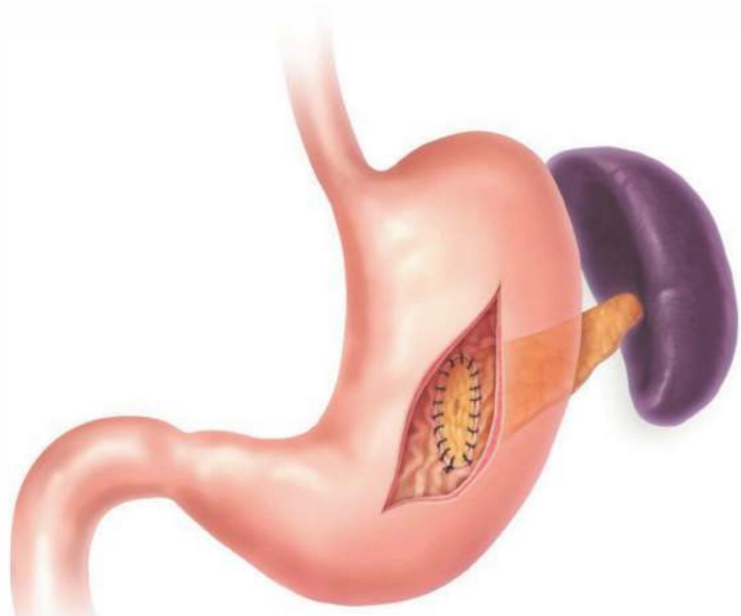

FIG 1 ● The PG anastomosis described by Aranha.[9] The pancreatic remnant is invaginated into a posterior gastrotomy while being visualized through a generous anterior gastrotomy. In a single layer of interrupted sutures, the pancreatic parenchyma is sutured to full-thickness bites of the stomach.

is finished at the caudal aspect. This approach facilitates exposure to each subsequent bite without having to put undue tension on previously placed sutures.

- Interrupted 3-0 silk sutures are used. Pass the needle through the pancreas tissue outside of the stomach lumen so that the needle can be retrieved on the extraluminal side. Then, pass the suture through the gastrotomy and then "back inside-out," taking a full-thickness bite of the stomach wall.
    - Most experienced surgeons prefer to tag each suture; they will be tied after all sutures have been thrown.
    - Place the sutures circumferentially, spaced every 3 to 4 mm.
- As the sutures are tied, the pancreas is invaginated into the lumen of the stomach.
- The anterior gastrotomy is closed in two layers as classically described.

INVAGINATING PANCREATICOGASTROSTOMY

- Aranha[9] describes a one-layer invaginating PG after pancreaticoduodenectomy.
- For this approach, the pancreatic remnant is mobilized for a distance of 4 cm.
- As mentioned earlier, the size of the gastrotomy must accommodate stretching of the gastric wall, and an anterior longitudinal gastrotomy is created to provide exposure to the lumen.
- Interrupted 3-0 silk sutures are placed.
- The beauty of this technique is the visualization and simplicity. It is performed entirely while visualizing the luminal aspect of the anastomosis.
- Begin inside the lumen of the stomach, taking a full-thickness bite. In one move, take a bite of pancreas, entering the exterior gland exiting in the transected edge that can be seen from the luminal side of the intended anastomosis.
- The sutures are tied as they are placed; the end result is a mild invagination of the pancreas into the stomach (FIG 2).

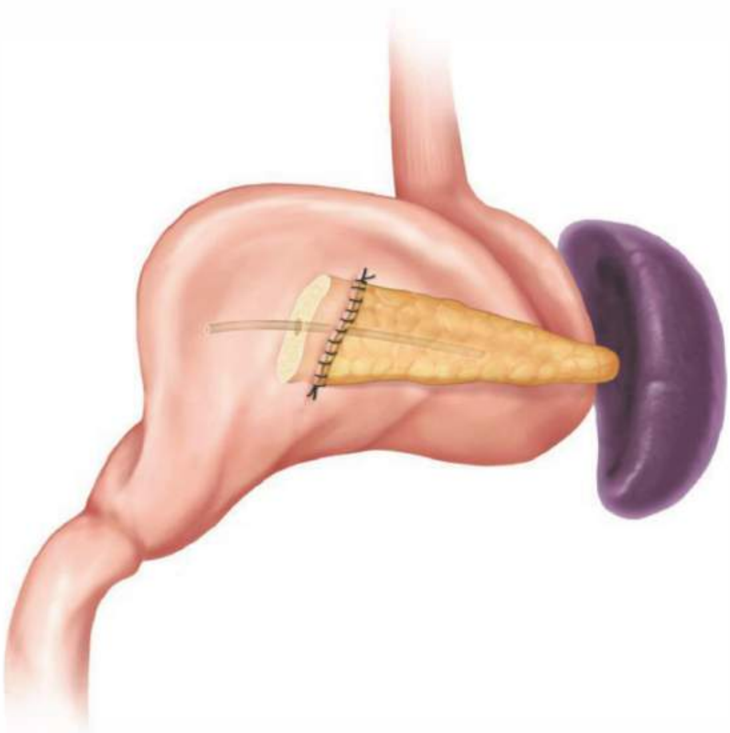

FIG 2 ● Line art drawing of the completed anastomosis. The value of the surgeon's ability to visualize the intussusception through a generous, longitudinal gastrotomy cannot be overemphasized.

DUCT TO MUCOSA

- As an alternative PG, Telford and Mason[10] have reported that direct anastomosis of the pancreatic duct to gastric mucosa provides better patency of the pancreatic duct as compared to a simple invagination procedure (**FIG 3**).
- Initially, silk sutures are placed from the posterior, cephalad gastric wall to the anterior pancreas body. Importantly, this is contrary to PJ, where the posterior aspect of the pancreas is first addressed.
- With this layer in place, a duct-to-mucosa anastomosis is fashioned.
- A small gastrotomy is made adjacent to the pancreatic duct. Posterior, cephalad, interrupted 5-0 absorbable, monofilament sutures are placed so that the subsequent knots are within the lumen of the anastomosis. With the surgeon on the right side of the patient, these sutures enter the lumen of the pancreatic duct, exit the parenchyma, and then proceed outside-to-inside, incorporating the full thickness of the gastric wall.
- Magnification is highly recommended during the placement of these sutures.
- The report by Telford and Mason[10] included the use of a silastic stent. This is optional, but if used, the stent should be placed after the sutures of the posterior row have been thrown and tied.
- The anterior, inferior suture line of the duct-to-mucosa anastomosis is placed and the sutures tied. These knots lie outside the lumen.
- Sutures (3-0 silk) are placed to oppose the posterior, inferior gastric wall to the posterior pancreas body.

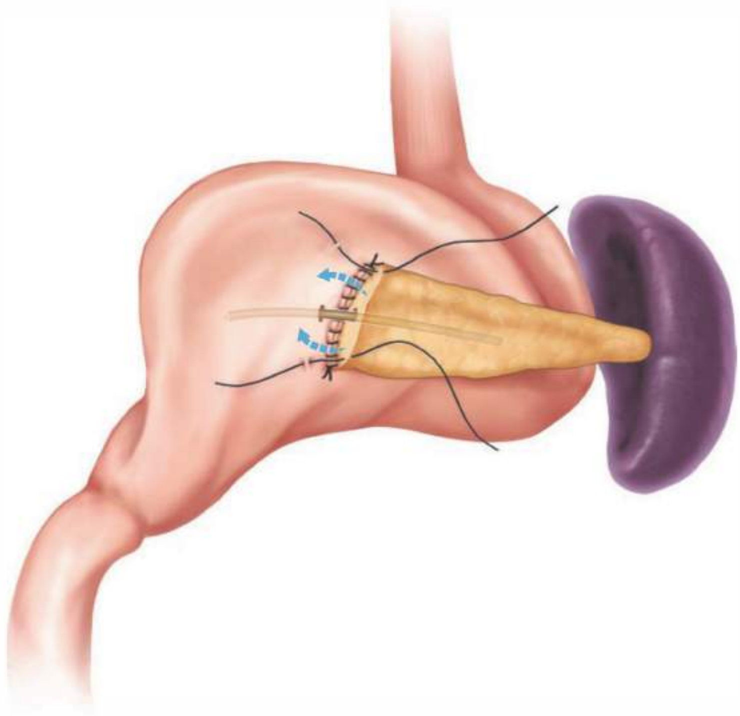

FIG 3 ● Duct-to-mucosa anastomosis. The posterior row of the anastomosis is opposite of that of a PJ anastomosis; the anterior aspect of the pancreatic remnant is first approached.

GASTRIC PARTITION

- Recently, a new technique of pylorus-preserving PD with gastric partition has been reported.[6]
- Gastric partition is performed using two or three Endo GIA staplers along the greater curvature of the stomach, 3 cm from the border. This gastric segment, 10 to 15 cm in length, is placed in close proximity to the cut edge of the pancreatic stump. An end-to-side, duct-to-mucosa anastomosis or invagination anastomosis is constructed (**FIG 4**).
- The construction of this duct-to-mucosa anastomosis is essentially identical to that described earlier, differing only in that the anastomosis is to the gastric partition conduit. This technique is particularly attractive for resections that are performed for IPMN. It provides access to the PD, should completion pancreatectomy prove indicated at a later date, and has profound implications regarding the complexity of that procedure; one only needs to fire a staple load across the stomach to manage the restorative conduit.

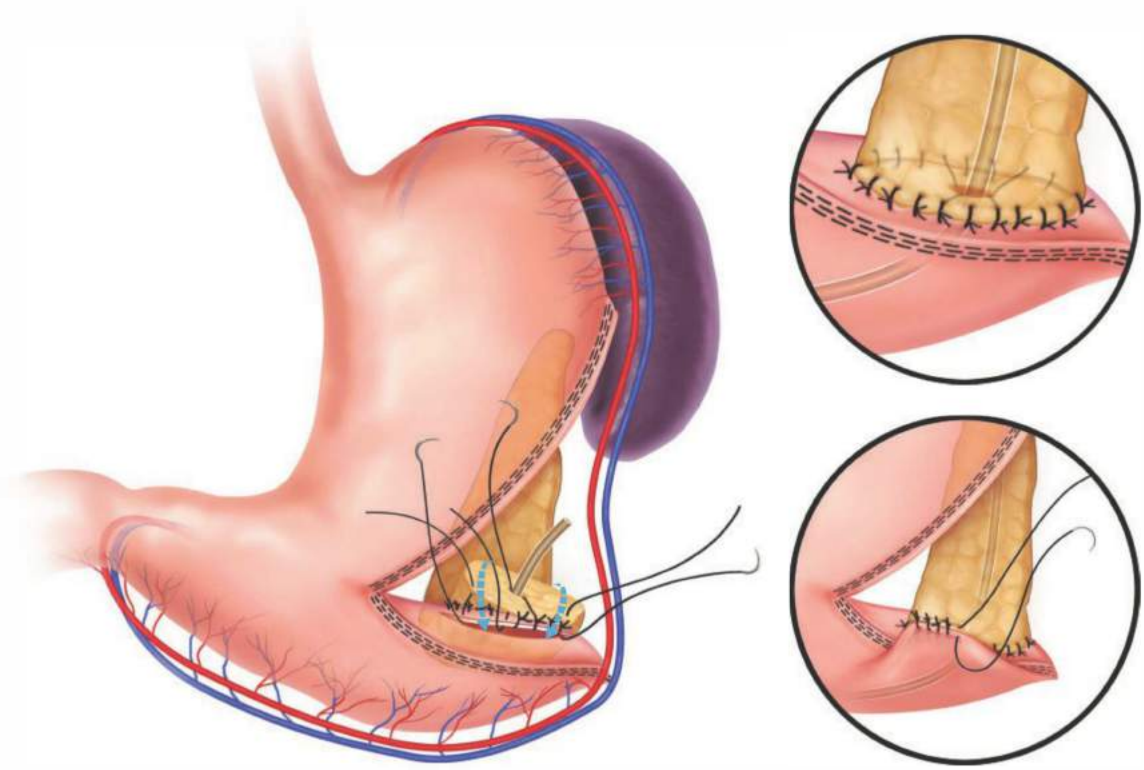

FIG 4 ● Gastric partitioning and duct-to-mucosa anastomosis. The setup to this approach is identical to that of pancreaticojejunostomy. The partition provides additional mobility and access for surveillance and simplifies completion pancreatectomy.

PEARLS AND PITFALLS

History and physical exam	■ PG should be considered when the remnant pancreas is at risk of IPMN progression; it facilitates surveillance and completion pancreatectomy. ■ PG is an attractive option when central pancreatectomy is performed. It avoids the need to fashion a Roux limb.
Surgical management	■ The reduced technical demands of invaginating a soft pancreatic remnant deeply into a posterior gastrotomy, when compared to a duct-to-mucosa PJ, largely explain the enthusiasm for this approach. ■ The back suture row of a PG is to the anterior aspect of the pancreas.
Outcomes	■ Outcome comparisons of PG to PJ have been hampered by variations in technique.

POSTOPERATIVE CARE

- A nasogastric tube is left in place. Despite natural concerns, it can safely be removed on postoperative day 1 in the majority of patients.
- A liquid diet is initiated the following day, provided the patient does not complain of hiccups, nausea, or excessive belching and does not have a distended stomach by physical examination.
- A drain is left in the pancreatic bed and a drain amylase is checked after postoperative day 3. Drains with normal amylase (<1,000 IU/dL) are removed prior to patient discharge.

OUTCOMES

- The analysis of the four RCT[3,5–7] comparing PG and PJ does not allow us to conclude that one of the techniques is superior to the other regarding prevention of complications after PD.
- In the Yeo et al.[7] study, PJ was performed in either end-to-end or end-to-side fashion, at the surgeon's discretion. PG was accomplished by anastomosing the pancreatic remnant to the posterior gastric wall; the average size of the posterior gastrotomy is 2.5 to 3 cm. In the Bassi et al.[5] study, PJ was carried out using a single-layer PJ or duct-to-mucosa technique, and PG was carried out by telescoping the pancreatic remnant into the gastric cavity.
- In the Duffas et al.[6] study, PJ could be performed end-to-end or end-to-side, but the technique of PG was not described.
- In the Fernández-Cruz et al.[3] study, PJ was carried out as an end-to-side, duct-to-mucosa anastomosis, and PG was performed using a gastric partition and duct-to-mucosa anastomosis. Transanastomotic internal stent was used for both PJ and PG.
- Given this variability in techniques, these RCTs have not resolved the notion that PG is superior to PJ with respect to the rate of pancreatic fistula, and this topic remains a subject of controversy.

COMPLICATIONS

- Pancreatic fistula
- Pseudoaneurysm
- Delayed gastric emptying

Chapter **38**

Laparoscopic Pancreaticojejunostomy

Steven J. Hughes

DEFINITION

- Laparoscopy indicates the use of a camera combined with minimal access techniques to perform surgical, abdominal procedures.
- Pancreaticojejunostomy (PJ) is the operative anastomosis of a remnant pancreas (distal pancreas) to a limb of jejunum to restore continuity of pancreatic secretions into the intestinal tract. This procedure is necessary following pancreaticoduodenectomy.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Pancreatic texture will vary depending on the underlying indication for pancreaticoduodenectomy as well as associated patient factors.[1] The pancreatic duct may also vary in size, depending on whether the duct has been previously obstructed, has been involved in intraductal papillary mucinous neoplastic changes, or is of normal caliber.
- The major risk of PJ is leakage of pancreatic secretions leading to abscess or fistula. A classification scheme for the severity of this complication has been characterized.
- This complication is less frequent when the pancreas is firm in texture, thus providing a substrate that firmly anchors sutures and is not prone to laceration.

SURGICAL MANAGEMENT

Positioning

- The patient is positioned supine; tucking of the arms is not necessary (**FIG 1**). Some surgeons prefer a "split-table" approach, where the surgeon is positioned between the patient's legs.
- Reverse Trendelenburg position facilitates the exposure. Thus, a footboard should be used.

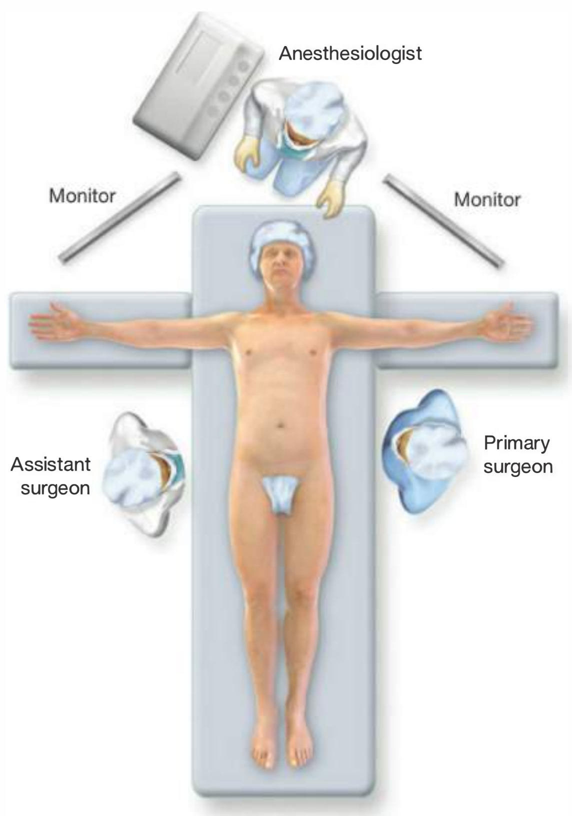

FIG 1 • The patient is positioned supine with both arms extended. The operating table is placed in reverse Trendelenburg to facilitate exposure of the upper abdomen. The surgeon is positioned to the patient's left. Some surgeons use a split-leg position so that the operating surgeon can be positioned between the patient's legs.

TROCAR PLACEMENT

- Trocar placement is depicted in **FIG 2**. Five access points are the minimum required to perform the technique laparoscopically. A fixed retractor is placed in the far right port to elevate the left lobe of the liver and improve exposure to the pancreatic remnant. The other trocars are used for the camera, a first assistant, and the operative surgeon.

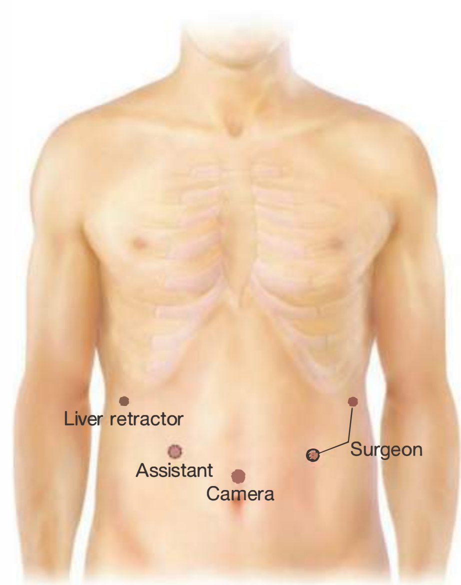

FIG 2 ● Trocar placement. A five-trocar scheme is employed.

MOBILIZATION OF THE REMNANT PANCREAS

- To complete the posterior suture row of the anastomosis, a minimum of 1 cm and ideally 2 cm of the remnant pancreas must be mobilized (**FIG 3**). Increased mobilization of the remnant pancreas facilitates elevation of the gland during the anastomosis and results in improved visualization.
- The reconstructive limb should be fashioned focusing on adequate mesenteric length and preservation of the arterial and venous blood supply. A number of options regarding reconstructive anatomy are available. The author favors positioning the reconstructive limb posterior to the mesenteric vessels as a "neoduodenum."[2] Given the natural orientation of the mesentery of the proximal jejunum, this reconstructive approach minimizes the length of the mesentery necessary to perform the PJ in a tension-free environment. This approach also reduces the potential for internal hernia or other technical errors associated with creating a window in the transverse mesocolon. Importantly, this approach avoids excessive rotation of the jejunal limb behind the mesenteric vasculature.

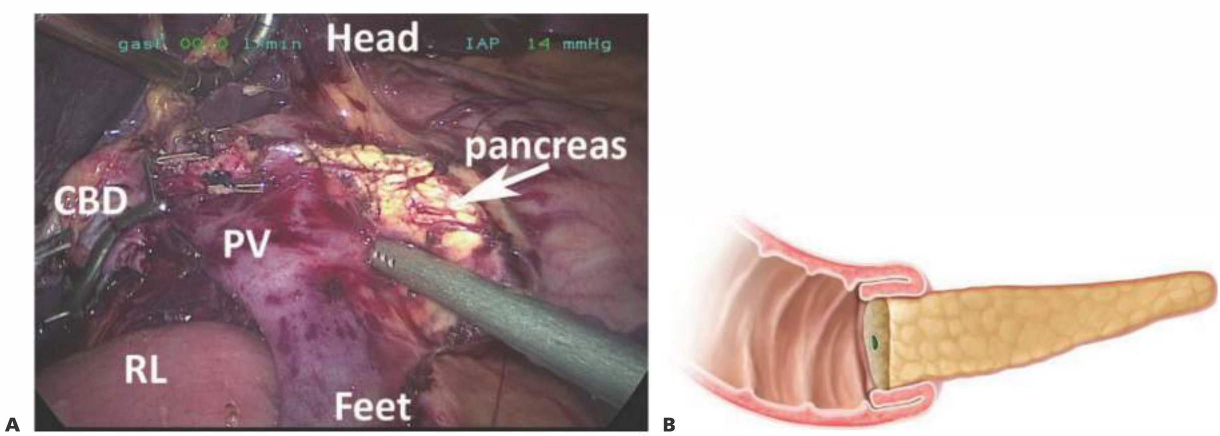

FIG 3 ● **A.** The surgical field prior to initiation of the PJ. After completion of the dissection, the pancreatic neck is circumferentially mobilized for at least 1 to 2 cm. *CBD*, common bile duct; *PV*, portal vein; *RL*, reconstructive limb of jejunum. **B.** Schematic drawing of the completed anastomosis with the pancreas intussuscepted approximately 1 cm into the end of the reconstructive limb of jejunum.

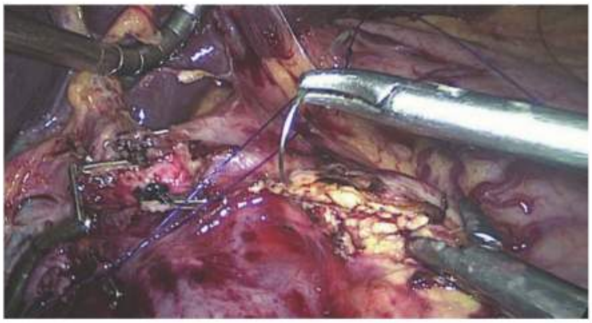
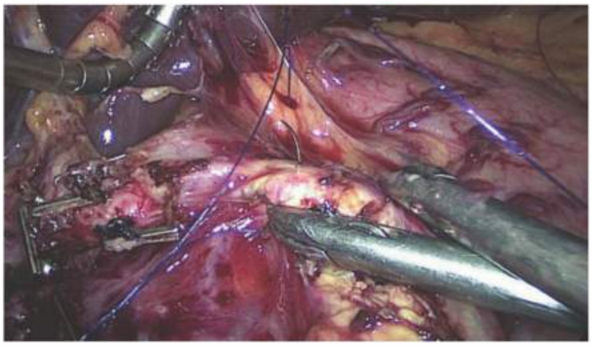
TECHNIQUE 1: END-TO-END INTUSSUSCEPTING ANASTOMOSIS

- The anastomosis is constructed with a running 4-0 polydioxanone suture on a vascular RB-1 needle. A double-armed suture measuring 40 cm in length (20 cm for each arm) is fashioned by tying two sutures together. The suture is placed through a 12-mm trocar and one arm is positioned out of the surgical field in the left upper quadrant. This arm will be used later for the anterior suture line. The staple line on the reconstructive limb of jejunum is removed using electrocautery.
- The anastomosis is initiated by placing the first suture in the reconstructive limb as shown in **FIG 4**. This will facilitate forehand suturing for the entire anastomosis and place the tension of posterior suture line on the serosa of the bowel rather than the soft parenchyma of the pancreas. This suture should be placed at the antimesenteric border of the reconstructive limb.
- The first bite of the pancreatic parenchyma is placed back hand at the cephalad aspect of the remnant pancreas as depicted in **FIG 5**. This suture is typically oriented transverse to the longitudinal plane of the pancreatic remnant. Subsequent sutures in the pancreas will be oriented longitudinally.
- The suture is then passed posterior to the suture that now bridges the bowel and the pancreas as shown in **FIG 6**. This maneuver is essential to prevent locking of the suture as the posterior suture line of the anastomosis is initiated.
- An additional purchase of the reconstructive limb is taken and then the suture is "parachuted" down to appose the reconstructive limb to the remnant pancreas (**FIG 7**). Care should be taken to ensure that the knot securing the two arms of the suture is in good apposition to the serosa of the bowel. Failure to do so will subsequently impact the ability to obtain adequate tissue apposition at the cephalad aspect of the anastomosis with the first tissue bites of the anterior suture line.
- The first assistant provides exposure and maintains tension on the suture line by grasping the suture with an



A



B

FIG 5 ● **A.** The first bite of pancreatic parenchyma is taken at the cephalad aspect of the gland. This suture can be thrown in a longitudinal, proximal-to-distal orientation; however, this orientation can be difficult to achieve without the placement of an additional 5-mm trocar in the subxiphoid space. **B.** A posterior-to-anterior orientation (as shown) is an acceptable alternative often employed to avoid the need for this additional trocar.

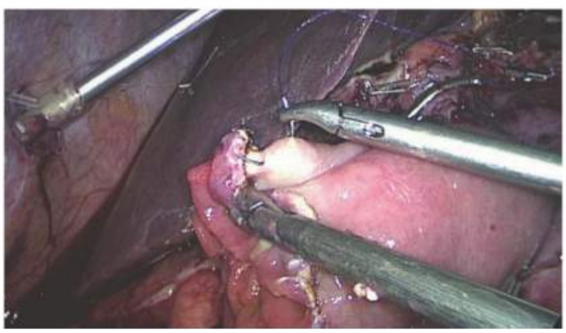


FIG 4 ● The initial bite of tissue is taken in the jejunum in a longitudinal, distal-to-proximal orientation. This suture should be placed at the antimesenteric border to facilitate the orientation of the reconstructive limb to the base of the mesentery. By starting the posterior row on the side of the jejunum, this row and the anterior row of the anastomosis are placed forehand.

FIG 6 ● To place the second bit of the posterior row in the jejunum without locking the suture, the needle is passed posterior to the strand that now bridges the jejunum and pancreas. The second bite of jejunum is then taken, advancing 3 to 4 mm along the posterior row.

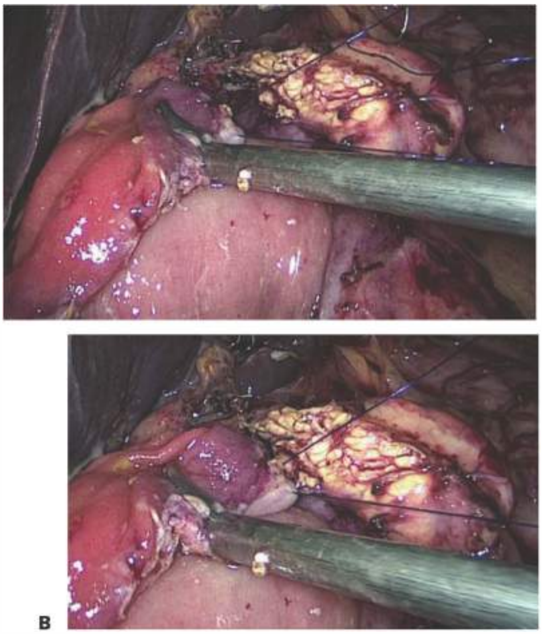

FIG 7 ● The suture is parachuted, bringing the pancreas and jejunum into apposition. **A.** The knot that was fashioned to create the double-armed suture (cannot be visualized in this photograph) is brought into apposition with the serosa of the jejunum and then the suture is tightened while the jejunum is grasped and moved into position adjacent to the pancreas. **B.** The serosa of the jejunum is now in apposition with the posterior capsule of the pancreas.

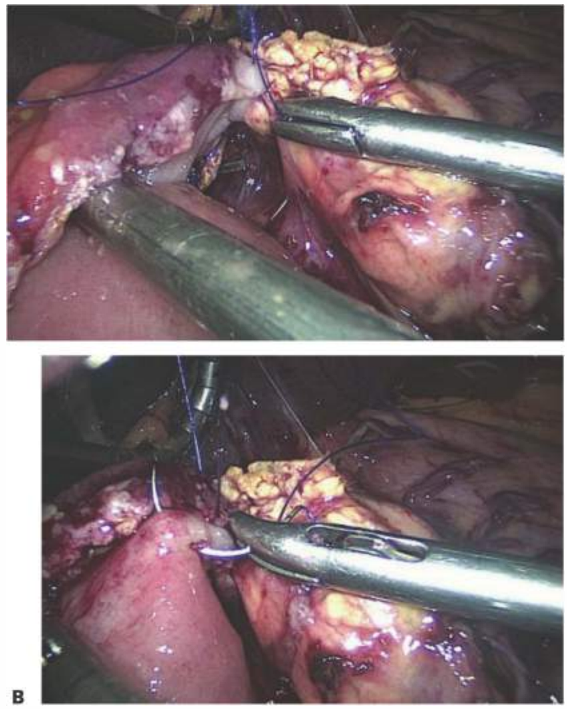

FIG 9 ● **A.** Formation of the posterior row is continued with a forehand bite of the pancreas, followed by **(B)** a seromuscular bite of the adjacent jejunum. The surgeon then applies tension to the stitch and passes it back to the assistant who again maintains tension and exposure. This process is repeated every 3 to 4 mm until the caudad aspect of the suture line is reached.

atraumatic grasper approximately 1.5 to 2 cm above suture line as shown in **FIG 8**. The posterior suture line is then run continuously (**FIG 9**). The operating surgeon sets the tension of the suture on the tissue after each bite of jejunum, and then passes the suture on tension to the first assistant. At the caudad aspect of the pancreas, the suture is held by the placement of a Lapra-Ty™ (**FIG 10**).

- The anterior suture line is performed next. The first bite of tissue is taken on the cephalad aspect of the pancreas immediately adjacent to the initial suture of the posterior row (**FIG 11**). The first bite of the reconstructive limb is similarly positioned in close proximity to the knot that holds the two arms of the suture together and also serves to provide tension on the cephalad aspect of the posterior suture line (**FIG 12**).
- The assistant applies tension to the suture line after each subsequent bite of jejunum as the primary surgeon inverts the mucosa of the bowel. Applying this tension to the left side of the patient facilitates the drawing of the

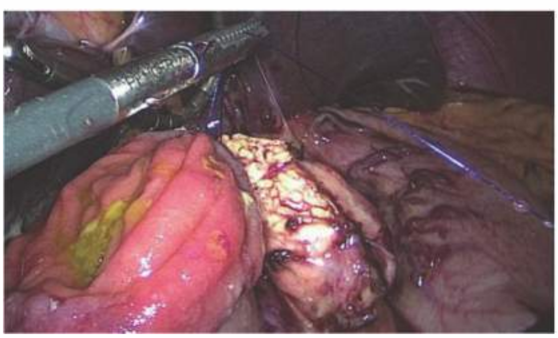

FIG 8 ● The first assistant provides anterior tension to the suture line. This tension also facilitates exposure to the posterior surface of the pancreas.

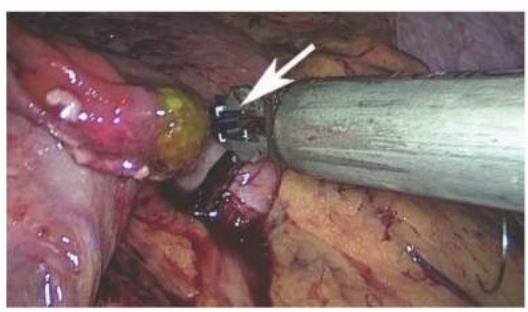

FIG 10 ● At the caudad aspect of the posterior suture line, a Lapra-Ty™ is placed to maintain tension.

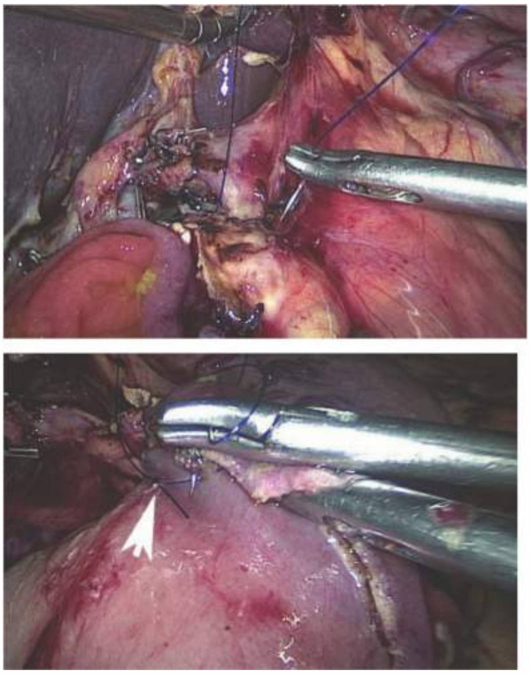

A

B

FIG 11 ● **A.** The first bite of the anterior suture line is taken in the cephalad aspect of the pancreas. **B.** Placement of the initial bite of jejunum. The *arrow* marks the suture knot that holds the two arms of the suture together and is now located at the cephalad aspect of the posterior suture line.

jejunum up over the anterior aspect of the pancreas, thus inducing the intussusception.

- As this suture line is continued caudally, the intussusception progresses, and typically, the tension on the jejunum will lead to completion of the intussusception prior to the placement of the last few bites of tissue (**FIG 13**).
- At the completion of this suture line, a second Lapra-Ty™ is placed to maintain tension. The suture is then tied (**FIG 14**).

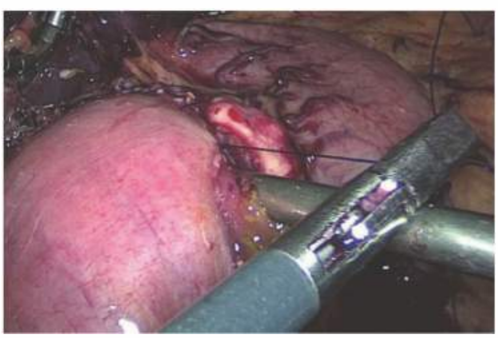

FIG 12 ● The surgeon inverts the jejunal mucosa as the first assistant applies tension to the suture. This tension should be applied to the patient's left to facilitate rolling of the jejunal wall over the anterior aspect of the pancreas, resulting in the pancreas intussuscepting into the lumen of the jejunum.

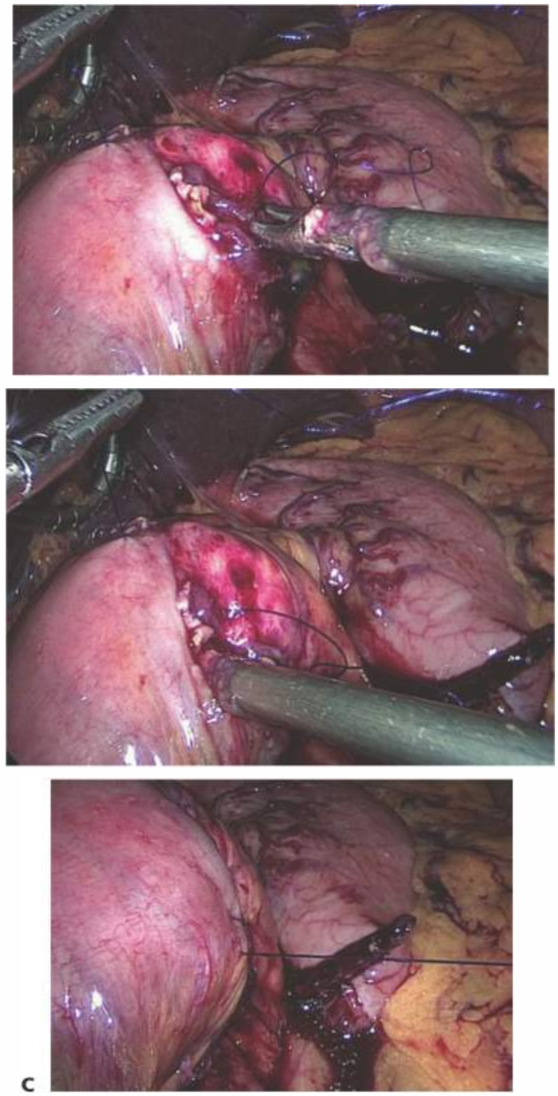

A

B

C

FIG 13 ● **A–C.** As the anterior suture line nears completion, a final tuft of jejunal mucosa is typically present and subsequently inverted with each additional suture until the intussusception of the pancreas into the lumen of the jejunum is complete.

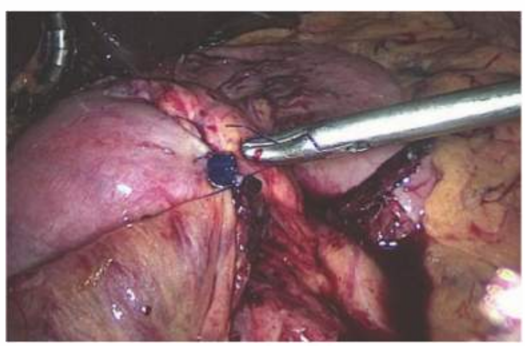

FIG 14 ● The anterior suture is secured with a second Lapra-Ty™ and the anterior and posterior sutures are tied.

TECHNIQUE 2: END-TO-SIDE, DUCT-TO-MUCOSA (BLUMGART) ANASTOMOSIS

- There are two technical challenges to laparoscopically performing this proven approach to PJ.[3]
  - The surgeon must maintain an organization system for the multiple, interrupted sutures that are placed and not immediately tied.
  - Orienting the course of the needle during the placement of the duct-to-mucosa sutures with the standard trocar placement can prove difficult. The strategic placement of an additional 5-mm trocar(s) (often best positioned in the midline, below the xiphoid) can overcome this challenge.
- The anastomosis is initiated by the placement of a series of 3-0 polyglactin sutures on an SH-1 needle. These interrupted sutures are placed full thickness as depicted in **FIG 15**. The suture passes anterior to posterior through the full thickness of the pancreas. A longitudinal, seromuscular bite of jejunum is taken posterior to the intended duct-to-mucosa anastomosis at the antimesenteric border, and the suture is brought back through the full thickness of the pancreas. Care is taken not to traverse the pancreatic duct with these sutures. Typically, five to six sutures are required. To maintain organization of the suture pairs, clips should be applied across the paired strands. This approach will also maintain proximity of the bowel to the pancreas as the duct-to-mucosa sutures are placed. Varying the length of each suture can also be helpful in maintaining organization.

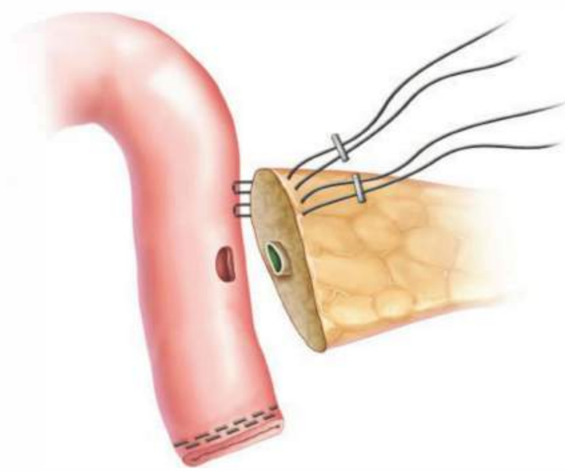

FIG 15 ● An end-to-side, duct-to-mucosa PJ is initiated by placing a posterior row of sutures. This row opposes the posterior aspect of the pancreas to the reconstructive jejunal limb. The sutures are placed through the full thickness of the pancreas to allow all of the sutures to be thrown prior to tying the sutures. This provides additional exposure during subsequent steps but does mandate that an organizational system is employed to prevent confusion regarding the paired strands.

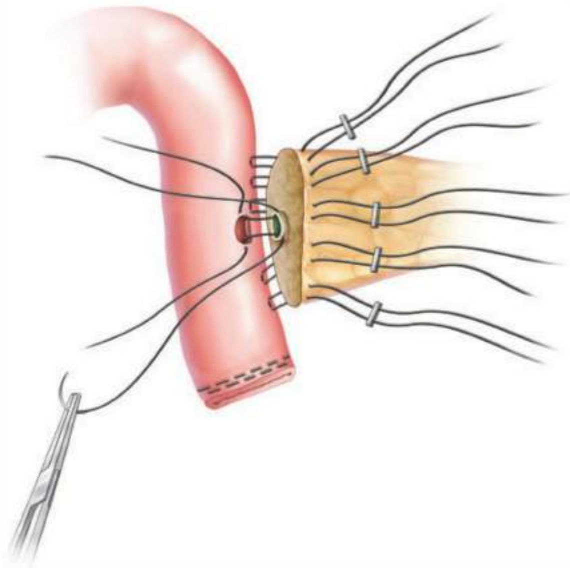

FIG 16 ● Typically, two sutures are placed to initiate the posterior aspect of the duct-to-mucosa anastomosis. As shown, the knots are positioned outside of the lumen. Some surgeons place these sutures so that the knots are within the lumen.

- Two 4-0 polyglactin sutures on an RB-1 needle are then placed in a duct-to-mucosa fashion as shown in **FIG 16**. Once both are placed, these sutures are tied down, bringing the bowel and pancreatic duct into apposition. Care must be taken to prevent any tension to the anastomosis at this point, as these sutures will easily tear through the soft pancreatic duct.
- The anterior row of duct-to-mucosa anastomosis is then fashioned with additional interrupted 4-0 polyglactin sutures (**FIG 17**). Some surgeons favor the placement of a silastic stent prior to this step to prevent accidentally

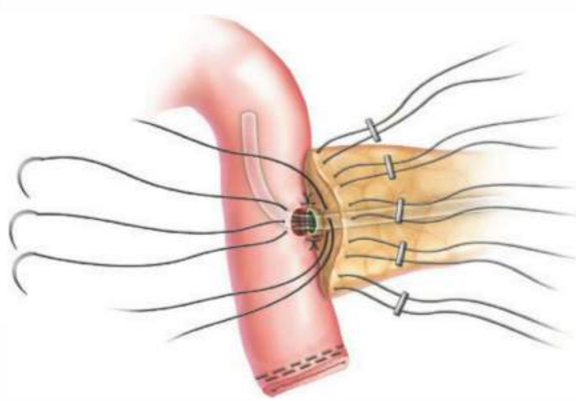

FIG 17 ● The anterior duct-to-mucosa sutures are placed. An optional silastic stent can be placed to prevent inadvertently incorporating the posterior wall of the anastomosis. This may be particularly useful when the pancreatic duct is of small caliber. The stent should be removed prior to completion of the anastomosis.

incorporating the back wall of the anastomosis in one of these sutures. Once all sutures are in place, these are then all tied. If used, the stent should be removed prior to this step to avoid inadvertent retention and the need for subsequent endoscopic retrieval.

- The sutures placed as shown in **FIG 15** are tied (**FIG 18**).
- The anterior row of sutures is oriented longitudinally in the pancreatic parenchyma and then a seromuscular bite of the jejunum is taken. The pioneer of this anastomotic technique advocates incorporating the tied suture from the posterior sutures to minimize laceration of the often soft pancreas tissues (**FIG 19**).

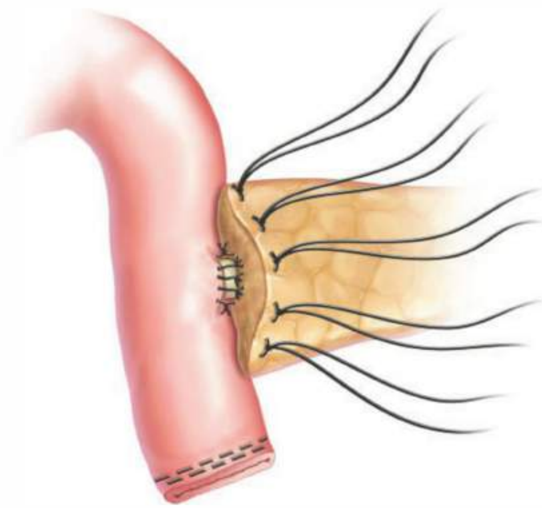

FIG 18 ● The posterior interrupted suture line is tied.

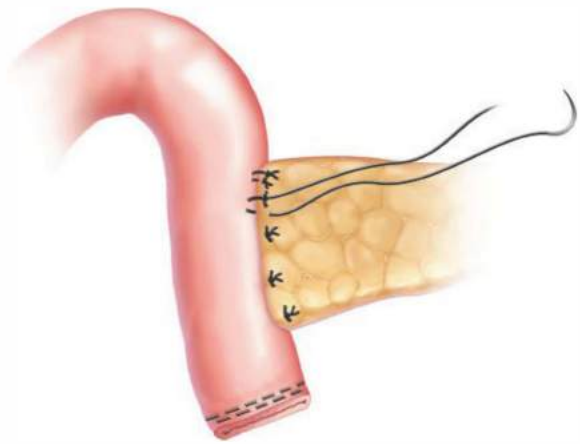

FIG 19 ● Construction of the anterior suture line to approximate the anterior aspect of the pancreas to the jejunum. Note the incorporation of the tied suture placed as shown in **FIGS 15** and **18**.

PEARLS AND PITFALLS

Patient history and physical findings	■ Anticipate a soft-textured pancreas in the clinical setting of neuroendocrine, intrapancreatic bile duct, and duodenal neoplasms. A soft-textured gland is associated with higher complication rates.
Surgical management	■ Adequate mobilization of the pancreatic remnant is essential for placement of posterior sutures. ■ Attention to restrictive fluid resuscitation and minimizing clamp time on the portal vein when necessary can dramatically impact bowel edema and thus the technical challenge of the anastomosis. ■ Place additional 5-mm trocar(s) in the subxiphoid space or elsewhere if the orientation of the stitch cannot be optimized with the standard trocar placement. ■ If using the interrupted suturing technique, keep the sutures as short as possible and strictly adhere to an organization method; that is, clip paired strands together. ■ Neither tissue sealants nor stents have been shown to reduce pancreatic fistula.
Postoperative care	■ Bleeding (either intraluminal or via operatively placed drains) that occurs after 5–7 days in the setting of a pancreatic fistula is due to a life-threatening pseudoaneurysm until proven otherwise. ■ Delayed gastric emptying should be assumed to be due to an evolving pancreatic fistula.

POSTOPERATIVE CARE

- Patients typically require admission postoperatively to a closely monitored setting.
- Drain amylases are obtained on postoperative days 1 and 4.
- Drains can be removed provided the amylase content is less than 1,000 IUD on postoperative day 4.
- Drains rich in amylase content should be left in place until the content returns to that of serum, or the drain output is less than 10 mL per day.
- Sandostatin therapy does not reduce rates of pancreatic fistula but may shorten the time required for a fistula to close.
- Delayed gastric emptying often accompanies evolving pancreatic fistula. If a surgical feeding system was not placed at the time of the operation, a nasojejunal feeding tube can be placed, understanding that this is associated with increased risk given the recent enteric anastomosis. Alternatively, total parental nutrition may be necessary. Nutritional support should be in place by postoperative day 7.

Table 1: Pancreatic Fistula Rates following Pancreaticojejunostomy

Grade	n	%
Intussuscepting PJ[a]	**31**	
A	5	16.1
B	1	3.2
C	1	3.2
Duct-to-mucosa PJ (open series)[b]	**187**	
A	25	13.4
B	7	3.7
C	6	3.2

PJ, pancreaticojejunostomy.

COMPLICATIONS

- Fistula[4]
- Delayed gastric emptying
- Hemorrhage (pseudoaneurysm)
- Sepsis
- Death

OUTCOMES

- Expected outcomes with respect to pancreatic fistula are summarized in Table 1. The overall fistula rate should be approximately 25% (range of 15% to 40%) over a large series and typically correlate with the percentage of soft glands in the series.[5,6]

Chapter **39**

Portal Vein Resection and Reconstruction

Steven J. Hughes   Kevin E. Behrns

DEFINITION

- Borderline resectable pancreatic cancer is defined by tumor involvement of mesentericoportal venous axis.[1]
- En bloc portal vein (PV) resection with immediate reconstruction is now routinely performed by most high-volume pancreatic surgery centers. Large clinical series have demonstrated that this additional operative complexity does not result in increased morbidity.[2,3]
- Arterial resection and reconstruction is not indicated because existing data do not show a favorable benefit-to-risk ratio.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Most borderline resectable patients will ultimately be staged with N1 disease.[4] Thus, these patients have a 5-year survival that is very close to the operative mortality.
- Previous central venous access or venothromboembolic events may be a contraindication to venous reconstruction because of venous hypertension.
- A history of hypercoagulability must be considered as an additional risk and factored into consideration for surgical therapy and potential for postoperative anticoagulation.
- Lower extremity edema is a contraindication for use of the deep femoral vein as conduit.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- A high-quality, multidetector, thin-slice, triphasic computed tomography (CT) scan is essential (**FIG 1**). Pay particular attention to the PV phase; loss of the fat plane for greater than 180 degrees or narrowing of the mesentericoportal complex are predictive of PV involvement by neoplasm.[5]
- Obtain bilateral duplex ultrasound studies of the deep femoral and jugular veins. Surface mapping of deep femoral vein assists in harvesting the conduit but is not required for success.

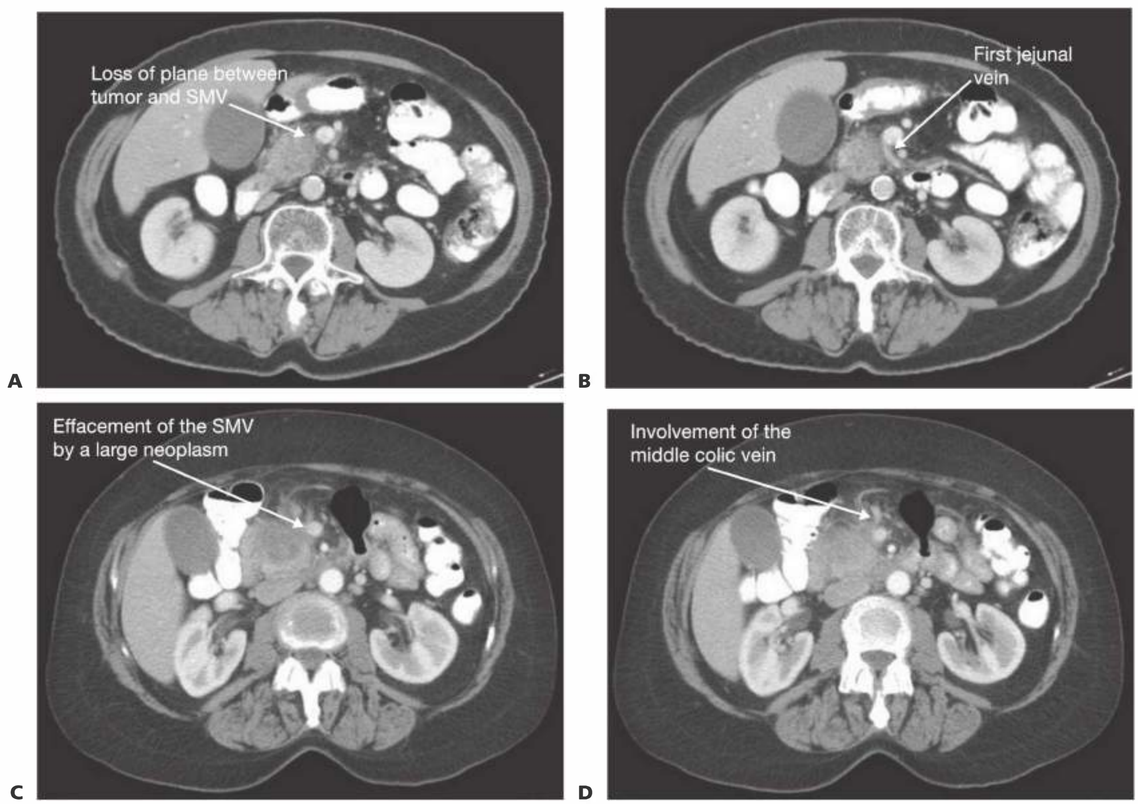

FIG 1 ● **A.** CT of a patient with pancreatic cancer demonstrating SMV involvement. **B.** The insertion of the first jejunal branch proved to be involved. The resulting lateral wall defect was repaired with a bovine pericardial patch. **C.** CT of a patient with large pancreatic cancer demonstrating 180-degree effacement of the SMV and **(D)** middle colic vein involvement. An interposition graft was planned and ultimately required to obtain an R0 resection and perform the subsequent reconstruction.

PREOPERATIVE PLANNING

- Key to success is the accurate, preoperative determination that an interposition graft will be required.
- If the vein is narrowed, plan for a circumferential excision with primary repair versus interposition graft. Using the CT scan, estimate the length of the PV involved and the resulting defect requiring reconstruction (**FIG 2**).
- A defect measuring less than 2 cm can usually be repaired primarily.
- A defect 2 to 4 cm typically can be reconstructed using an interposition graft.
- Defects measuring more than 4 cm will result in a long-segment conduit; the risk of graft thrombosis is proportional to the length, and longer segment reconstructions may preclude surgical therapy.

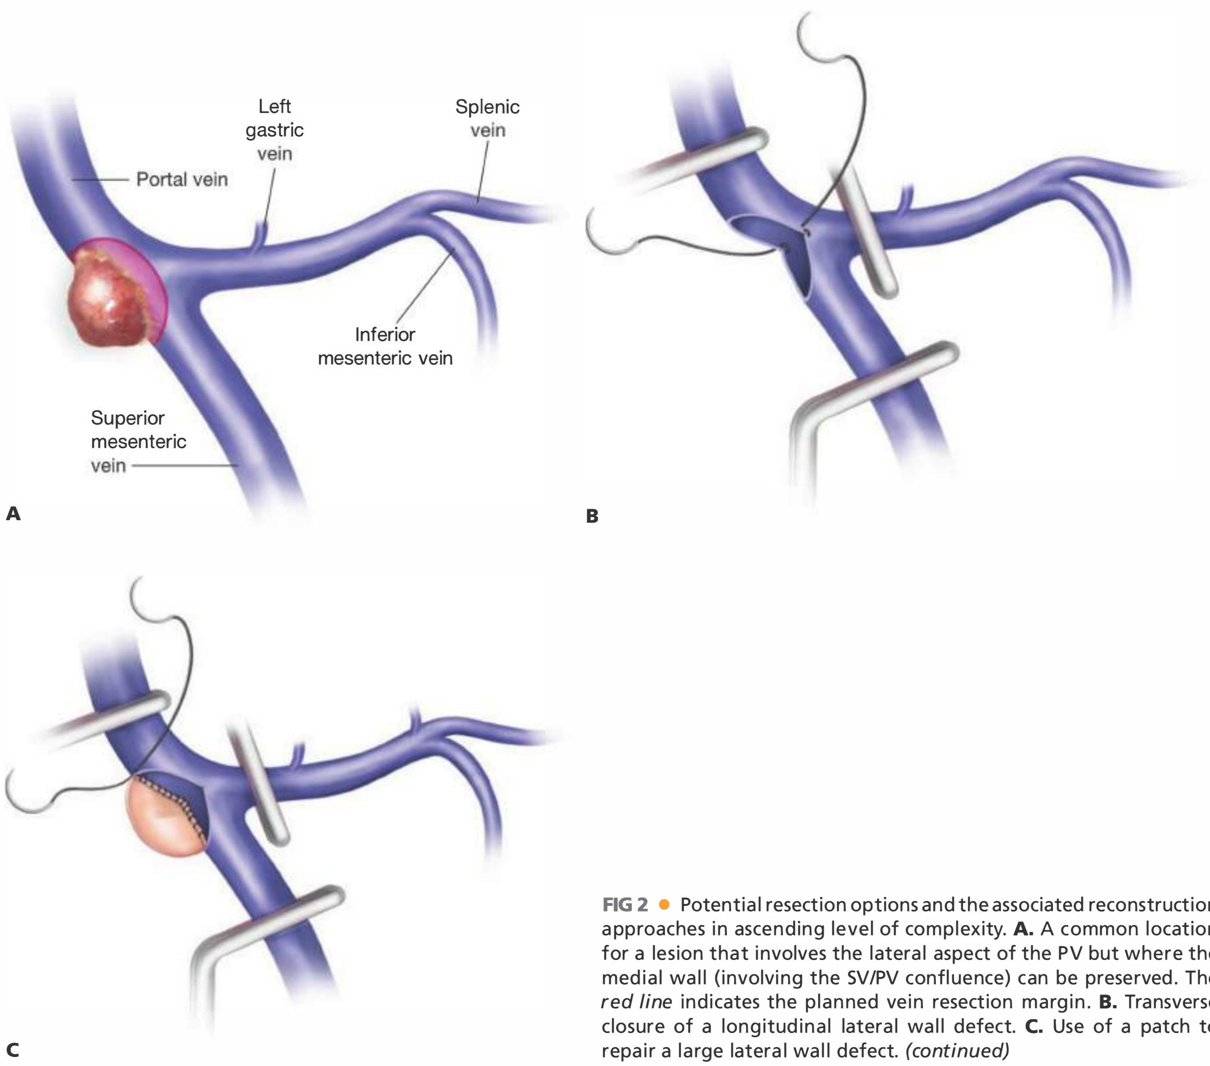

FIG 2 ● Potential resection options and the associated reconstruction approaches in ascending level of complexity. **A.** A common location for a lesion that involves the lateral aspect of the PV but where the medial wall (involving the SV/PV confluence) can be preserved. The *red line* indicates the planned vein resection margin. **B.** Transverse closure of a longitudinal lateral wall defect. **C.** Use of a patch to repair a large lateral wall defect. *(continued)*

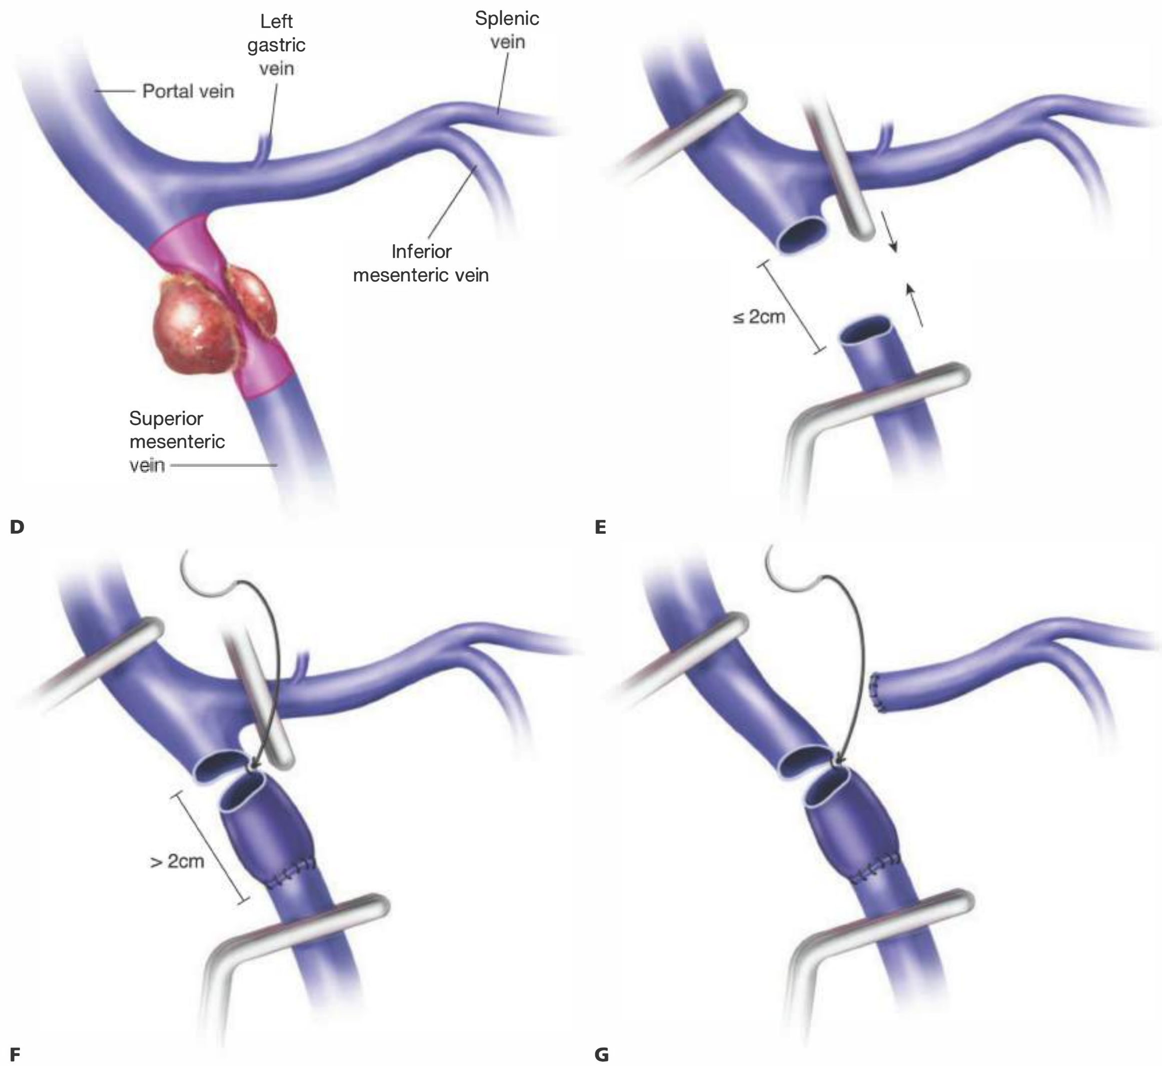

FIG 2 ● *(Continued)* **D.** A lesion resulting in significant narrowing of the SMV requiring excision of the vein. The *red areas* represent the planned resection margin. **E.** Primary end-to-end venous anastomosis for reconstruction. This approach is appropriate when the vein defect is less than a 2-cm gap or with mesenteric mobilization; the ends can be approximated without tension. **F.** Reconstruction using an autologous vein graft (gap in excess of 2 cm or under tension). **G.** If the SV confluence with the SMV is involved, reconstruction of SV inflow is optional.

- Tumor involvement with respect to the splenic vein (SV) and superior mesenteric vein (SMV) confluence must be considered.
  - If the lateral wall is involved, a primary transverse repair or patch repair is ideal.
  - If a circumferential vein resection is required and a primary end-to-end anastomosis or interposition graft planned, most experienced surgeons do not reinsert the SV—this significantly increases the complexity of the procedure. Rather, the SV is ligated proximally. The risk of sinister portal hypertension leading to symptoms is acceptably low.
- Consider initiating or continuing a daily enteric-coated aspirin (81 mg) through the perioperative period.
- Have a bovine pericardium patch available.
- Most centers have abandoned the use of cadaveric vein grafts.
- Strongly consider a neoadjuvant approach for all patients with borderline resectable disease. An R1 resection confers no survival benefit over a nonsurgical, palliative therapeutic approach.
- Neoadjuvant therapy should be offered to all patients in whom there is a loss of the fat plane around the superior mesenteric artery (SMA).

POSITIONING

- Tuck the left arm. This will provide better access to the left neck should the jugular vein need to be procured as a graft (**FIG 3**).
- Place either an upper or lower body active warming device; this decision is driven by the planned source of conduit.
- Prepare the patient's skin. Then, isolate the left neck or left thigh and abdominal operative fields with sterile towels (**FIG 4**). Ensure that these towels create a sterile field between these isolated sites. Use ¾ sterile drapes as indicated to achieve this objective. The authors support the use of iodine-containing, self-adhesive barriers to secure these fields under the additional overlying draping and reduce the risk of surgical site infections.
- To minimize the risk of hypothermia, drape the patient such that only the abdominal operative field is exposed. This drape will be cut to expose the graft harvest site when indicated.

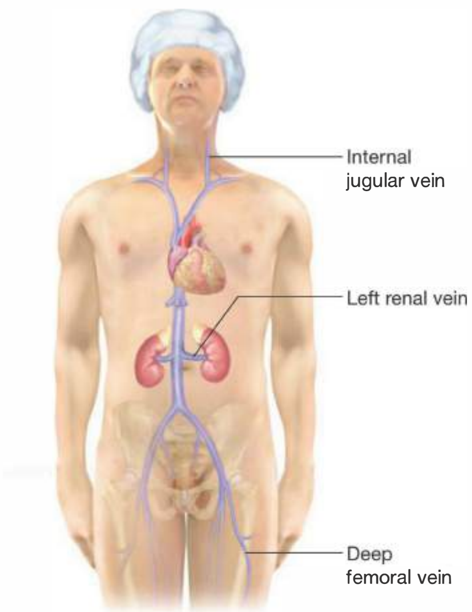

FIG 3 ● Autologous sources of interposition vein grafts include the jugular, left renal, and deep femoral veins.

FIG 4 ● The patient is positioned supine with the left arm tucked. The left leg is prepared and draped with towels, then the abdomen is prepped and draped in a way that should access need to be obtained for the left leg, the draping can be removed or exposed by cutting through the overlying drape without compromising either aseptic operative field.

INCISION AND EXPOSURE

- Either a midline or bilateral subcostal incision can provide adequate exposure. In addition to exposing the upper abdomen, the incision must allow for complete mobilization of the right colon and retroperitoneal attachments of the small bowel mesentery.

DISSECTION

- The dissection proceeds for the most part as presented in detail in Part 3, Chapter 33 but may include limiting particular portions of the dissection; *most importantly, the uncinate process/SMA dissection is performed prior to dissection of the SMV/PV*.
  - Perform a complete Cattell-Braasch maneuver, fully mobilizing the retroperitoneal attachments of the cecum, right colon, and small bowel mesentery to the left of the aorta and up to the third portion of the duodenum.
  - As part of the Kocher maneuver, establish a plane between the third portion of the duodenum and the aorta and extend this dissection cephalad to the origin of the SMA (**FIG 5**).
  - Mobilize the ligament of Treitz and derotate the small bowel such that the cecum is in the left upper quadrant.
  - These maneuvers will provide excellent exposure and mobility of the mesentery to facilitate primary reconstruction without undue tension following mesentericoportal resections up to 2 to 3 cm in length.
- This mobilization will also expose the anterior aspect of the left renal vein—a potential source of reconstruction conduit.
- Open the lesser space and expose the pancreatic head. Assess the root of the transverse mesocolon and bimanually palpate the lesion. Also, palpate the course of the SMA with respect to the palpable lesion.
- Proceed with the dissection of the inferior and superior borders of the pancreas, identifying the anterior borders of the SMV and PV proximal and distal to the area of tumor involvement, respectively.
- By palpation and visualization, identify the relationship of the tumor with respect to the SV/SMV confluence.
- Establish the plane between the root of the mesentery and the third and fourth portions of the duodenum and uncinate process.
- Determine resectability with respect to involvement of the SMV/PV and the extent of resection required (**FIG 2**).
  - A very small segment of the lateral wall of the SMV/PV is involved—a side-bite clamp placed longitudinal to the vein will provide adequate

A B

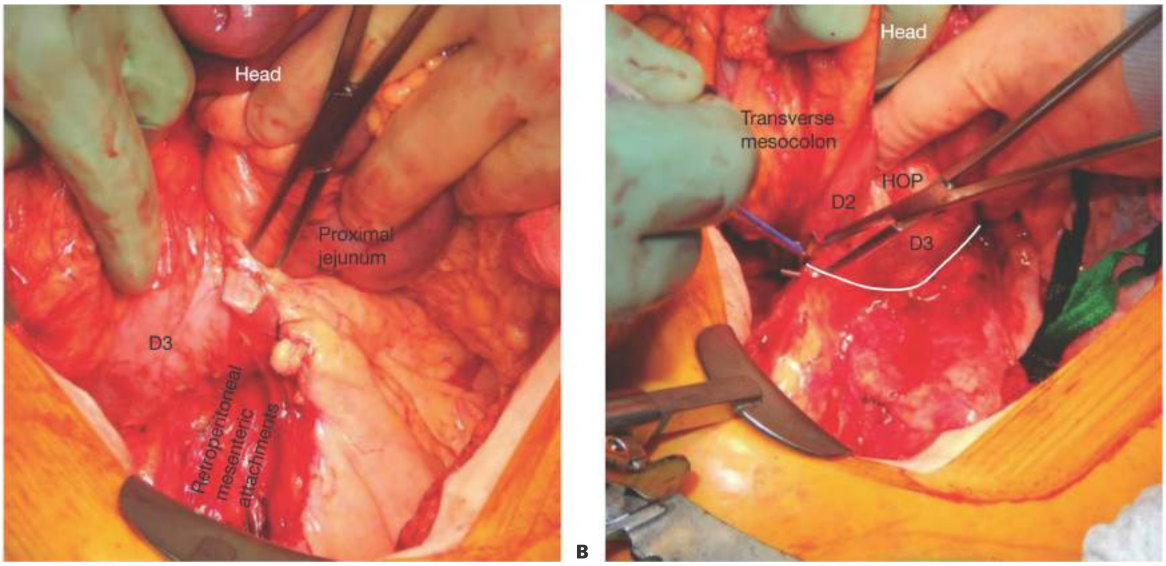

FIG 5 ● **A.** Completely mobilize the right colon and the retroperitoneal attachments of the small bowel. **B.** Extend the dissection by mobilizing the retroperitoneal attachments of the duodenum and pancreatic head to the origin of the SMA (*white line* represents plane of dissection). *D2*, second portion of the duodenum. *D3*, third portion of the duodenum. *HOP*, head of pancreas.

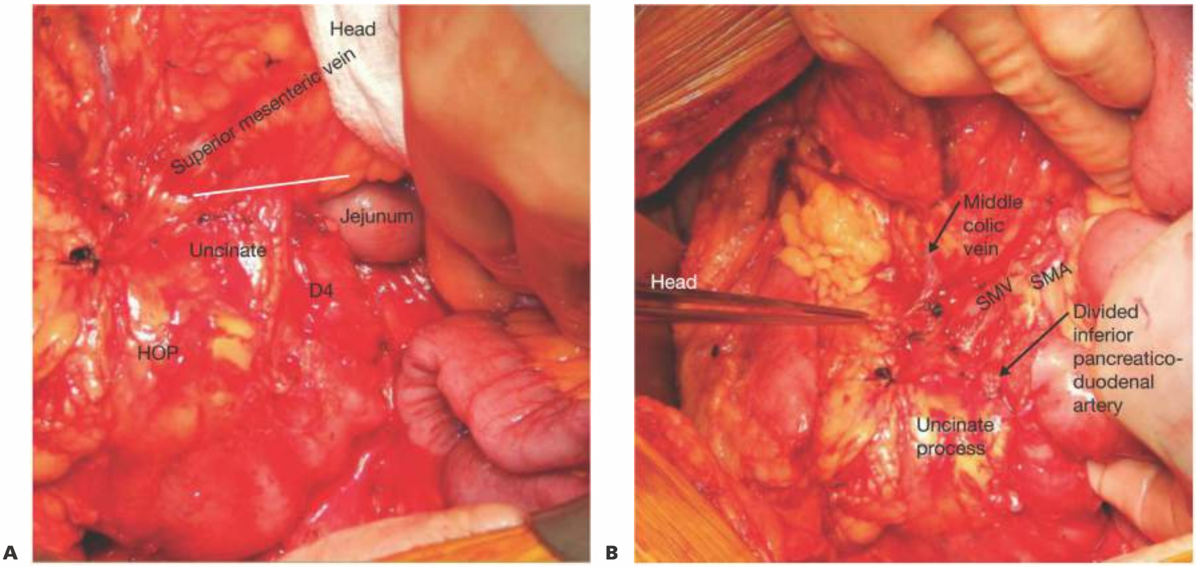

FIG 6 ● Establish the plane between the root of the mesentery and the third and fourth portions of the duodenum and uncinate process. **A.** Mobilize the uncinate process along the adventitia of the SMA (*white line* represents plane of dissection). **B.** Control the inferior pancreaticoduodenal arteries with ligatures. *HOP*, head of pancreas. *D4*, fourth portion of duodenum.

resection margin (2 to 3 mm) and vascular control. Note: A longitudinal clamp will not allow a transverse closure of the resulting defect due to tension; the clamp will typically need to be repositioned transversely. Thus, the authors rarely use a side-biting clamp technique and usually obtain circumferential, proximal, and distal control.

    - Unless a plane can be readily established anterior to the SMV/PV confluence (i.e., only the lateral wall of the vein is involved), save division of the pancreatic neck for later.
  - Proceed with the other steps of the dissection.
    - Dissect the porta hepatis and divide and control the bile duct and gastroduodenal artery.
    - Divide the proximal gastrointestinal (GI) tract (duodenum or stomach).
- Approaching from the posterior–inferior, dissect the uncinate process and duodenal mesentery from the SMA, hugging the adventitial plane while working caudad to cephalad until the lateral aspect of the SMA has been fully dissected up to its origin from the aorta. An energy device can be used for much of this dissection, but the authors recommend ligation or suturing of any identified inferior pancreaticoduodenal artery (**FIG 6**).
- Alternatively, the SMA dissection can be facilitated by approaching it from the anterior aspect, inferior to the takeoff of the middle colic artery but superior to the arborization of the artery. First, isolate and encircle with a vessel loop the SMV well inferior to the tumor (**FIG 7**). Dissect down to the adventitia and then continue dissecting along the right lateral border until you break through to the posterior dissection plane. Once this maneuver has been performed, continuing the dissection cephalad is straightforward from the posterior–inferior approach described earlier.
- Confirm the resection plan and required reconstruction. Particularly, determine if an interposition graft will be required. Harvesting of this graft *should be performed first* to minimize vascular clamp time and the resultant bowel edema that impacts reconstruction of intestinal continuity.

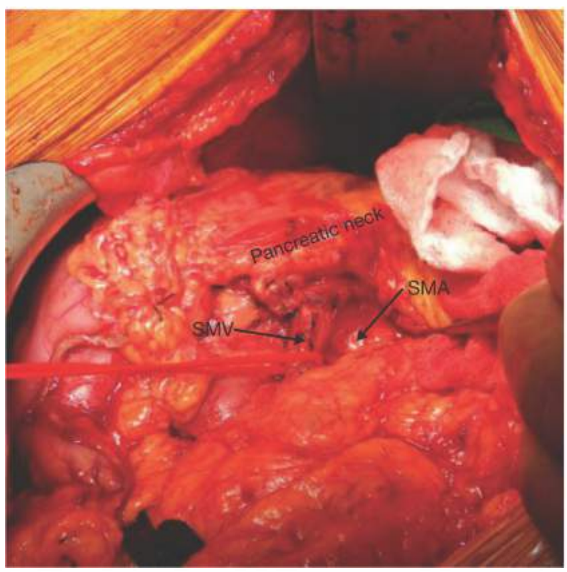

FIG 7 ● Circumferentially dissect the SMV and control it with a vessel loop. This also provides and anterior approach to the distal SMA. This approach also provides safe access to the adventitial plane of the SMA.

PROCURE THE RECONSTRUCTION CONDUIT

- Intravenously administer unfractionated heparin sulfate (50 IU/kg) and allow time for the drug to circulate.
- Have a basin with heparinized normal saline (100 IU/mL) available to store the conduit.

Left Renal Vein

- When of adequate length, the left renal vein is an ideal source of conduit as it can be procured without establishing another surgical field, is typically of appropriate caliber, and has a relatively thick wall that holds sutures well.
- Assess the left renal vein for caliber and length (from the insertion of the left gonadal vein to the inferior vena cava) and determine if it is suitable as the conduit for reconstruction. If the interposition graft is anticipated to need to be 3 cm, the length of conduit should be longer, that is, 5 cm.
- Circumferentially dissect the vein and control it with vessel loops. Using vascular clamps, control the vein proximally and distally and sharply excise the conduit. Place it in heparinized saline (100 IU/mL).
- Use a running 5-0 Prolene to control the proximal renal vein and vena cava.

Femoral Vein

- The deep femoral vein is also an excellent source of conduit as it is relatively thick walled, of good caliber and never inadequate in length, and complications associated with the procurement site are surprisingly rare.[6]
- Prepare the surgical field for conduit procurement by cutting the overlying draping. Use additional towels as indicated.
- Use a clean set of instruments and keep them separate from those used for the abdominal surgical field.
- The left thigh is more readily available.
- See Lee et al.[7] for details of the exposure and other details of the technique.

Jugular Vein

- The left jugular vein is the preferred conduit for PV reconstructions at some centers.
- The exposure and surgical anatomy are available in Part 6, Chapter 3.

VASCULAR CONTROL AND RESECTION

- If the pancreatic neck has not been divided, establish a plane posterior to the pancreas at the level of planned transection (this is often at the level of the pancreatic body to the left of the SMV/PV confluence). Divide the pancreas and obtain hemostasis on the cut surface.
- Isolate and control the SV with a vessel loop (**FIG 8**). During this dissection, be mindful of the left gastric vein. It typically inserts into the cephalad aspect of the SV approximately 1 cm proximal to the SMV/PV confluence. It is at risk for injury during isolation of the SV or inserting distal to the point of control; this will lead to a lack of hemostasis after clamping during the vein resection. The authors typically ligate and divide this vein.
- The insertion of the IMV into the SV is quite variable. It may need to be independently isolated if it inserts in close proximity to the SMV/PV confluence.
- Circumferentially dissect the SMV proximal to the area of venous involvement. Control it with a vessel loop. Be mindful of the first jejunal branch of the SMV. This vessel usually receives a larger tributary vein from the uncinate process and injury or loss of control can be quite challenging. Furthermore, obtaining control proximal to the vessel will not lead to a hemostatic field.
- Get control of the PV above the planned level of vein resection. Identify the superior uncinate vein (vein of Belcher) and isolate, ligate, and divide it.

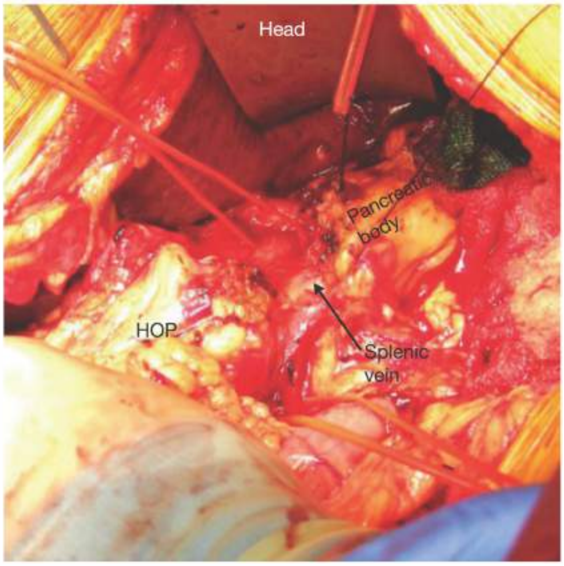

FIG 8 ● If indicated, isolate and control the SV. In this circumstance, the tumor is attached to the lateral aspect of the SMV/PV confluence. The pancreas has been divided to the left of the pancreatic neck to provide an adequate margin and expose the anterior surface of the SV. During this dissection, be mindful of the left gastric vein. It typically inserts into the cephalad aspect of the SV approximately 1 cm proximal to the SMV/PV confluence. It is at risk for injury during isolation of the SV or inserting distal to the point of control; this will lead to a lack of hemostasis after clamping during the vein resection.

- At this point, proximal and distal control has been achieved (FIG 9).
- If a conduit was not procured, intravenously administer unfractionated heparin sulfate (50 IU/kg); allow at least 1 minute for the drug to circulate prior to placing clamps. The authors prefer to have the clamps relatively remote from the planned resection planes; this length provides better exposure and mobility of the vessels during the construction.
- Mark the anterior surface of the vessels using a marking pen. This will facilitate maintenance of the vessels' orientation. Alternatively, consider marking the anterior aspect of the vein with a fine monofilament suture. Loss of this orientation is surprisingly easy and can result in torsion and narrowing of the reconstruction. Sharply divide the vein(s) along the planned resection plane.
- Orient the pathologist to the specimen using sutures. One or more of these sutures should identify the venous margins.

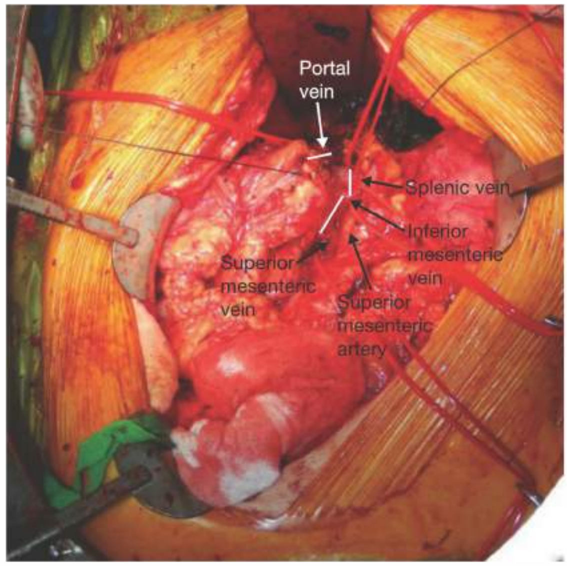

FIG 9 ● Proximal and distal control with complete mobilization of the uncinate process off of the superior mesenteric artery. The *white lines* represent the planned venous resection lines. This plan includes a tangential proximal anastomosis that incorporates and aberrant IMV insertion into the SMV and ligation of the SV.

RECONSTRUCTION

- The vascular reconstruction proceeds immediately.
- Place moistened white towels around the field and over the fixed retractor blades/arms to better see the fine reconstructive suture and avoid tangling it on the retractor.
- Use 6-0 Prolene on a fine vascular needle for the repair.
- The authors do not reverse the systemic anticoagulation effects of the heparin unless necessary to control nonsurgical bleeding at the completion of the procedure.

Primary Transverse Closure

- Place single-armed 6-0 Prolene sutures at the (1) anterior and (2) posterior longitudinal midpoints of the venotomy (FIG 10). The two stitches are placed longitudinally, 1 mm from the cut edge from outside in and then immediately back inside out so that they can be tied and result with the knot outside the lumen.
- Begin with the posterior suture, advancing 1 mm cephalad from outside the lumen into the lumen.
- Run the posterior suture visualizing the placement of the sutures from inside the lumen until the anterior suture can be used to complete the anastomosis with visualization from outside the vessel lumen.
- Release the PV clamp to allow retrograde blood flow. Allow the vessel to fill, thus degassing the anastomosis. Hold minimal tension on the sutures to allow the suture line to maximally expand before tying the two sutures together to complete the anastomosis.
- Place interrupted repair sutures as necessary to obtain a hemostatic anastomosis.
- Hemostatic agents such as cellulose may facilitate control of oozing from needle tracts.
- Release the remaining clamps.

Patch Closure

- When a lateral defect in the vein cannot be transversely closed without undue tension, employ a patch venoplasty using bovine pericardium (FIG 11).
- Cut the patch to size. Leaving the patch about 80% of the length of the defect and twice as wide as the defect will minimize the risk of narrowing the vessel.
- Initiate the double-armed suture line at the apex of the venotomy. The assistant retracts the patch caudally and laterally to expose the posterior suture line from the lumen side (FIG 11B).
- Use care to align the patch with the vein—bites of the vein should be spaced further apart to prevent a size mismatch.
- Place a second double-armed suture at the heel of the repair and then tie the posterior suture to this second suture.
- Alternatively, this suture can be placed at the same time as the apex suture and each suture can be run toward the middle. This approach reduces the risk of a significant size mismatch but limits the exposure.
- Run the anterior suture line to the midpoint of the repair and then use the heal suture to complete the anastomosis. Do not tie down the suture until retrograde restoration of blood flow has been accomplished.

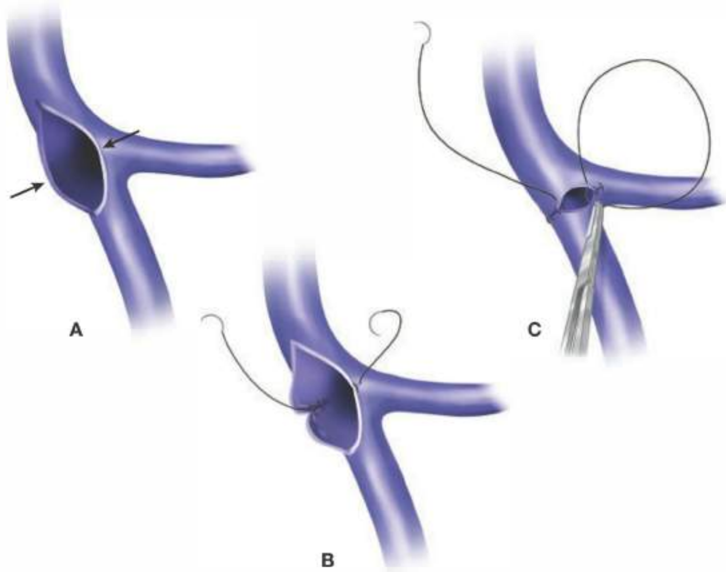

FIG 10 ● A transverse closure of a longitudinal defect. **A.** The suture line is initiated at the anterior and posterior mid-points of the longitudinal venotomy *(arrows)*. **B.** The posterior suture is run first, visualizing the repair from inside the lumen of the vessel. **C.** The anterior suture completes the anastomosis.

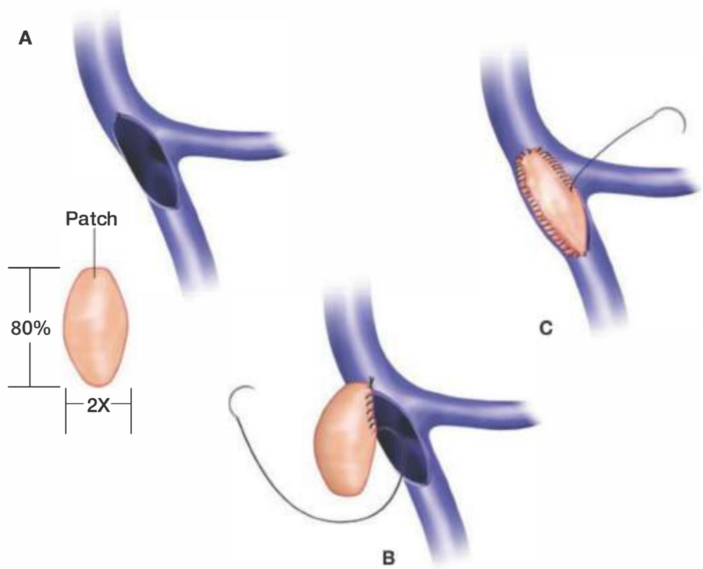

FIG 11 ● A pericardial patch repair of a large lateral wall defect. **A.** Estimate the width of the patch, and then double it to prevent narrowing. The authors prefer to also shorten the length of the defect by purposely shortening the patch. **B.** The lateral posterior suture line is placed first with exposure from the lumen side of the vein. The "heal" of the patch can be anchored to the proximal wall of the venotomy to assist in alignment (not shown). **C.** The anterior suture line is then placed to complete the patch repair.

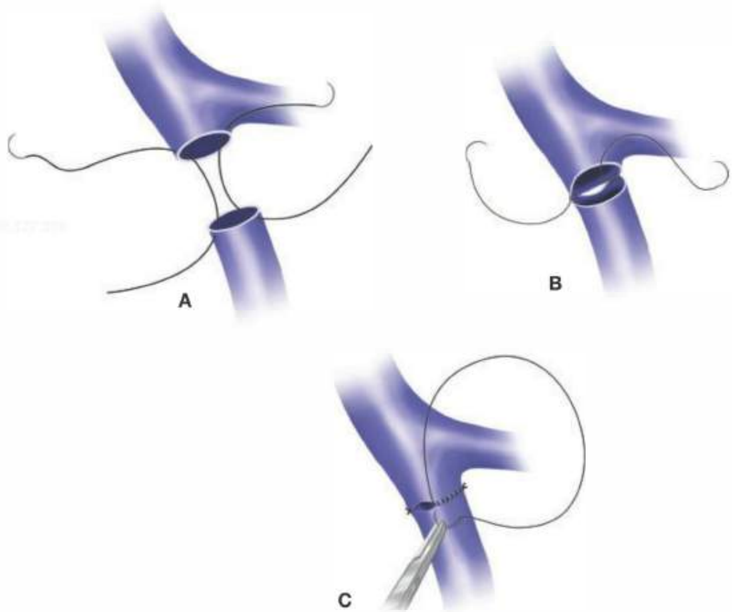

FIG 12 ● End-to-end native vein reconstruction. Size mismatch is often an issue; the authors recommend interrupted sutures in this clinical setting. When compared to interrupted sutures, a running suture takes less time and is more hemostatic but puts the anastomosis at risk for narrowing by producing a purse-string effect. **A.** Double-armed, 6-0 Prolene sutures are placed at the 3 o'clock and 9 o'clock positions. **B.** The posterior suture line is placed under visualization from inside the lumen. The suture line is completed at the 9 o'clock position by tying the sutures together. **C.** The anterior suture line is then placed.

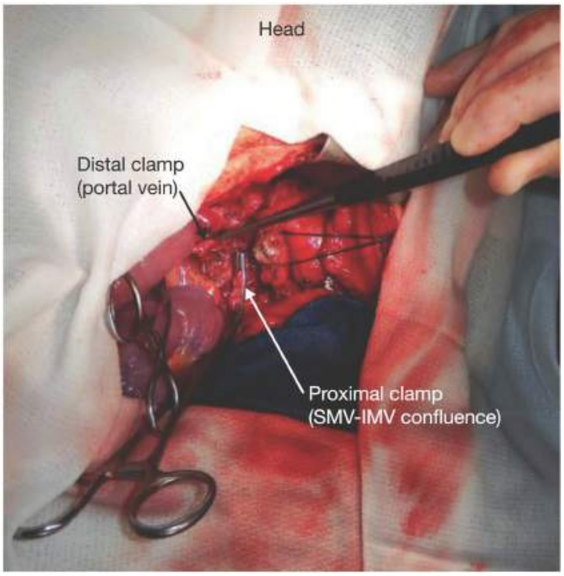
- Release the remaining clamps; place repair sutures as needed.

Primary End-to-End Anastomosis

- When the vein has been circumferentially excised to obtain a margin, a primary repair can often be accomplished. Typically, gaps of even greater than 2 cm can be closed by cephalad mobilization of the root of the mesentery.
- Begin by placing double-armed sutures at 3 o'clock and 9 o'clock positions (**FIG 12**). If there is a significant size mismatch, consider using interrupted sutures. The vein can usually be "rolled" 180 degrees to expose the posterior wall so that these sutures can be placed with good exposure.
- Begin a running suture line using one of the 3 o'clock position strands. Pass this outside in the distal (hepatopedal) vein orifice. Then, run the suture using exposure from the lumen side. At 9 o'clock position, pass the suture outside the lumen on the proximal side (hepatofugal) and tie it to one of the 9 o'clock position suture arms. Use care not to "purse-string" this posterior suture line. Some surgeons advocate not tying this suture until portal blood flow has been restored, thus allowing the suture line to "parachute" open and minimize the risk of narrowing the lumen.
- Run the anterior suture line from both the 3 o'clock and 9 o'clock positions so that the anastomosis is completed at the 12 o'clock position.
- Release the proximal clamp to degas the vessel and allow the suture line to parachute. Then, tie the sutures to complete the anastomosis and place repair sutures as needed.

Interposition Graft

- When the gap cannot be closed without undue tension, an interposition graft is indicated (**FIG 13**).
- Do not cut the conduit to length until the proximal anastomosis is completed.
- Each anastomosis is fashioned as described for the primary repair. The assistant maintains cephalad tension on the graft to facilitate the exposure.
- Minimize trauma to the endothelium of the conduit. When possible, only grasp the adventitia of the conduit with fine, atraumatic forceps.
- If the defect involves the splenoportal confluence, oversewing the SV is a reasonable option with acceptable morbidity. Reimplantation can be considered to avoid sinister portal hypertension and augment flow through the conduit thus theoretically reducing the risk of thrombosis.



A

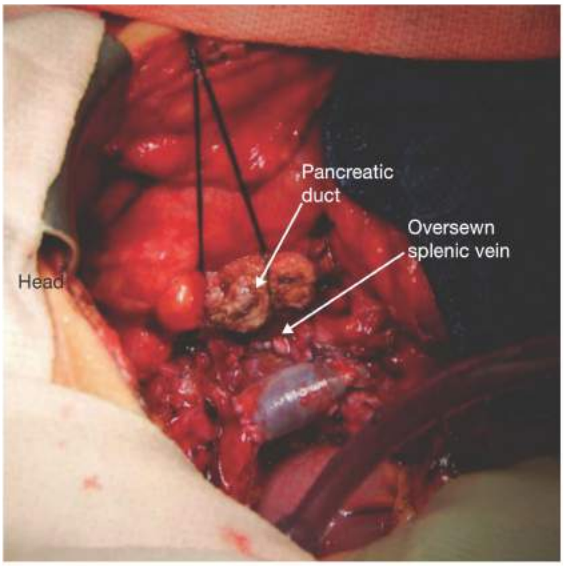
B,C,E

E

FIG 13 ● An interposition graft repair of the SMV/PV using a deep femoral vein conduit. In this example, the SMV/PV confluence has been resected. **A.** Intraoperative photograph of proximal and distal control with vascular clamps prior to placement of an interposition graft. The SV has been oversewn and is not visualized. As nearly 4 cm of vein was resected, an interposition graft will be required but will only be 2 cm in length. This is facilitated by the mobilization of the retroperitoneal attachments of the mesentery. **B.** Reconstruction begins with the proximal anastomosis using identical technique to that depicted in **FIG 12**. **C.** The distal anastomosis is then constructed. **D.** Intraoperative photograph during performance of a proximal anastomosis. **E.** Reimplantation of the SV is at the surgeon's discretion. If it is performed, portal flow can be re-established prior to beginning the anastomosis by placing a side-biting clamp on the conduit. *(continued)*



F

FIG 13 ● *(Continued)* **F.** Reperfused interposition graft—the SV has been ligated by oversewing with Prolene.

PEARLS AND PITFALLS

Preoperative planning	■ The key to successful PV resection and reconstruction is being prepared to perform the procedure. ■ Assess potential conduit and inform the patient of the possible need for a second surgical incision.
Operative technique	■ Dissect the uncinate process from the SMA prior to controlling and dividing the vein. This provides superior exposure to the posterior aspect of the vein, minimizes clamp time, and avoids the tedious and occasionally bloody dissection of the uncinate while the PV is clamped. ■ Gain early control of the SMV and PV. ■ Procure the reconstruction conduit prior to clamping the mesoportal vessels and completing the resection.
Postoperative care	■ Prescribe antiplatelet therapy.

POSTOPERATIVE CARE

- Administer an aspirin suppository in the recovery room and continue daily antiplatelet therapy at least until discharge. The authors continue enteric-coated aspirin (81 mg) indefinitely after surgery.
- Admit the patient to a monitored environment capable of frequent assessment of vital signs, drain output, and so forth.
- Instruct nursing team to immediately contact the service for a sudden increase in drain output; this can be the first sign of spontaneous thrombosis of the graft—early recognition of thrombosis is essential for any reasonable attempt at surgical revision.
- Bedside ultrasound with Doppler assessment is the first diagnostic modality to assess flow in the PV. Portal venous-phase CT can reliably assess patency of the PV.
- Return to the operating room or angiographic maneuvers to restore patency of a thrombosis have been reported but are rarely employed—reported patency rates of PV reconstruction exceed 90%.

OUTCOMES

- Morbidity, mortality, and disease-free and overall survival do not differ between standard resection and resection requiring a PV/SMV resection/reconstruction.[8]

COMPLICATIONS

- Bleeding
- PV thrombosis
- Deep venous thrombosis
- Venous insufficiency
- Harvest site wound morbidity

Chapter 40 Open Distal Pancreatectomy

Susanne G. Warner Rebecca M. Minter

DEFINITION

- Distal pancreatectomy is defined as resection of the body and tail of the pancreas with or without splenectomy with transection at any point distal to (left of) the superior mesenteric vessels. This chapter will discuss techniques and indications for open distal pancreatectomy and will focus predominantly on resection for malignancy.

PATIENT HISTORY AND PHYSICAL FINDINGS

- In the era of minimally invasive surgery, there are fewer indications for open distal pancreatectomy than ever before. Whenever possible, minimally invasive techniques for distal pancreatectomy should be pursued. Indications for open distal pancreatectomy are dictated either by the clinical circumstance mandating resection or by a comorbidity or contraindication to laparoscopy. Both can be identified during a thorough history and physical (Table 1). Patients suffering ductal rupture as a result of trauma or those with extensive adhesions or anatomic anomalies resulting from prior surgery are two such examples. Other conditions include a history of peripancreatic inflammation in the setting of acute or chronic pancreatitis or a malignant diagnosis with known vascular involvement. Local advancement into the retroperitoneum without evidence of distant spread is yet another indication.
- In an elective practice, the majority of distal pancreatectomies will be precipitated by suspicion for malignancy,[1] and those being performed open will likely have been selected as such, secondary to local extension of disease. This chapter will thus focus on oncologic principles of resection.
- A relevant history and physical examination in the setting of potential malignancy should include a detailed past medical history with discussion of known pancreatic cancer risk factors such as family history of pancreatic cancer, chronic pancreatitis, history of diabetes, obesity, and smoking. Character, duration, and mitigating factors of any abdominal or back discomfort or sensations should be discussed and considered carefully to guide differential diagnosis.

Table 1: Indications for Distal Pancreatectomy

Indications for Open Distal Pancreatectomy	Contraindications for Minimally Invasive Procedure
• Malignancy with concern for vascular involvement or substantial retroperitoneal local invasion	• Unable to tolerate pneumoperitoneum (i.e., severe cardiopulmonary disorder)
• Trauma/pancreatic duct disruption	• Untreated coagulopathy or liver failure
• Sequelae of acute/chronic pancreatitis (e.g., stricture or disconnected pancreatic tail)	• Documentation of hostile abdomen

- Medical comorbidities as well as cardiovascular and pulmonary functional status should be evaluated, and any relevant testing needed for preoperative clearance such as stress echocardiograms or pulmonary function tests should be performed in accordance with anesthesia guidelines.[2]
- A detailed past surgical history and special attention to family history can help identify patterns of hereditary malignant disease, which can in turn guide preoperative decision making, postoperative surveillance, and genetic testing of the patient and their families. If a neuroendocrine tumor is suspected, symptoms of functional tumors such as rash, diabetes, diarrhea, hypoglycemia, and signs of peptic ulcer disease should be discussed.
- A thorough physical exam should evaluate for any abdominal abnormalities such as organomegaly. Splenomegaly should raise concern for segmental portal hypertension, which could be precipitated by tumor thrombosis or vascular invasion. Hepatomegaly can imply the presence of hepatic metastases. Special attention should also be paid to a patient's nodal basins, specifically left supraclavicular and periumbilical nodes to evaluate for any palpable nodal metastases that would prompt a workup.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- The nature of preoperative testing depends heavily on the nature of the diagnosis. Most conditions will warrant further definition with laboratory evaluations and contrasted, cross-sectional imaging, at times, in conjunction with endoscopic ultrasound for tissue diagnosis and for definition of a pancreatic lesion as it relates to surrounding structures.
- Laboratory testing should include a complete blood count and a comprehensive metabolic panel, including evaluation of liver enzymes and amylase. A preoperative carbohydrate antigen 19-9 (CA 19-9) level is important for postoperative surveillance and can contribute to decision making when neoadjuvant therapy is being considered. When an endocrine tumor is suspected, functional urine and relevant hormone stimulation tests should be performed. If a patient has experienced substantial weight loss, a prealbumin level can be helpful in establishing nutritional status and can guide recommendations for perioperative supplemental alimentation, if appropriate.
- Preoperative workup of a pancreatic mass or injury should almost always include a contrasted, cross-sectional imaging study. Although there is some debate regarding the optimal choice of imaging modality, the most common standard is a computed tomography (CT) "pancreas protocol," which is a triple-phase CT that allows evaluation of arterial, pancreatic, and portal venous phases, and is critical to determining resectability and to establishing an appropriate operative plan. Three-dimensional reconstruction, where available, can also add insight regarding resectability. **FIG 1** demonstrates a lesion with adrenal involvement that would be appropriate for radical antegrade distal pancreatectomy.

FIG 1 ● CT scan showing distal pancreatic mass with adrenal involvement.

- In the case of cystic neoplasms of the pancreas, many surgeons use magnetic resonance cholangiopancreatography (MRCP) in order to assess cystic nature and communication with the main pancreatic duct or side branch ducts in order to further characterize risk of cystic lesion.
- Endoscopic ultrasound (EUS) is another available tool that can elucidate possible lymph node metastases and confirm spatial relationships between a mass and peripancreatic vasculature. EUS can also secure a tissue biopsy of the mass and any suspicious lymphadenopathy as relevant. EUS is not always needed if surgical planning can be completed with cross-sectional imaging, and the results of the EUS would not change the surgical plan. Multidisciplinary collaboration between surgeons and gastroenterologists is important to ensure the appropriate information is gathered and conveyed.
- The role of positron emission tomography (PET)-CT in pancreatic cancer staging for consideration of resection is currently poorly defined and is not currently considered standard of care.

SURGICAL MANAGEMENT

Preoperative Planning

- Preoperative imaging guides surgical treatment. Location of a tumor to the left of the superior mesenteric vessels obviates the possibility of successful disease eradication with a distal or subtotal pancreatectomy. The imaging studies mentioned earlier should be reviewed thoroughly. Close attention should be paid to the planned resection margins, as they relate to surrounding organs and vasculature; particular attention must be given to the retroperitoneal margin, major mesenteric and celiac vessels, left adrenal gland, and left renal vasculature and kidney. If a portion of the colon is involved, a bowel preparation should be considered in anticipation of en bloc colonic resection.
- The anesthesiology team should be informed in advance if a surgeon anticipates an arduous dissection that poses a risk for significant hemorrhage. A type and screen should be drawn on all patients to facilitate blood availability in case of emergent need.
- In addition to adequate peripheral or central intravenous access, a Foley catheter, nasogastric tube, and arterial line should be placed.
- Preoperative antibiotics should be administered within 1 hour of incision. Coverage should be broad spectrum and should include gram-positive skin flora as well as gram-negative and anaerobic intestinal pathogens.
- The entire abdomen from nipples to pubis should be shaved including flanks, even if a midline incision is anticipated. This facilitates subcostal and perixiphoid incisional extension if needed.

Positioning

- The patient is positioned supine with arms out unless precluded by patient shoulder mobility. The secure placement of the post of a self-retaining retractor should be considered.

INCISION

- Left subcostal and midline incisions are both reasonable choices; obesity and costal margin angularity should influence the exposure. Incision location varies based on patient body habitus, tumor location, and surgeon preference. Generally, a slender patient or a patient with a sharp costal margin angle is appropriate for a midline incision as this incision is less morbid. Other candidates for a midline incision are patients with previous midline incision and those with tumors closer to the midline. In obese patients or those with a particularly high splenic flexure or a tumor that is quite distal on the pancreas, a subcostal incision may provide enhanced visualization of the left upper quadrant.
- A vertical midline incision is made from xiphoid to just below the umbilicus.
- A left subcostal incision is made two fingerbreadths below the costal margin and is carried from the midline, obliquely to approximately the anterior axillary line.

INITIAL SURVEY AND EXPOSURE

- The abdomen is explored for signs of extrapancreatic metastases. The liver and peritoneal surfaces are visually examined and palpated. The omentum is examined for caking or nodularity. The gastrohepatic ligament and lymphatic tissues around the celiac plexus are inspected for any evidence of metastasis. Any unexpected findings should be biopsied and sent for frozen section analysis prior to an extensive dissection. When a distal pancreatectomy is anticipated, the head of the pancreas should also be examined and palpated in order to confirm the absence of major abnormalities.
- A self-retaining Omni-Trak or Bookwalter retractor should be placed. Our institutional preference is the Omni-Trak retractor as this provides superior exposure in the upper abdomen using the sternal retractors to elevate the costal margin.
- The splenic flexure is mobilized and reflected downward. In select patients, one may consider laparoscopic mobilization of the splenic flexure and division of the short gastric vessels prior to open distal pancreatectomy to allow for a more limited incision.

EXPOSURE OF THE PANCREAS

- The gastrocolic ligament is divided to gain entry into the lesser sac. The transverse colon is gently retracted inferiorly, taking care not to avulse the middle colic vein as it inserts into the superior mesenteric vein (SMV) at the inferior neck of the pancreas.
- The short gastric vessels are divided with an energy device, or rarely between clamps and ties. Any posterior gastric attachments to the pancreas are divided and the stomach is retracted superiorly to expose the anterior surface of the pancreas.
- In the case of a small lesion that is not readily visualized, the inferior attachments of the pancreas can be freed to facilitate posterior palpation. At the inferior border of the pancreas, gentle separation of pancreatic parenchyma from posterior attachments can be achieved. The splenic vein can be identified and isolated just to the left of its union with the portal vein (PV) usually beneath the pancreas. Intraoperative ultrasound can also be used to locate small lesions in the tail of the pancreas that are not readily identified.
- More typically, the celiac trunk is identified at the superior border of the pancreas and the hepatic and splenic arteries are identified and followed to their origins. The splenic artery is then ligated and divided using either a vascular stapler or silk ties, double securing with a stick tie (3-0 silk) followed by free tie (**FIG 2**).

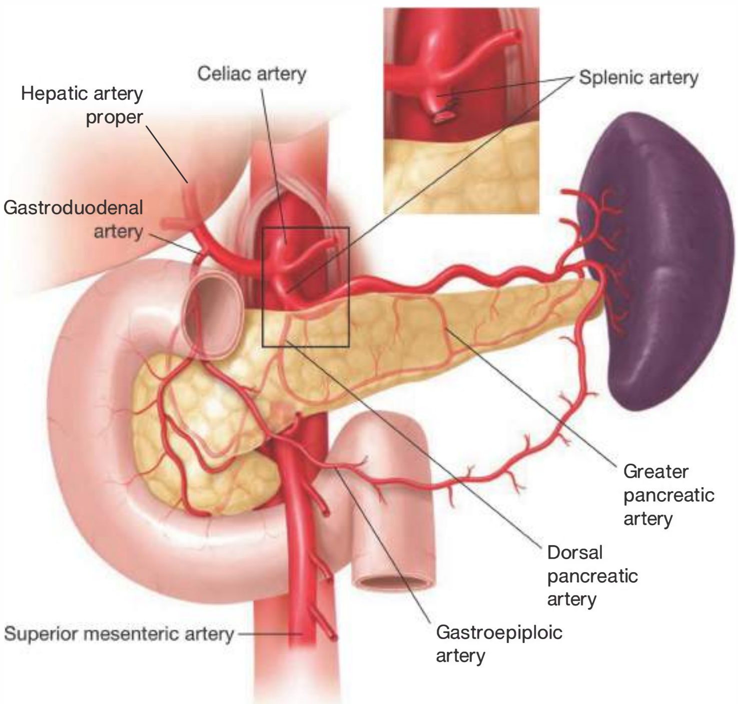

FIG 2 ● Splenic artery division.

CHOICE OF PANCREATIC DISSECTION TECHNIQUE

- As with any operation, there are a wide variety of techniques available to achieve the intended resection. One should decide preoperatively whether to undertake a lateral to medial (retrograde) or a medial to lateral (antegrade) resection and whether a spleen-preserving procedure is appropriate to consider. In the setting of malignancy, our preferred practice is typically a radical antegrade resection with N1 resection.

Splenectomy with Lateral to Medial (Retrograde) Dissection

- Beginning at the inferior pancreatic border, the posterior pancreatic attachments to the retroperitoneum are divided until the inferior mesenteric vein (IMV) and SMV are visualized (**FIG 3**). The pancreas is gently retracted anteriorly, which should help develop the avascular plane between the pancreas and retroperitoneum. The IMV is divided and the splenic vein is elevated with the specimen along the posterior aspect of the pancreas.

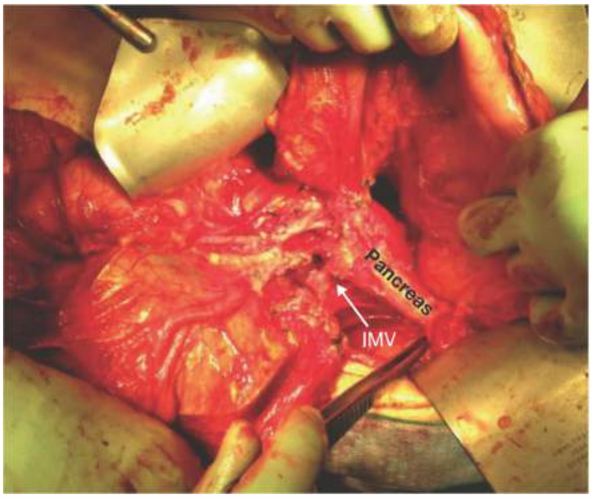

FIG 3 ● Exposure of inferior pancreatic border—SMV and IMV.

- With the body and tail freed, the lienorenal and lienophrenic attachments can be divided, and the spleen should be freed from the posterior abdominal wall. Posterior mobilization should be predominantly complete and the spleen and distal pancreas can be reflected medially. At this point, the splenic artery is identified, typically running along the superior border of the pancreas, although there can be significant anatomic variability including an intraparenchymal location. The splenic artery is isolated 2 cm proximal to the mass lesion at the site of planned parenchymal transection or just distal to its origin and divided between clamps. It is doubly secured with a stick tie and a free tie. The splenic vein can then be clearly followed to its confluence with the PV and can be divided and oversewn at the level of the PV.
  - With the distal pancreas now entirely mobilized, it should be palpated to ensure that anticipated point of transection is in fact free from the mass of interest or any other abnormalities. If the point of transection needs to occur proximal to the splenic vein/PV confluence and the PV is free of tumor, a plane on the anterior surface of the vein can be developed to facilitate pancreatic parenchymal transection closer to the pancreatic neck.
- Pancreatic transection is now performed (see "Pancreatic Transection" for details).

Splenectomy with Medial to Lateral (Antegrade) Dissection

- This is our preference for patients with locally advanced pancreatic cancer in the body or tail of the pancreas. This procedure may be more time consuming but facilitates early vascular isolation and enhanced lymph node procurement as well as early and safe establishment of margin status. With this technique, early pancreatic transection is necessitated.
- Once the greater omentum is elevated and the colon retracted inferiorly, the lesser sac is opened and the common hepatic artery is traced to the proper hepatic. The gastroduodenal artery is identified and occasionally requires division if a more proximal point of transection at the neck of the pancreas is required.
- Lymph nodes are dissected free of the left border of the proper hepatic artery, PV, and common hepatic artery. The avascular plane between the PV and posterior pancreatic neck is developed and the pancreatic neck is divided.
- The celiac trunk is identified and a celiac lymph node dissection is carried out from the superior border of the pancreas, ultimately exposing the origin of the splenic artery, which is then ligated as previously shown (**FIG 2**). The artery is typically ligated with a 2-0 silk free tie and a 3-0 silk stick tie but can also be stapled if the angle is appropriate and there is no compromise to the celiac trunk. Rarely, the left gastric artery warrants ligation at this juncture in order to facilitate complete lymph node dissection. However, this is not an option in the case of a replaced left hepatic artery, and it is very important to carefully review the preoperative CT angiogram preoperatively to be fully aware of any aberrant arterial anatomy.
- The splenic vein is encircled and divided at the junction with the PV. Dissection in a sagittal plane then proceeds until the superior mesenteric artery (SMA) is identified. The periaortic lymph tissue between the celiac trunk and SMA is then removed. An adequate dissection exposes the left side of the aorta from the origin of the SMA superiorly to the origin of the celiac trunk (**FIG 4**).
  - This dissection can be carried down onto the diaphragm, if necessary, to include the adrenal gland as part of the resected specimen if needed.
  - The left renal vein should be the inferior border of dissection. The adrenal vein is identified and remains undisturbed if the adrenal gland is not part of the specimen. Gerota's fascia is resected from the superior pole of the kidney in the case of more lateral malignancies.

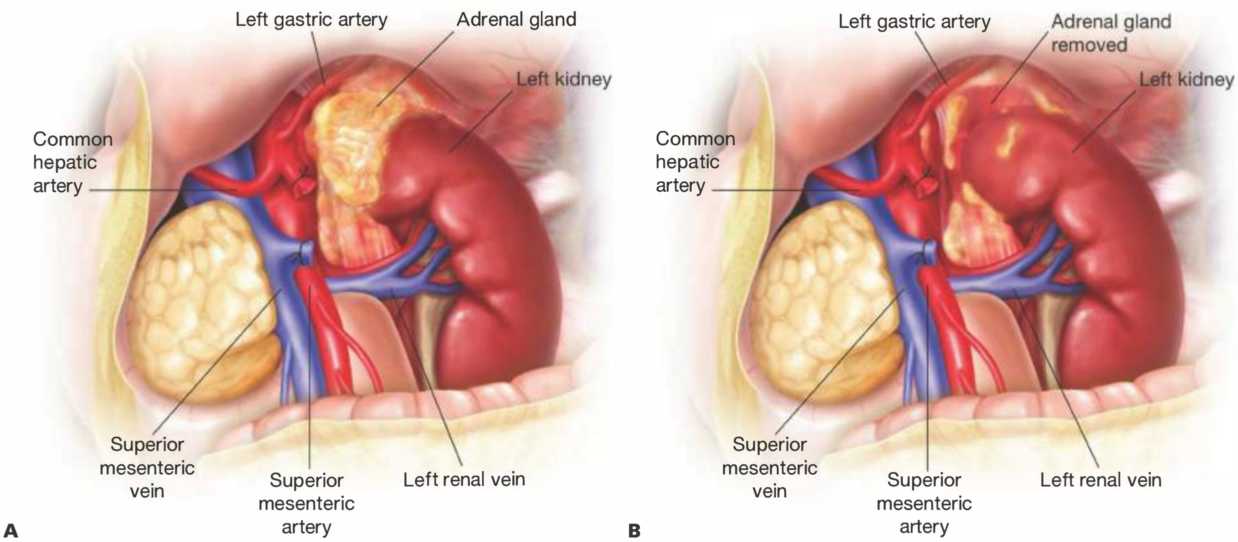

FIG 4 ● Exposure of left aorta from SMA to celiac trunk **(A)** with left adrenal in place, **(B)** with left adrenal removed.

- The superior and inferior pancreatic peritoneal attachments are then divided and dissection proceeds laterally. The IMV is ligated and transected and the spleen is separated from the kidney as the final operative step prior to specimen removal.
  - Although rare, adrenal resection is sometimes necessary and has been described in detail by Strasberg et al.[3]

Spleen-Preserving Distal Pancreatectomy

- Splenic preservation can be considered in the case of cystic lesions or small well-differentiated neoplasms for which a large radical excision is oncologically unnecessary.
- There are several techniques for splenic preservation:
  - The Warshaw[4] technique of dividing the splenic artery and vein proximal to the tumor and then again at the splenic hilum, leaving the short gastrics and as the primary blood supply for the spleen is occasionally attempted but is less commonly performed secondary to the severity of complications that can occur, namely splenic infarcts, splenic abscess, and gastric varices.
- The more common method of splenic preservation involves preservation of the splenic vessels and careful dissection of the vessels away from the posterior pancreas until the splenic hilum is reached. The small arterial and more numerous venous branches are isolated between clamps and ligated or controlled with a surgical energy device. FIG 5 shows the resection bed following spleen preserving distal pancreatectomy.

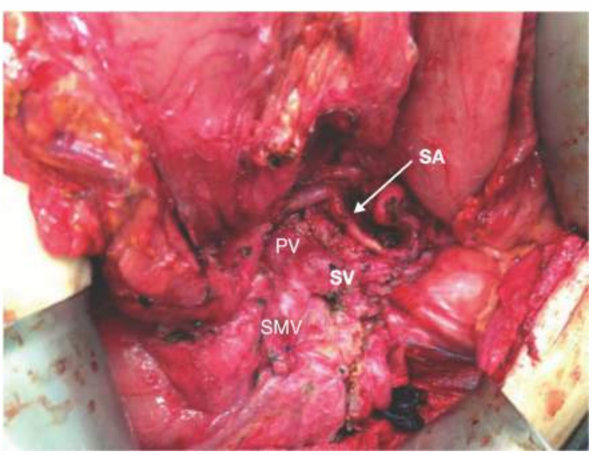

FIG 5 ● Resection bed following spleen preservation. SV, splenic vein; SA, splenic artery.

PANCREATIC TRANSECTION

- In cases of relatively nonedematous or nonfibrotic pancreatic parenchyma that is typically not greater than 1.5 cm in thickness, an Endo GIA stapler can be used to transect the pancreas (3.0-mm load). In cases of pancreatic edema or a thicker gland, an energy device can be used for parenchymal transection, and the line of transection is then oversewn using a running, locking 3-0 Prolene stitch. **FIG 6** shows pancreatic transection using a thoracoabdominal (TA) stapler.
- The specimen is removed and marked for margins on a back table. The surgeon may wish to walk to pathology personally to ensure specimen orientation and discussion of margins.
- The transected specimen should be sent to pathology for margin assessment—typically, the pancreatic margin is assessed and, if in question and there is the possibility of additional retroperitoneal clearance, then a frozen section on the retroperitoneal margin may be obtained as well. Serial sections may be required to establish adequate margins.
- The resection bed may be marked with clips for postoperative radiation if procedure is for a malignancy, particularly, if there is a margin which is felt to be in question following radical resection. A closed suction drain is left in the resection bed near the pancreatic stump. Size and type of drain are based on surgeon preference. In general, our practice is to use a 10-Fr flat Jackson-Pratt drain. The colon and stomach are placed in their usual anatomic position.

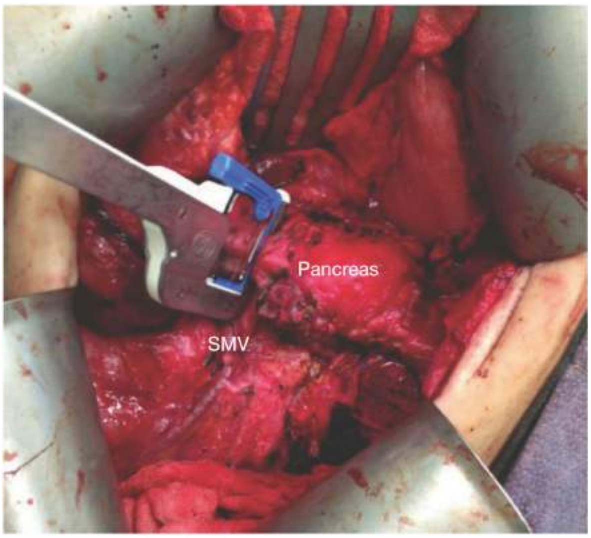

FIG 6 ● Pancreas division using TA stapler.

CLOSURE

- Midline fascial incision is closed using running looped 0 or 1-0 polydioxanone (PDS) suture. Skin is then reapproximated with interrupted 3-0 Vicryl deep dermal sutures and 4-0 Monocryl suture in a running subcuticular fashion.
- Subcostal fascial incision is closed in one or two layers using 0 or 1-0 PDS suture depending on surgeon preference.

PEARLS AND PITFALLS

Indications	▪ A complete history and physical and review of imaging must be performed to ensure the patient is an appropriate surgical candidate and to review for any aberrant anatomic considerations. If appropriate, minimally invasive techniques are preferred.
Incision	▪ Midline incision is preferred for more slender patients or those with a sharply angled costal margin. The splenic flexure can be mobilized laparoscopically for enhanced ease of dissection and potentially a more limited midline incision. ▪ Patients with high splenic flexure or those undergoing a splenic-preserving procedure may benefit from left subcostal incision.
Initial survey and exposure	▪ Retractor placement (Omni-Trak) ▪ Any unanticipated lymphadenopathy outside the planned plane of dissection or unexpected suspected metastases should be biopsied and sent for frozen section prior to any dissection. Be certain to examine the head of the pancreas.
Exposure of the pancreas	▪ When mobilizing the posterior stomach away from the anterior pancreas, vessels encountered between the gastrum and mesocolon should be ligated with care taken not to injure the middle colic vessels. Do not apply undue tension in retracting the colon down as the middle colic vein can be avulsed off the SMV.
Lateral to medial (retrograde) dissection	▪ If the point of transection needs to occur proximal to the splenic vein/PV confluence and the PV is free of tumor, a plane on the anterior surface of the vein can be developed to facilitate pancreatic parenchymal transection closer to the pancreatic neck. This may require ligation of the gastroduodenal artery.
Medial to lateral (antegrade) dissection	▪ During splenic arterial ligation, control is obtained proximal to anticipated site of ligation prior to tie or stapler placement. ▪ Prior to ligating the splenic artery, encircle and occlude it, then verify that the proper hepatic is still pulsatile to verify ligation of the correct structure. ▪ If needed, secondary to extensive posterior involvement, dissection can be carried down onto the diaphragm to include the adrenal gland as part of the resected specimen. ▪ If transverse colon involvement is suspected, a full bowel preparation is recommended in anticipation of possible en bloc resection.
Splenic preservation	▪ Splenic preservation can be considered in the case of cystic lesions or small well-differentiated neoplasms for which a large radical excision is oncologically unnecessary.
Pancreatic transection	▪ In cases of severe edema or fibrosis or a thicker gland (>1.2 to 1.5 cm), hemostasis and pancreatic duct closure can be incomplete with the use of a stapler. In this instance, our preference is to use and energy device to transect the pancreas. ▪ Regardless of transection method, the pancreatic stump is always oversewn using a running, locking 4-0 Prolene suture.
Specimen analysis	▪ It is important to work with pathology colleagues both on specimen orientation and to encourage appropriate nodal retrieval analysis. Inking of margins by the surgeon is encouraged.

POSTOPERATIVE CARE

- Blood glucose should be closely monitored postoperatively. Development of diabetes in the postoperative setting is widely variable, ranging from 9% to 40% and may depend on the preoperative pancreatic function and severity of chronic pancreatitis.[5] Whichever the case, blood glucose must be closely monitored in the perioperative setting and at regular intervals in the long term.
- A transient elevation of pancreatic enzymes may be noted but should trend down within several days. Closed suction drainage should remain in place until the patient's diet has been advanced, and drain output should be monitored for signs of pancreatic fistula. Although there is a trend toward drainless pancreatic surgery, it remains our preference to use a closed suction drain to monitor for postoperative fistula. The reported incidence of fistula is 9% to 35%, regardless of pancreatic transection technique. If there is persistent amylase-rich output at 4 weeks postoperatively, the patients are treated with pancreatic duct stenting, which typically resolves the fistula and allows for drain removal.
- We typically begin clear liquid diet on postoperative day 2, depending on patient status. From there, diet is advanced in the standard fashion, based on patient distension and abdominal comfort level. Postoperative nasogastric tube placement is not used as a standard, although in the case of a longer operative duration with retraction of the stomach upward and more extensive dissection, it may be used for 24 to 48 hours after surgery.
- Once diet is advanced, providers should be vigilant for symptoms of pancreatic insufficiency even if blood glucose control remains adequate. Many patients will benefit from perioperative pancreatic enzyme supplementation, particularly if they had any underlying chronic pancreatitis preoperatively. Approximately 17% will need supplementation in the long term.[6]

- For any patients undergoing pancreatic resection, it is important that they are monitored by their primary care physicians for vitamin D deficiency and osteoporosis in the long term at their health maintenance exams, which can result from long-standing pancreatic exocrine insufficiency. The surgeon should communicate this surveillance need to the patient's primary care physician, as they may otherwise be unaware of this possible disease-specific deficiency.

OUTCOMES

- An R0 resection should be the goal in every oncologic resection. Long-term results for distal pancreatectomy vary significantly based on pathology. With adenocarcinoma of the body and tail of the pancreas, long-term results of the antegrade technique have shown improved negative margin rates with only 9% positive tangential margins in recent years as compared to the more traditionally observed approximate 25% R1 resection rate seen with the retrograde method.[7] With the antegrade method, Strasberg and colleagues[3] are reporting an actual 5-year survival of 30.4% with an actuarial survival of 35.5%. However, one must bear in mind that most of the evidence surrounding open distal pancreatectomy for malignancy is underpowered, single-institution, and retrospective in nature.

COMPLICATIONS

- Most of the available outcomes data for distal pancreatectomy exists as retrospective case series or large reviews of case series. Therefore, reporting of certain complications is highly variable.
- Overall complication rates are reported as high as 40% for open distal pancreatectomy in large series.[5,8]
- The data regarding pancreatic bed and subphrenic abscesses is conflicting with some authors demonstrating increased abscess formation following spleen-conserving surgery, and others reporting the opposite.[9,10] With increasing popularity of splenic preservation as more solid and cystic pancreatic lesions are identified incidentally, a more clear picture of benefit and risk of splenectomy versus splenic preservation will hopefully emerge.

Chapter **41**

Minimally Invasive Distal Pancreatectomy

Paul D. Hansen   W. Cory Johnston

DEFINITION

- Laparoscopic and robotic approaches to distal pancreatectomy were initially reserved for small, benign lesions of the pancreatic body and tail. As surgical expertise and refinements of the techniques progressed, indications have expanded to include larger lesions and invasive malignancies.
- Minimally invasive resections are now commonly performed in cases of malignant neoplasms with oncologic outcomes equivalent to open resection in experienced hands.
- The decision to attempt splenic preservation is dictated by the underlying pathology, the size and location of the lesion, and its relationship to the spleen and splenic vasculature.

DIFFERENTIAL DIAGNOSIS

- Pancreatic adenocarcinoma
- Pancreatic neuroendocrine tumors
- Cystic pancreatic lesions
- Pancreatic metastases
- Sequelae of chronic pancreatitis

PATIENT HISTORY AND PHYSICAL FINDINGS

- Tumors of the pancreatic body and tail are typically asymptomatic and are, therefore, more likely to manifest in the later stages of disease progression. Consequently, regional and distant disease is commonly encountered during the initial evaluation or at the time of surgical exploration.
- Careful attention should be made in the history and physical examination to elicit symptoms and signs of advanced disease including back pain from invasion of the celiac plexus, nausea and early satiety from invasion or compression of the stomach or duodenum, and splenomegaly caused by thrombosis of the splenic vein.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- The primary imaging modality is pancreatic protocol, multiphase computed tomography (CT) scans including precontrast, arterial, and portal venous phases. 1- to 3-mm cuts with coronal and sagittal reconstructions allow a detailed analysis of the pancreas, the pathologic target, and the surrounding vasculature and viscera (**FIGS 1–3A**). Abdominal and pelvic CT is also useful in identifying the presence of lymphadenopathy, metastatic peritoneal or omental implants, and hepatic metastases. In patients with known or suspected pancreatic adenocarcinoma, a staging chest CT is also recommended.
- Abdominal magnetic resonance imaging (MRI) is slightly more sensitive in identifying liver metastases but provides less anatomic soft tissue detail regarding the pancreas and vasculature. Magnetic resonance cholangiopancreatography (MRCP) can be helpful in grossly examining ductal anatomy but does not provide fine detail. MRI requires a higher degree of patient cooperation but may be helpful in patients with contrast allergies or other contraindication to contrast-enhanced CT.
- Endoscopic ultrasound (EUS) is operator-dependent but can result in a more accurate assessment of tumor size and relationship to the portal and superior mesenteric veins (SMV) (**FIG 1B**). Assessment of superior mesenteric artery (SMA) and celiac involvement is no better than CT. Tissue sampling via ultrasound-directed fine needle aspiration (FNA) of primary tumor or regional lymph nodes may provide confirmatory tissue diagnosis. EUS-guided sampling of fluid from pancreatic cystic lesions may help distinguish between benign and premalignant tumors.
- Endoscopic retrograde cholangiopancreatography (ERCP) can be useful in providing fine details of pancreatic and bile duct anatomy, such as dilatation, strictures, luminal defects, or masses.

A

B

FIG 1 ● **A.** Venous-phase CT showing a hypodense mass in the pancreatic body adjacent to the splenic artery. The distal pancreatic duct is dilated. **B.** EUS showing the pancreatic body mass with direct abutment with the splenic artery (SA).

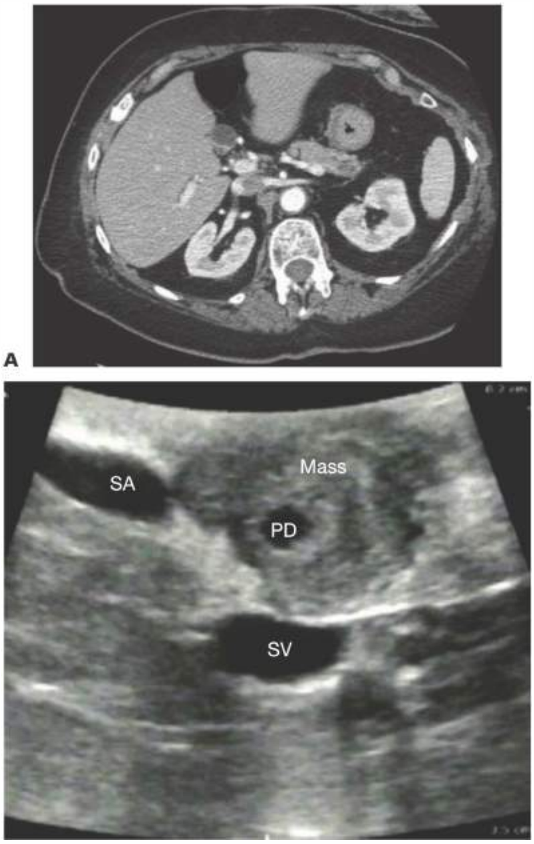

FIG 2 ● **A.** Venous-phase CT showing an irregular hypodensity in the pancreatic tail. This was proven to be a ductal adenocarcinoma on EUS/FNA. **B.** IOUS image showing an irregular, hypoechoic mass in the pancreatic tail around the pancreatic duct (PD). The mass abuts both the splenic vein (SV) and the splenic artery (SA).

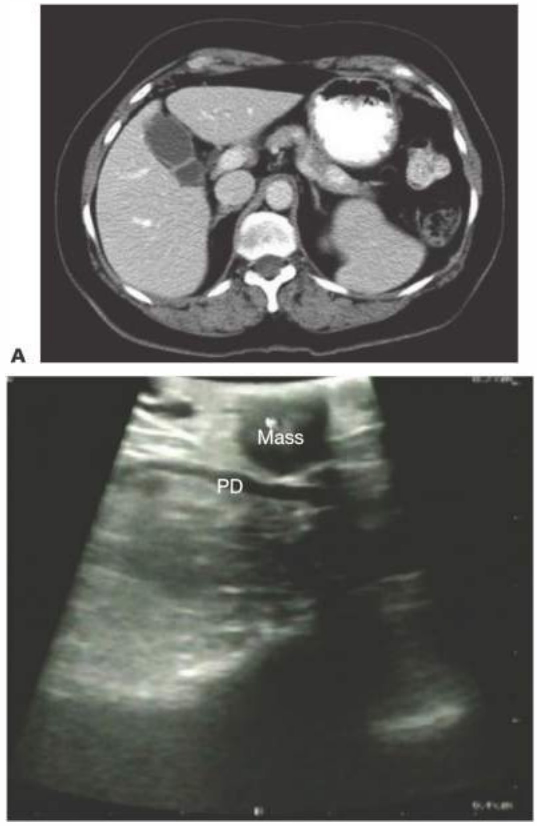

FIG 3 ● **A.** Venous-phase CT showing a rounded hypervascular mass in the pancreatic tail. The patient presented with symptomatic hypoglycemia. The tumor was proven to be an insulinoma by EUS/FNA. She was treated with a spleen-preserving distal pancreatectomy. **B.** IOUS showing the insulinoma at the time of resection. The deep margin was within 2 mm of the pancreatic duct (PD).

- Intraoperative ultrasound (IOUS) is used routinely to define the relevant pathology, to identify important vascular structures, and to determine resectability during operative staging (**FIGS 2B** and **3B**).

SURGICAL MANAGEMENT

Preoperative Planning

- Feasibility of resection should be determined preoperatively based on cross-sectional imaging and EUS. We use National Comprehensive Cancer Network (NCCN) guidelines for resectability based on the tumor's relationship to the SMA and celiac trunk.[1] Portal, superior mesenteric, splenic, and left renal vein involvement do not preclude resection but may suggest a role for neoadjuvant therapy.[2] Resection of the celiac trunk with reconstruction of the hepatic artery has been described in numerous series, but most major American centers have not adopted this approach.[3]
- The extent of gland resection is variable and should be directed by tumor location within the pancreas and its relationship with relevant blood vessels. Lesions in the tail of the pancreas can be resected with preservation of the neck and body, whereas more proximal lesions may require division of the gland closer to the portal vein. The gastroduodenal artery (GDA) is generally considered the landmark for the proximal limit of transection, as division of the pancreas more proximally places the intrapancreatic bile duct at risk of injury.
- The decision to include the spleen in the resection is typically made preoperatively based on surgeon preference and the characteristics of the tumor. If malignancy is suspected, the spleen and lymphatic tissue along the splenic vessels should be resected en bloc with the pancreas. Cystic lesions that are considered low risk for malignancy can be considered for a spleen-preserving approach. Intraoperative findings may alter plans for spleen preservation.
- Central venous access is typically not necessary as long as reliable, large-bore peripheral intravenous (IV) lines are established. An arterial blood pressure catheter can be placed at the discretion of the anesthesiologist.

Positioning

- The patient is positioned supine or, in some cases, in a gentle right semilateral decubitus position on a padded mattress.

The arms are supported on arm boards at just under 90 degrees to prevent stretch of the brachial plexus. Alternatively, the arms may be tucked at the patient's side to facilitate placement of fixed retractors.

- During the dissection, the operating table is positioned in reverse Trendelenburg with the left side slightly elevated so that the hollow viscera fall caudad and to the right, away from the operative field.
- The position of the operating surgeon depends on the position of the tumor within the pancreas and may change during the procedure. During mobilization of the stomach and colon, the surgeon is typically on the patient's right with the assistant on the patient's left. Once the body and tail of the pancreas are exposed, the surgeon's position depends on tumor location. If the tumor is distal and the transection of the pancreas will be in the body, the surgeon stays on the patient's right. If the tumor is in the proximal body and the point of transection will be at the pancreatic neck, the dissection may be easier by having the surgeon stand on the patient's left. This facilitates the surgeon's ability to dissect along the superior mesenteric and portal veins and create the window behind the neck of the pancreas.
- We typically use a 10-mm high-definition (HD) laparoscope to ensure optimal visualization. Alternatively, a 5-mm HD laparoscope may be used.
- We prefer to use dual carbon dioxide (CO_2) insufflation devices. This can be valuable in cases where bleeding occurs, as laparoscopic suction devices can rapidly decompress pneumoperitoneum.

DIAGNOSTIC LAPAROSCOPY

Port Placement

- For exploratory laparoscopy, we start with two ports. The first is typically 11 or 12 mm and placed just below the umbilicus. The second is an 11 or 12 mm and placed just lateral to the left rectus muscle, at the level of the umbilicus. These ports facilitate peritoneoscopy and laparoscopic ultrasound examination.
- Two or three additional ports are placed, depending on the complexity of the procedure and on the position of the tumor within the pancreas (**FIG 4**).
- A high, right 5-mm subcostal port will ultimately serve to retract the stomach cephalad to expose the pancreas. Additional 5-mm ports may be placed just lateral to the right rectus muscle above the level of the umbilicus or laterally along the left subcostal margin. Which ports are used for the camera, surgical dissection, or assistant's retraction will depend on the position of the tumor as described earlier.

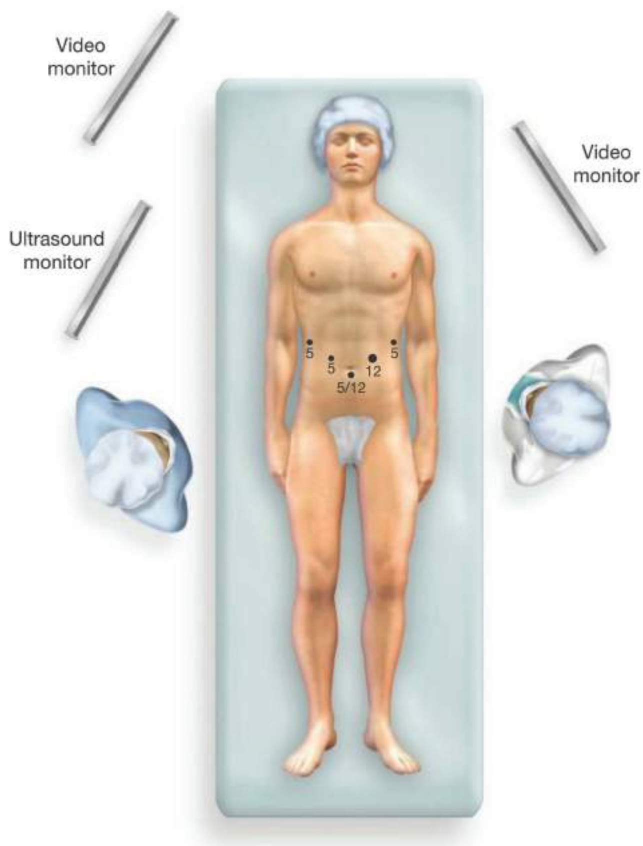

FIG 4 ● Illustration showing port positions. The patient is positioned supine with the left side bumped slightly with a padded wedge. The arms can be tucked or extended. The surgeon can stand on either side; typically, patient's right for distal tumors and patient's left for proximal tumors.

- A hand port may be used at the surgeon's discretion. Hand assistance can be very useful for large tumors that invade the surrounding viscera, inflammatory masses, and proximal tumors that abut the celiac axis. The optimal position of the port is variable. Right-handed surgeons will prefer to have the left hand in the port, and a lower midline position is preferred. Left-handed surgeons typically prefer to have their right hand in the port, which should be positioned laterally beneath the left costal margin.

Examination of Peritoneum and Viscera

- The entire peritoneal surface is examined for carcinomatosis. Suspicious lesions are biopsied and sent for immediate pathologic analysis.
- The abdominal viscera are likewise examined and any suspicious lesions are sampled. Although we look at the omentum and easily accessible viscera, we typically do not "run the bowel" unless otherwise indicated.
- The root of the small bowel mesentery and the undersurface of the transverse mesentery are examined in cases of large malignant tumors and those located in the central pancreas.
- Ascitic fluid is sent for cytology.

Intraoperative Ultrasound

- The liver is systematically examined for evidence of metastases. Surface lesions are wedged out with a small margin and sent for frozen section analysis. Intraparenchymal nodules are biopsied with a coring needle and sent for immediate pathologic analysis.
- The pancreatic parenchyma is examined. The exact location and dimensions of the tumor are determined as well as its relationship to the duct (**FIG 3B**).
- The relationship of the tumor to the SMA, SMV, splenic vessels, and left renal vein is determined (**FIG 2B**). The intended location of pancreatic gland transection is estimated.
- Paraaortic lymph nodes as well as those along the origins of the celiac trunk and the SMA are examined. Suspicious lymph nodes outside the limitations of the proposed resection should be biopsied and sent for frozen section.
- The procedure is terminated or a predetermined palliative bypass is performed if diagnostic laparoscopy reveals metastatic or locally unresectable disease.

LAPAROSCOPIC DISTAL PANCREATECTOMY AND SPLENECTOMY

Mobilization of the Splenic Flexure

- With the patient in reverse Trendelenburg position with the left side rotated up, the lateral peritoneal reflection is incised and the proximal descending colon is medialized. The distal transverse colon and splenic flexure are brought down away from the inferior splenic pole. This dissection occurs in the avascular plane between Gerota's fascia and the mesocolon.
- The inferior pole of the spleen is mobilized by dividing the avascular retroperitoneal attachments.
- The lesser sack can be entered anterior to the tail of the pancreas during this dissection. This "clockwise approach" is described by Asbun and Stauffer[4] and can be useful for exposure of the pancreatic body via a left to right division of the gastrocolic ligament (**FIG 5A,B**).

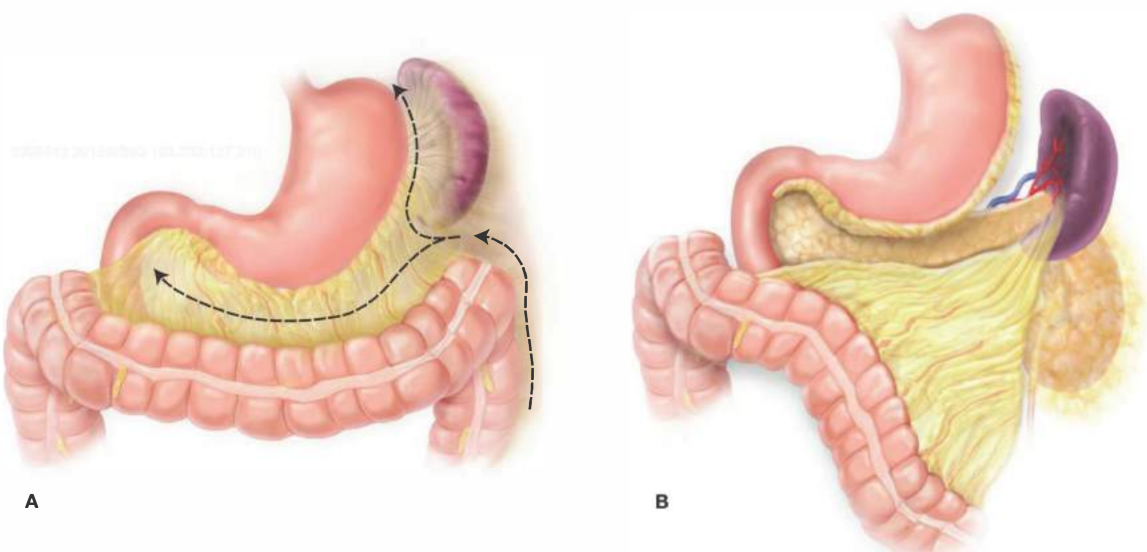

FIG 5 ● Illustration showing "clockwise" technique for exposure of the distal pancreas. **A.** The left colon and splenic flexure are mobilized from left to right. The lesser sack is entered in the plane between the pancreatic tail and the transverse mesocolon. **B.** The gastrocolic and gastrosplenic ligaments are then divided to expose the pancreas and to drop the transverse colon out of the field of dissection.

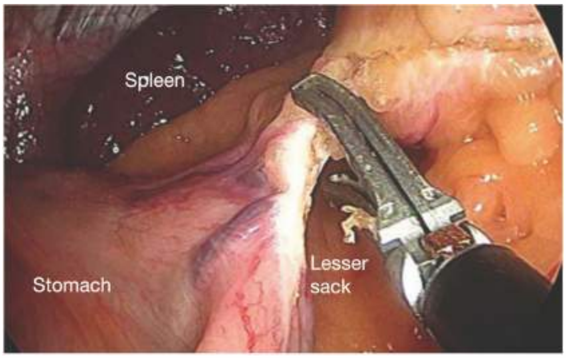

FIG 6 ● Operative image showing division of the short gastric vessels between the greater curvature and the spleen. These vessels can be taken safely with bipolar or ultrasonic coagulating devices unless they are engorged due to splenic vein thrombosis.

Entry into the Lesser Sack and Division of the Short Gastric Vessels

- Preserving the right gastroepiploic arcade, the lesser sack is traditionally entered through the gastrocolic ligament just below the greater curve of the stomach. The gastrocolic and gastrosplenic omentums are then divided from right to left using ultrasonic shears or a bipolar electrocautery device (**FIG 6**).
- Enlarged venous collaterals may be present in this area if the splenic vein is invaded or thrombosed. A linear stapler or individual vessel ligation with clips or ties is often preferred for division of varices greater than 3 mm in diameter.
- Mobilization of the fundus continues all the way to the left crus. The posterior wall of the stomach is mobilized anteriorly to completely expose the body and tail of the pancreas. Avascular congenital adhesions are frequently present between the stomach and pancreas and can be divided bluntly or with electrocautery (**FIG 7**).
- For proximal tumors of the pancreatic body, the dissection continues toward the patient's right. The transverse mesocolon is swept caudally in an avascular plane that exposes the middle colic and gastroepiploic vessels, which are followed to their confluence with the SMV. The anterior surface of the SMV is cleared cephalad in its adventitial plane up to the inferior margin of the pancreas.

Mobilization of the Pancreatic Body and Tail

- The stomach is retracted anteriorly, away from the pancreas using a liver retractor or by suturing the greater curve to the abdominal wall (**FIG 8**).
- Using electrocautery or ultrasonic energy, the retroperitoneum is incised along the inferior border of the pancreas from medial to lateral. Gentle retraction is used on the pancreas, as it is prone to tearing and bleeding.
- The line of transection of the pancreas is dictated by the location of the pathology. Tumors from the tail to the midbody can be resected with a generous margin by transecting the proximal pancreatic body. Tumors involving the proximal body require subtotal distal pancreatectomy with gland transection of the pancreatic neck anterior to the SMV. Tumors involving the pancreatic neck require transection to the right of the SMV. The most proximal resection plane is where the GDA passes anterior to the pancreatic head. Attempts to resect further to the right may result in injury to the intrapancreatic bile duct.
- The plane between the posterior wall of the pancreas and the retroperitoneal fat is entered and the gland is mobilized anteriorly with blunt dissection or electrocautery.
- The pancreatic tail is mobilized anteriorly, taking care not to enter the splenic hilum. The plane of this dissection will intersect in the lesser sack with the plane previously opened during mobilization of the splenic flexure of the colon.
- The retroperitoneum along the superior margin of the pancreas is divided along the length of the gland. The splenic artery is frequently seen in a superficial retroperitoneal plane and can be dissected and encircled with a vascular loop.

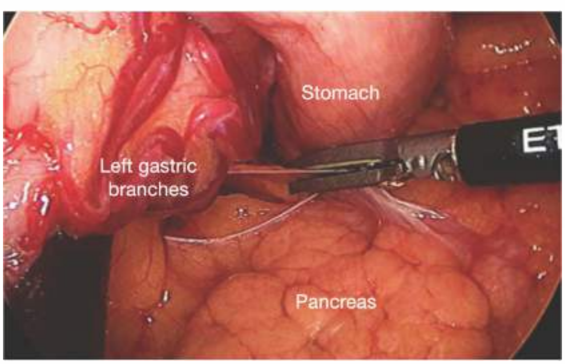

FIG 7 ● Operative image demonstrating the division of the congenital adhesions from the posterior wall of the stomach to the pancreatic body.

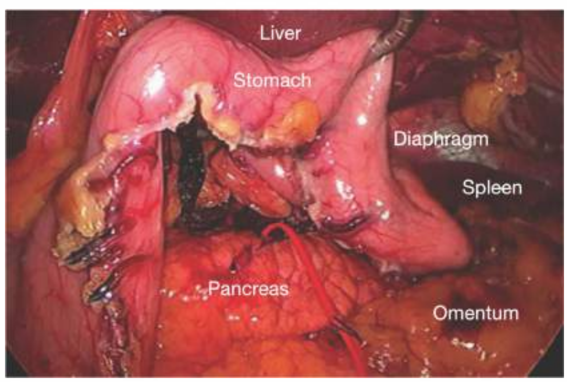

FIG 8 ● Operative image showing excellent exposure of the pancreatic body after division of the gastrocolic omentum and elevation of the stomach with a retractor placed through a right upper quadrant port.

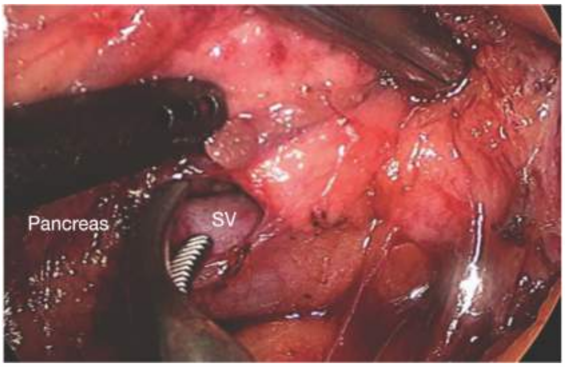

FIG 9 ● Operative image demonstrating dissection of the splenic vein behind the posterior aspect of the pancreatic body. A window is created between the splenic vein and the superior edge of the pancreas. The splenic artery is often seen behind the vein from this perspective.

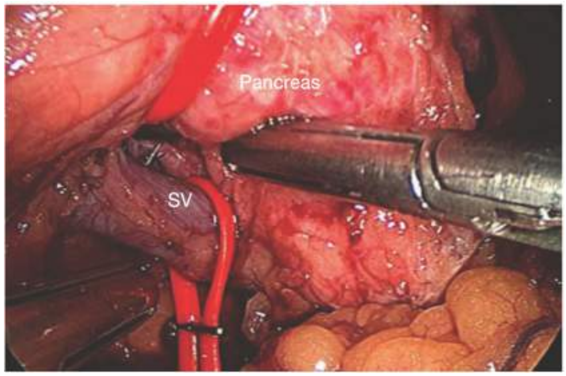

FIG 11 ● Mobilization of the splenic vein (SV) away from the posterior wall of the pancreas, and encirclement of the vein with a vascular loop to facilitate retraction.

Isolation and Division of the Splenic Vein

- Ultrasound is used to confirm the location of the tumor and to select an appropriate line of gland transection. The splenic vessels are also visualized and their relationship to the pancreas is noted (**FIG 2B**). For distal tumors, the vein is dissected and divided behind the pancreatic body. For proximal tumors, the SMV/splenic vein confluence is dissected behind the pancreatic neck and the splenic vein is divided here.
- With the pancreas reflected anteriorly and cephalad, the splenic vein is located behind the pancreas in the intended region of transection. The vein may be partially or completely enveloped in pancreatic tissue, particularly at the more distal aspects of the gland.
- A curved dissector is used to enter the adventitial plane around the vein and create a tunnel between the vein and pancreas (**FIG 9**). The tunnel is extended cephalad and anteriorly up to the superior margin of the pancreas. The splenic artery may be encountered and exposed during this dissection.
- A short vessel loop may be passed around the pancreas and the tails retracted anteriorly, facilitating excellent exposure to the splenic vein (**FIG 10**).
- The splenic vein is dissected circumferentially and may be encircled with a second vessel loop. The loop is used for retraction as the vein is mobilized away from the pancreas along a sufficient length to provide passage of a linear stapler (**FIG 11**).
- The vein is divided with a linear vascular stapler or between locking clips or nonabsorbable ties. If the vein is closely opposed to the pancreas at the point of transection, it can be included in the staple line if a linear stapler is used.
- For proximal tumors, the anteromedial surface of the SMV is bluntly dissected away from the pancreatic neck to expose the confluence of the splenic vein (**FIG 12**),

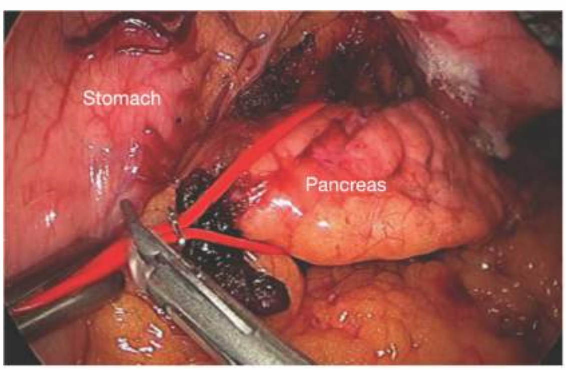

FIG 10 ● Operative image of the mobilized pancreatic body. Passage of a vascular loop around the pancreas helps with retraction during vascular dissection and positioning of the stapling device.

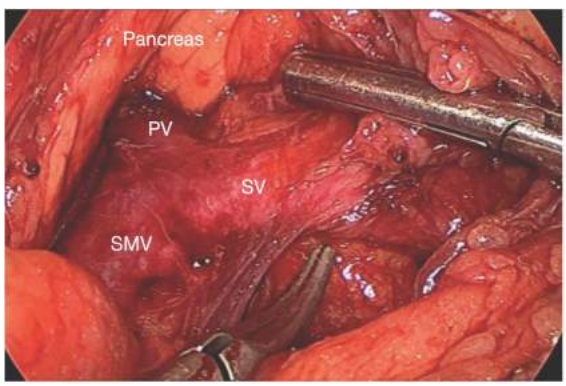

FIG 12 ● Operative image showing the dissection of the SMV/splenic vein (SV)/portal vein (PV) confluence behind the neck of the pancreas. This is the margin of transection for more proximal tumors of the pancreatic body. Pathology involving the pancreatic neck requires division of the pancreas even further to the patient's right in the region of the GDA.

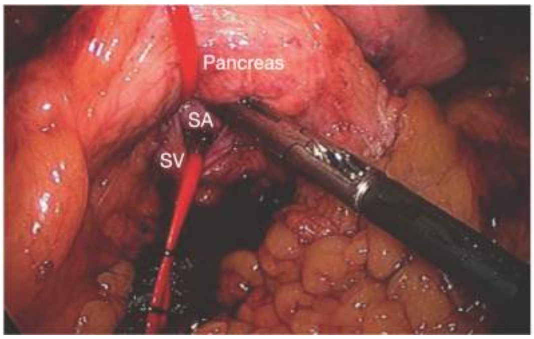
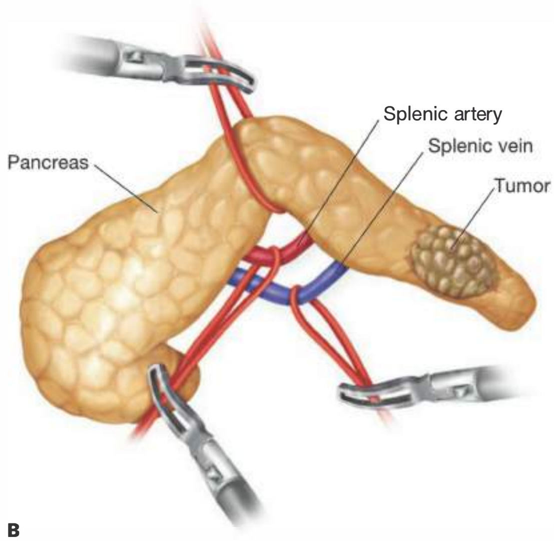


A



B

FIG 13 ● **A.** Operative image demonstrating anterior retraction of the pancreas to expose the splenic vein (SV; looped and retracted posteriorly) and the splenic artery (SA). **B.** Illustration demonstrating anterior retraction of the pancreas to expose the SV (looped and retracted posteriorly) and SA.

which can then be encircled and divided either proximal or distal to the inferior mesenteric vein (IMV) confluence.

Isolation and Division of the Splenic Artery

- The splenic artery is typically encountered cephalad to the splenic vein along the superior edge of the pancreas, although it is a tortuous vessel and its course can be unpredictable (**FIG 13**).
- As with the splenic vein, the region of dissection and division of the splenic artery varies with tumor location. For tumors of the tail and midbody, the artery is divided distal to its origin from the celiac. For tumors of the proximal body and neck, the artery is divided at its origin.
- The artery is cleared circumferentially and encircled with a vessel loop (**FIG 14**). We recommend routine use of IOUS in proximal transections to confirm isolation of the splenic artery, as inadvertent division of the celiac trunk and common hepatic artery have been reported (**FIG 15A–C**).
- The artery is divided with a linear vascular stapler, between locking vascular clips or between permanent suture ligatures (**FIG 16**).
- Alternatively, the splenic artery can be included in the pancreatic staple line for distal transections. We do not recommend this for more proximal tumors, as the celiac trunk or hepatic artery may be at increased risk of inadvertent incorporation into the staple line.

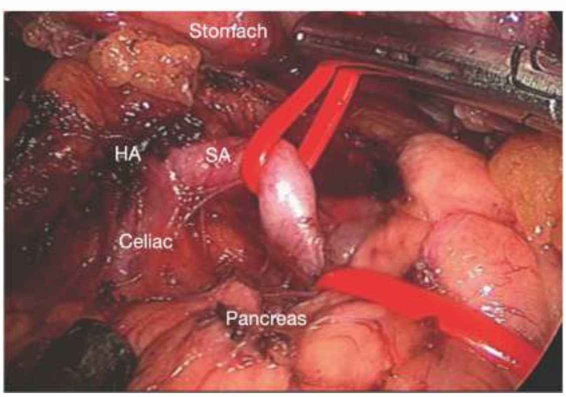


FIG 14 ● Operative image showing the splenic artery (SA) just distal to its origin from the celiac axis. The artery is looped to assist with retraction during vascular dissection. *HA*, hepatic artery.

Division of the Pancreas

- Once sufficiently mobilized away from the splenic and mesenteric vessels, the pancreas can be transected at any point in the operation. We prefer to divide the gland early on, as this will greatly enhance exposure of the underlying vascular structures.
- The line of gland transection is determined by the location of the pathology. A minimum 1-cm margin is desirable for malignant tumors, and this can be confirmed with immediate frozen tissue examination. The proximal (or right-sided) limit of transection is typically the plane where the GDA crosses the anterior aspect of the pancreatic head.
- The perfect method of dividing the gland and controlling the pancreatic duct remains elusive. Numerous techniques have been applied with similar rates of leakage from the pancreatic stump.
- Soft glands that are relatively thin (<2.0 cm in thickness) are best divided with a linear stapler (**FIG 17**). Biologic or synthetic Seamguard have been used with mixed results. We recommend slow compression of the gland prior to division, as this minimizes parenchymal lacerations that can result in postoperative leaks.

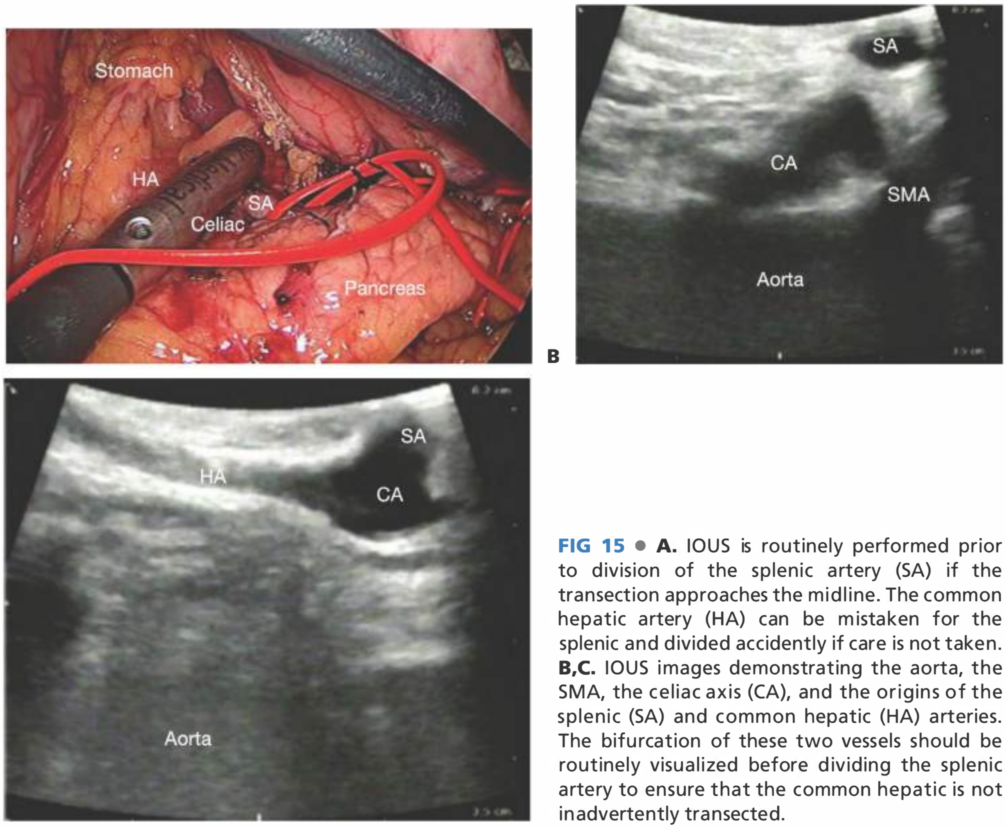

FIG 15 ● **A.** IOUS is routinely performed prior to division of the splenic artery (SA) if the transection approaches the midline. The common hepatic artery (HA) can be mistaken for the splenic and divided accidently if care is not taken. **B,C.** IOUS images demonstrating the aorta, the SMA, the celiac axis (CA), and the origins of the splenic (SA) and common hepatic (HA) arteries. The bifurcation of these two vessels should be routinely visualized before dividing the splenic artery to ensure that the common hepatic is not inadvertently transected.

- Fibrotic or thick glands can be divided with linear staplers, electrocautery, saline-enhanced monopolar cautery, or Harmonic scalpel. The pancreatic duct should be identified during the division.
- The pancreatic duct can be secured with either mattressed sutures or a bipolar tissue-sealing device.

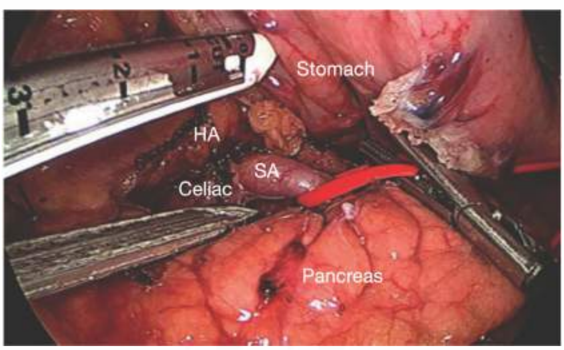

FIG 16 ● Operative image showing placement of a vascular stapler across the splenic artery (SA) near its origin from the celiac axis. A vascular loop around the artery helps with retraction during positioning of the stapler. *HA*, hepatic artery.

Dissection of the Specimen off the Retroperitoneum

- After division of the pancreas and splenic vessels, the specimen is swept off the retroperitoneum in an avascular plane anterior to the left adrenal gland and Gerota's fascia, typically using hook electrocautery or an ultrasonic dissector.
- The remaining retroperitoneal and diaphragmatic attachments to the spleen are divided, completing the mobilization of the specimen.

Extent of Lymphadenectomy

- In the setting of suspected malignancy, en bloc distal pancreatectomy and splenectomy should be performed with the intention of harvesting the lymphatic tissue within the splenic hilum and along the splenic vessels.
- For pancreatic neuroendocrine tumors, cystic neoplasms, and small (<3 cm) pancreatic adenocarcinomas, the earlier description typically results in an adequate lymphadenectomy.
- For larger adenocarcinomas, a more extensive lymphadenectomy may be desired. Laparoscopic D1 lymph node dissection with skeletonization of the celiac trunk, SMA, and lateral aorta along with resection of the left adrenal

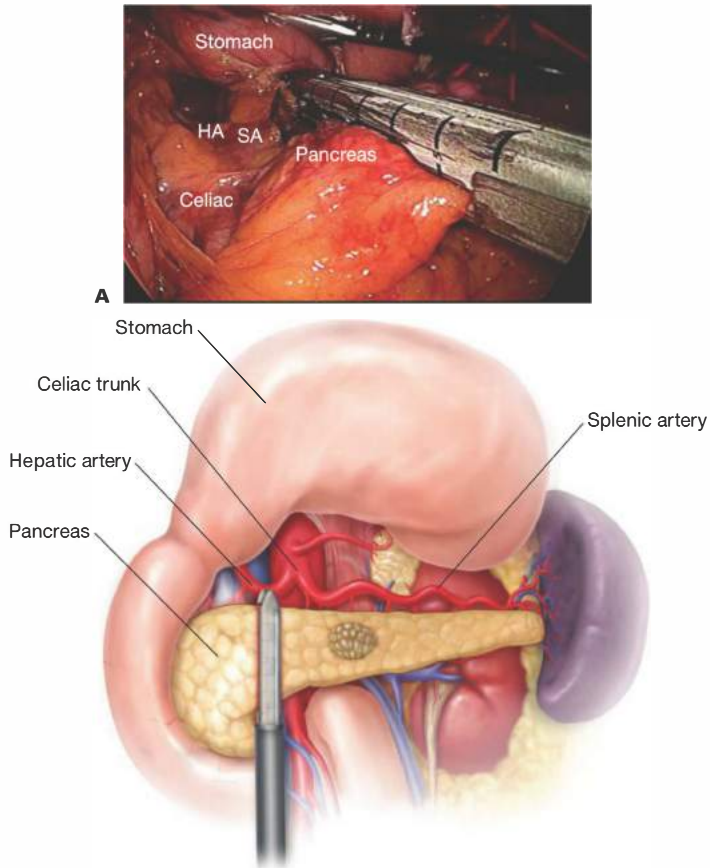

FIG 17 ● **A.** Operative image showing stapled transection of the pancreatic body for a tumor in the tail. Slow compression of the stapler is important to avoid crushing and fracturing the pancreatic parenchyma. The celiac axis, common hepatic artery (HA), and splenic artery (SA, divided with staples) are seen to viewer's left of the pancreas. **B.** Illustration showing stapled transection of the pancreatic body for a tumor in the tail. Slow compression of the stapler is important to avoid crushing and fracturing the pancreatic parenchyma. The celiac axis (CA), common HA, and SA are seen to viewer's left of the pancreas.

gland (radical antegrade modular pancreaticosplenectomy [RAMPS] procedure) can be performed by experienced surgeons.[5] However, we recommend an open approach to these lesions as is warranted in most situations, which is described in Part 3, Chapter 40.

Specimen Extraction, Placement of Drains, and Port Site Closure

- The specimen is placed into a large extraction bag, spleen first with the pancreas on top. The wound is slightly enlarged. The pancreas is removed and divided from the splenic hilum extracorporeally. The spleen is then morcellated and removed.
- Alternatively, if the site of pathology is not in the distal pancreas, the spleen can be separated from the pancreas intracorporeally once the dissection is complete. The pancreas is placed in a separate bag and removed intact through the 12-mm port site. The spleen is placed in a reinforced extraction bag, morcellated, and removed.
- In cases of malignancy, the transection margin should be shaved and sent for frozen section examination to ensure a negative margin.
- A closed suction drain may be placed selectively adjacent and posterior to the pancreatic stump. We do not routinely use drains, but this remains a controversial issue.
- After irrigation of the abdominal cavity and thorough sweep for foreign bodies, the port sites are closed using Vicryl suture.

SPLEEN-PRESERVING LAPAROSCOPIC DISTAL PANCREATECTOMY

Preservation of the Gastroepiploic Arcade and Short Gastric Vessels

- Initial steps for access and exposure are identical to that described earlier.
- Care is taken to preserve the right gastroepiploic arcade during division of the gastrohepatic ligament, as these vessels will provide perfusion to the spleen.
- The gastric fundus is not mobilized, and the short gastric vessels are preserved.

Retrograde Division of Splenic Vein Tributaries

- The splenic vein is separated from the pancreas as described earlier and encircled with a vessel loop, which is used for both retraction and vascular control.
- The vein is dissected away from the body and tail of the pancreas in a retrograde fashion from right to left using blunt or sharp dissection but avoiding monopolar cautery, as desiccating heat can easily injure small splenic vein tributaries.
- Venous tributaries from the pancreas are skeletonized and divided between clips or with bipolar energy along the length of the splenic vein (**FIG 18**).

Antegrade Division of Splenic Artery Branches

- The splenic artery is skeletonized along the superior border of the pancreas.

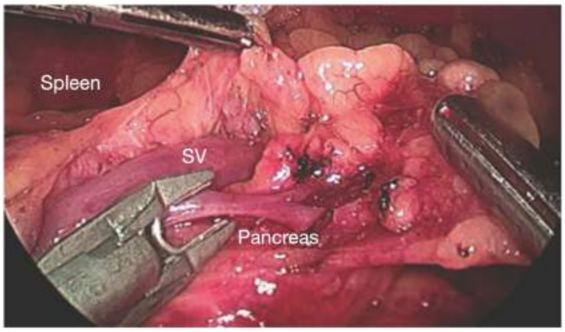

FIG 18 ● Operative image showing clips being placed across a splenic vein (SV) tributary along the distal pancreas during a spleen-preserving distal pancreatectomy. Small tributaries can be controlled with energy bipolar energy devices, but those larger than 3 to 5 mm should be controlled with clips or ties.

- Feeding branches to the pancreas are divided between clips, typically in an antegrade fashion proceeding from right to left.

Warshaw Technique

- In the technique described by Warshaw,[6,7] the splenic vessels can be ligated and divided at the proximal transection margin and again distally near the splenic hilum.
- The midportion of the splenic vessels is included with the resected specimen, whereas the spleen is left in situ to be perfused by the short gastric vessels. Preservation of the right gastroepiploic arcade and short gastrics are essential with this approach.

ROBOTIC DISTAL PANCREATECTOMY

General Concepts

- The robotic approach to a distal pancreatectomy is largely the same as the laparoscopic approach.
- The potential advantage of a robotic approach includes increased dexterity, possibly beneficial in cases where splenic preservation is prioritized.[8]
- The potential downside to a robotic approach include the loss of haptics, difficulty with altering the field of view, the complexities involved in docking and limited access to the patient, and cost.[9]

Patient Positioning

- The patient positioning is the same as a laparoscopic approach.
- The optimal position for the camera during the dissection again depends on where the anticipated area of most difficult dissection lies. Most commonly, the camera will be in the infraumbilical port and the direction of surgical approach will be from the patient's right, looking toward the spleen.
- Retraction of the stomach may be performed with the third robotic arm or may be via a bed-mounted fixed retraction.
- The assistant will stand on the opposite side of the bed from the camera for additional retraction and suction/irrigation.

Port Placement and Docking of the Robot

- Ports being used by the robot are typically better placed slightly farther away from the target than those used in a laparoscopic approach. This reduces the chance that ports will be inadvertently dislodged and allows the ports to be placed slightly farther away from each other, reducing the conflict between the robotic arms outside the patient.

Mobilization of the Colon and Pancreas

- The individual steps of colonic mobilization and exposure of the body and tail of the pancreas are the same as those described earlier for the laparoscopic approach.

TECHNIQUES

Mobilization of the Pancreas and Control of the Vasculature

- The individual steps of pancreatic mobilization and control of the vasculature are the same as those described earlier for the laparoscopic approach.

Splenic Preservation Using a Robotic Approach to Distal Pancreatectomy

- The primary advantage of a robotic approach to a distal pancreatectomy is thought to be the increased dexterity by which the vasculature of distal pancreas and spleen can be dissected away from the tail of the pancreas.
- Using the three-dimensional (3-D) visualization, the small branches of the splenic vein and artery are identified, dissected, and individually divided using monopolar or bipolar technology.

Specimen Extraction

- The individual steps of specimen extraction are the same as those described above for the laparoscopic approach.

PEARLS AND PITFALLS

Sequence and details of dissection can be altered based on individual anatomic characteristics.	■ Dissection of the splenic vein deep to the superior pancreas margin may result in difficult-to-control bleeding. The vein is more safely approached inferiorly from below the pancreas.
Bleeding from splenic vessels controlled with vascular loops, topical hemostatic agents, or nonabsorbable sutures.	■ The distal pancreatic duct is suture ligated with a U stitch if visualized when dividing the pancreas without duct-sealing technology.
Suction device recommended to maintain dry operative field. Consider dual insufflation systems to maintain pneumoperitoneum while suctioning.	■ Method of gland transection should be individualized based on thickness and texture of the pancreas. Vascular staplers are generally appropriate for glands up to 2.0 cm in thickness. Saline-linked monopolar cautery, ultrasonic energy, and radiofrequency ablation are alternative methods of transection.
Individualized port placement based on abdominal length and body habitus. Ports should be moved cephalad in large and obese patients.	■ Placement of drains is optional and should be individualized based on texture of the pancreas and confidence in the closure of the pancreatic stump.
A hand port is useful for central tumors with abutment of the celiac vessels and for bulky tumors that are difficult to mobilize laparoscopically.	■ The common hepatic artery should be visualized with IOUS prior to ligating the splenic artery to prevent inadvertent injury.

POSTOPERATIVE CARE

- Coverage with 24 hours of prophylactic antibiotics, as determined by institutional standards
- Initiation of low-molecular-weight heparin deep vein thrombosis (DVT) chemoprophylaxis, typically starting on postoperative day (POD) 1 in the absence of evidence of hemorrhage
- Clear liquid diet on POD 1, advance as bowel function resumes.
- Early mobility commencing on the day of surgery
- Drain amylase on POD 4 if a closed suction drain was used. Remove if within normal range of serum amylase.
- CT scan if patient develops leukocytosis, fever, prolonged ileus, or other signs of pancreatic fistula or intraabdominal infection.
- Percutaneous interventions are typically sufficient for management of postoperative fistulas and abscesses.
- Discharge on POD 4 or 7 in the absence of complications.

OUTCOMES

- Overall survival not related to minimally invasive surgery (MIS) versus open approach[10]
- Oncologic resection not compromised by MIS approach[11]
- Decreased blood loss compared to open resection[12]
- Increased length of surgery compared to open approach[13]
- Decreased average length of hospital stay compared to open approach[14]
- Morbidity and mortality equivalent or better than open surgery[15]

COMPLICATIONS

- Pancreatic fistula 15% to 30%
- Intraoperative/postoperative hemorrhage
- Intraabdominal abscess
- Pancreatic pseudocysts
- Splenic infarction
- Splenic vein thrombosis
- Overwhelming postsplenectomy sepsis (OPSS)

Chapter **42**

Distal Pancreatectomy with Splenic Preservation

Adam S. Brinkman *Sharon M. Weber*

DEFINITION

- Distal pancreatectomy with splenic preservation (DPSP) is the complete removal of the distal pancreas (lateral to the superior mesenteric vein/portal vein [SMV/PV] confluence) while preserving the spleen via meticulous dissection and preservation of the splenic artery (SA) and splenic vein (SV), or with sacrifice of these vessels (Warshaw technique) with preserved blood flow to the spleen through the short gastric vessels.
- Indications for DPSP include benign tumors for which local excision is inadequate (neuroendocrine tumors), pancreatic cysts, chronic pancreatitis limited to the distal pancreas, and selected cases of distal pancreatic trauma. DPSP for distal pancreatic malignancies (adenocarcinoma) is controversial as body and tail lesions may have lymphatic drainage to the splenic hilum.
- The majority of cases performed in the United States are accomplished either open or laparoscopically, whereas fewer are performed using robotic assistance or with a hand port. Variation in surgical technique with respect to preservation of the splenic vessels versus ligation of the vessels exists.

DIFFERENTIAL DIAGNOSIS

- Premalignant or malignant lesions a DPSP may be considered:
  - Solid pancreatic tumors
  - Functional and nonfunctional neuroendocrine (NE) tumors
  - Cystic pancreatic tumors
    - Intraductal papillary mucinous neoplasms (IPMNs)
    - Mucinous cystadenomas (MCN)
    - Solid pseudopapillary tumors
  - Benign conditions
    - Congenital cysts
    - Serous cystadenomas (SCA)
    - Chronic pancreatitis pancreatic pseudocysts can also be theoretically resected with a DPSP
- The location of the lesion and the anatomic relationships of the splenic vasculature are the major factors that should be evaluated before considering a DPSP as the surgical procedure of choice.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients being considered for DPSP should be evaluated with a thorough history and physical examination including a detailed past medical history, past surgical history (including previous foregut and pancreatic surgery), as well as personal and family history of pancreatic disease or malignancy.
- Particular attention should be paid to symptoms of pancreatic insufficiency, nutritional status, and ability to tolerate a pneumoperitoneum of 15 mmHg if a laparoscopic approach is chosen.
- Severely malnourished patients (more than 10% to 15% of ideal body weight [IBW] loss in the preceding 2 months) or serum albumin less than 3 g/dL should be considered for supplemental nutrition; enteral nutrition via Dobhoff tube or total parenteral nutrition through indwelling central venous catheter.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Pancreatic protocol helical computed tomography (CT) with oral and dual phase intravenous contrast is the preferred imaging modality for pancreatic diseases. The thin cuts through the pancreas allows for ideal delineation of vasculature, size of the lesion, involvement of surrounding structures, and evidence of local disease progression (**FIG 1**). Careful attention should be paid to the arterial and venous phases as well as the arterial blood flow to the spleen, as this can determine feasibility of splenic preservation.
- The relationship of the mass, cyst, or stricture should be noted and its anatomic relationship to the SV, inferior mesenteric vein (IMV), and SA should be noted in anticipation of potential intraoperative pitfalls.
- In addition to CT, consideration can also be given to endoscopic ultrasound (EUS) to better evaluate the pancreatic lesion and its relationship to the surrounding structures. In addition, sampling of the mass with fine needle aspiration for diagnostic purposes or aspiration of a cyst fluid for evaluation of carcinoembryonic antigen (CEA), amylase concentration, and mucin analysis may assist with diagnosis and operative planning. The presence of local disease discovered on CT imaging may be further investigated with EUS and suspicious masses (often lymph nodes) can be sampled.

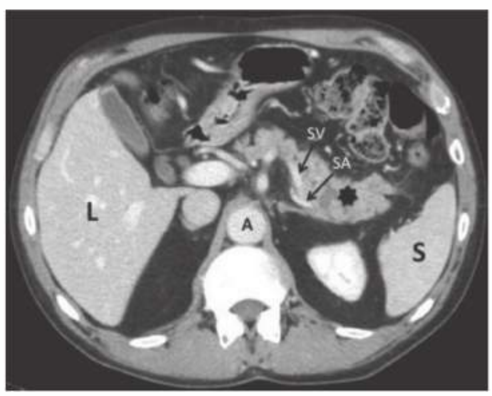

FIG 1 ● Pancreatic protocol helical CT scan of with dual phase intravenous contrast of the abdomen and pelvis demonstrating a solid 3.6 × 2.9-cm complex cystic lesion *(star)* in the tail of the pancreas concerning for malignant transformation of IPMN amenable for a DPSP. *A*, aorta; *L*, liver; *S*, spleen; *SA*, splenic artery; *SV*, splenic vein.

- Additional pathology can also be identified, including isolated gastric varices indicative of SV thrombosis and sinistral portal hypertension.
- Additional diagnostic testing that may be considered prior to a DPSP includes magnetic resonance imaging (MRI) or magnetic resonance cholangiopancreatography (MRCP), which may better define the pancreatic ductal anatomy.
- Consideration can also be extended to endoscopic retrograde cholangiopancreatography (ERCP), the gold standard to define pancreatic ductal anatomy, which also offers an opportunity for evaluation of communication with the main pancreatic duct for cystic lesions, which is diagnostic for IPMN.
- Additional imaging including a chest radiograph or chest CT scan may be obtained for complete staging and preoperative evaluation in patients with suspected malignancy.

SURGICAL MANAGEMENT

Preoperative Planning

- Prior to proceeding to the operating room (OR), all patients should be evaluated with a full history and physical examination with cardiovascular and pulmonary testing as medically needed. Patients scheduled to undergo a laparoscopic distal pancreatectomy should be made aware of the potential need to convert to an open approach during the operation.
- Consideration should also be given to vaccinating against encapsulated bacteria including *Neisseria meningitidis*, *Haemophilus influenzae*, and *Streptococcus pneumoniae*.
  - These vaccines should be given 1 to 2 weeks prior to operative intervention in the event splenic preservation is not possible.
  - Should a splenectomy be required in a nonvaccinated patient then vaccines should be administered within 2 weeks following surgical intervention to mitigate postsplenectomy sepsis.
- Patients should also obtain baseline laboratory function including type and screen, serum electrolytes, hemoglobin and hematocrit as well as pregnancy testing in reproductive-aged females.
- Preoperative antibiotics and deep venous thrombosis (DVT) prophylaxis should be ordered prior to patient arrival to the OR. Arterial lines and central venous catheters are placed selectively for high-risk patients.

Positioning

- Patients should be positioned supine on the OR table with arms extended wide with easy access to the OR table should a Bookwalter retractor need to be placed. Preoperative DVT prophylaxis with heparin should be administered subcutaneously prior to the induction of general anesthesia, bilateral lower extremity sequential compression devices should be placed, and a single dose of a second-generation cephalosporin should be administered within 60 minutes of skin incision.
- After the patient is intubated, a Foley catheter should be placed under sterile technique and a nasogastric tube should be placed for gastric decompression.
- The abdomen is shaved, prepped, and draped, with the xiphoid process, umbilicus, and right and left anterior superior iliac spines exposed.
- An adequate prep will allow for easy incision planning should there be a need to convert to the open technique.
- Some surgeons prefer a semilateral positioning in a relaxed right lateral decubitus position to assist with visualization of the left upper quadrant, whereas others prefer a split leg (Nissen) table to allow the surgeon to stand between the patient's legs.
- Standard laparoscopic instruments (including 0- and 30-degree laparoscopes), ultrasonic dissector or bipolar electrocautery, laparoscopic staplers (vascular and bowel staple loads), and clip appliers should be available.

LAPAROSCOPIC APPROACH

Port Placement

- Access to the abdominal cavity can be accomplished with either a supraumbilical Veress needle or Hassan trocar depending on surgeon preference and a pneumoperitoneum is established at 15 mmHg.
- Three to four additional ports are placed under direct visualization, usually with one in the upper midline or just right of midline, depending on the patient's anatomy. Two additional ports (a 5 mm and a 10 mm to accommodate the laparoscopic stapler) can be placed in the left middle or lower quadrant (**FIG 2**).
- Once all ports are placed, a thorough diagnostic laparoscopy is performed to rule out metastatic disease. If abnormal lesions are identified, they should be biopsied and sent for frozen sectioning. Adhesions are freed to allow full visualization of the left upper quadrant.

Opening the Lesser Sac

- The lesser sac is then opened along the greater curvature of the stomach inferior to the gastroepiploic vessels through the gastrocolic ligament. This allows visualization of the posterior stomach and the anterior surface of the pancreas (**FIG 3**).
- The short gastric vessels along the superior aspect of the fundus should be preserved, as they may be required for splenic preservation if the SA and SV are divided (Warshaw technique).
- If splenectomy is planned, all short gastric vessels will need to be transected.

Identification of the Pancreatic Lesion

- Every effort should be made to identify or palpate the pancreatic lesion and its relationship to the pancreatic neck. Lesions amenable to a DPSP are those to the left of the SMV/PV confluence (**FIG 4**). If the lesion cannot be identified then employment of the laparoscopic ultrasound or EUS can be performed to assist with localization.

Dissection of the Pancreas

- Dissection along the inferior border of the pancreas begins above the ligament of Treitz and should be extended toward the splenic hilum.

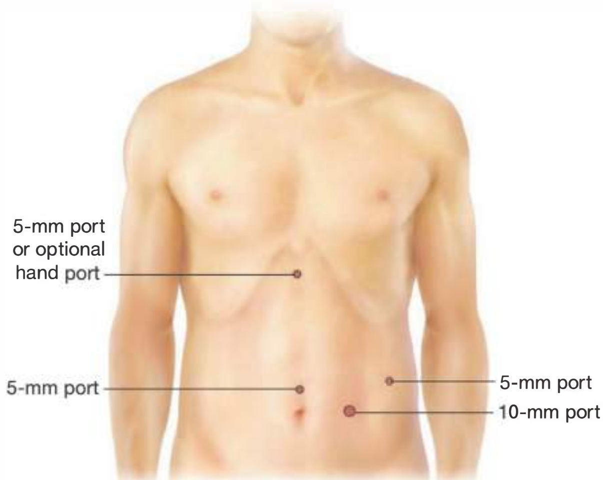

FIG 2 ● Port placement for a laparoscopic DPSP includes three 5-mm ports, one 10-mm port, and an occasional hand port placed in the upper midline to assist with specimen retraction and dissection.

- Careful attention is paid to opening just the thin peritoneum inferior to the pancreas and to elevate the pancreas from the retroperitoneal tissue by assuring the plane of dissection stays within the fibroareolar plane. If this is done correctly, the SV will usually be elevated with the pancreas and will result in mobilization of the pancreas anteriorly (**FIG 5**).
- Careful attention is required to avoid lacerating or transecting the posterior SV.
- The IMV should be identified and ligated if it enters the SV to the left of the mass or preserved if it enters the SV to the right of the planned pancreatic transection plane. Neoplastic involvement of the IMV requires ligation and resection.
- Some surgeons advocate for placement of a hand port in the left upper quadrant to assist with tissue manipulation and aid with dissection during this step.

Dissection and Control of the Splenic Artery

- With splenic vessel preservation
  - Attention should then be focused on identification of the serpiginous SA located on the superior aspect of the pancreas. The SA can then be carefully dissected from the pancreas using suture ligation or clipping plus energy-assisted ligation and division of small arterial branches running to the pancreatic tail until the pancreas is completely separated from the SA.

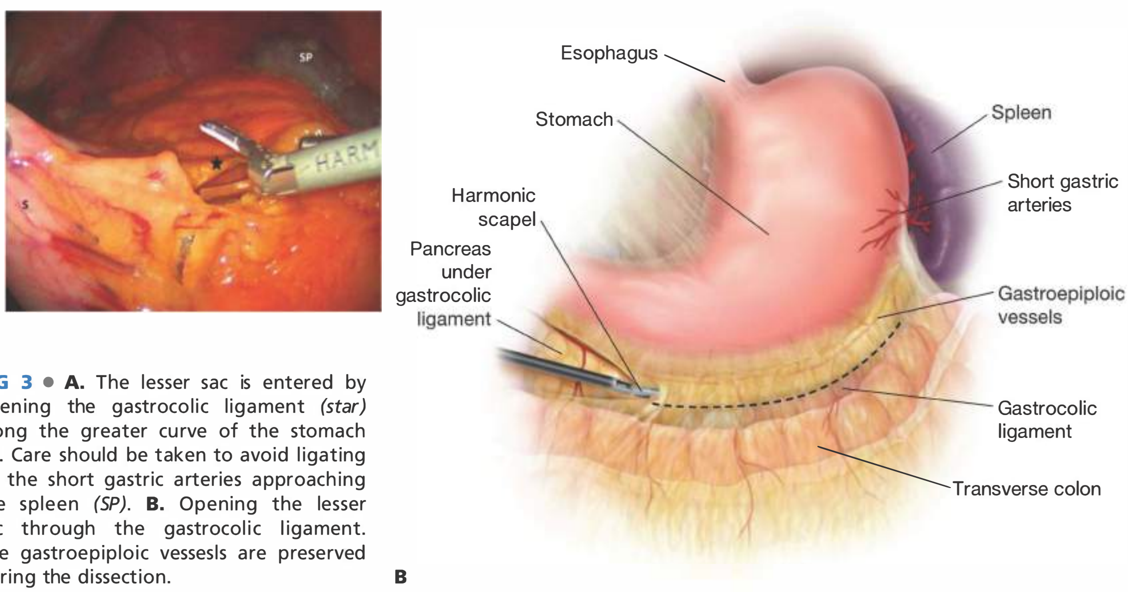

FIG 3 ● **A.** The lesser sac is entered by opening the gastrocolic ligament *(star)* along the greater curve of the stomach *(S)*. Care should be taken to avoid ligating all the short gastric arteries approaching the spleen *(SP)*. **B.** Opening the lesser sac through the gastrocolic ligament. The gastroepiploic vessesls are preserved during the dissection.

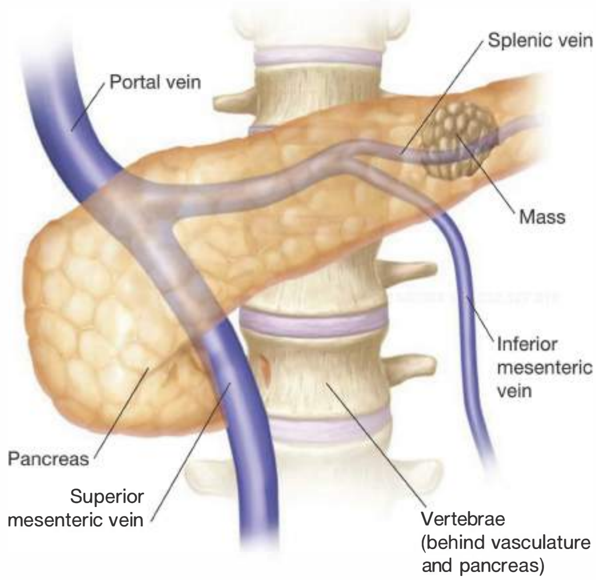

FIG 4 ● Lesions amenable to a DPSP are those left of the SMV/PV confluence.

- Without splenic vessel preservation (Warshaw technique)
    - The SA is dissected and controlled, followed by ligation using a vascular load of the laparoscopic stapler. The authors suggest additional, subsequent control of either ligation or clipping to minimize risk of pseudoaneurysm in the setting of pancreatic fistula. The SA (inflow) should be controlled before SV (outflow) to decrease bleeding.

Transection of the Pancreas

- With splenic vessel preservation
    - A tunnel should be created to the right of the lesion to free the pancreas from the vasculature for transection (**FIG 6**).
    - The pancreas can then be transected with a laparoscopic Endo GIA stapler, Harmonic scalpel, or LigaSure device.
        - In patients with thick pancreas, the pancreatic parenchyma can be thinned out with the ultrasonic dissector while avoiding the pancreatic duct, which usually is positioned posteriorly in the pancreas approximately one-third inferior to the superior border. This enhances the ability of a stapler to appropriately control the pancreatic duct.
- Without splenic vessel preservation (Warshaw technique)
    - Alternatively, the pancreas can be transected with the laparoscopic stapler incorporating the SA and SV in the staple line. Alternatively, the pancreas, SA, and SV can be dissected and transected individually. In most cases, it is simplest to ligate the SV with the pancreas using a stapler.

Dissection of the Distal Pancreas

- With splenic vessel preservation
    - The SV is identified and dissected off the pancreas posteriorly. This is often expedited by transection of the pancreatic parenchyma, with a right-to-left mobilization.
    - Small venous branches into the pancreas should be carefully dissected and either divided between clips, ties, or with the ultrasonic dissector (**FIG 7**). Often,

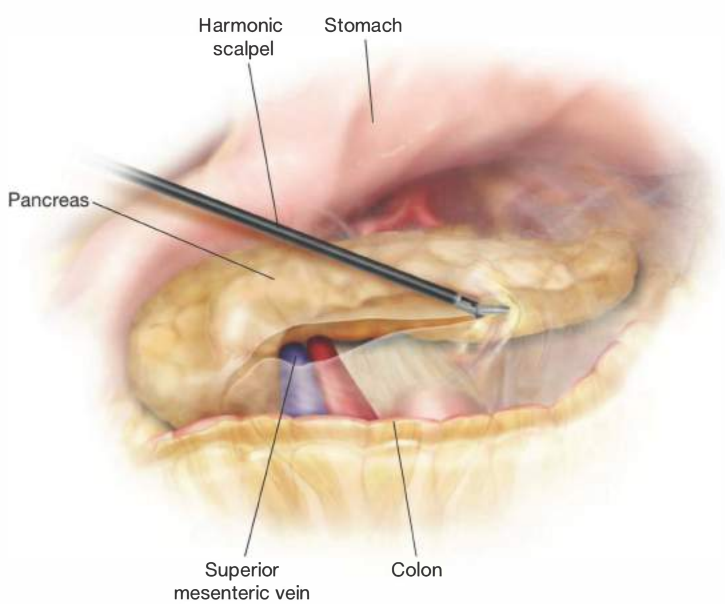

FIG 5 ● Dissecting and opening the peritoneum along the inferior aspect of the pancreas in a medial to lateral direction. The SV is posterior to the pancreatic body and at risk for injury during dissection if the posterior fibroareolar plane is violated.

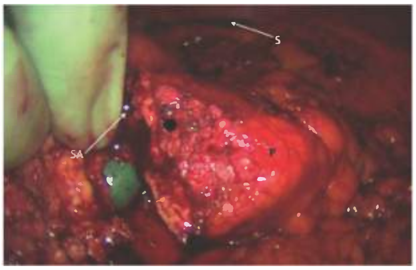

FIG 6 ● Transection of the pancreas *(P)* at the confluence of the SV and portal vein left of midline using a hand port. The SA is dissected circumferentially and stapled. The cut edge of the pancreas *(star)* is reflected anteriorly and toward the spleen *(S)* to assist with further posterior dissection.

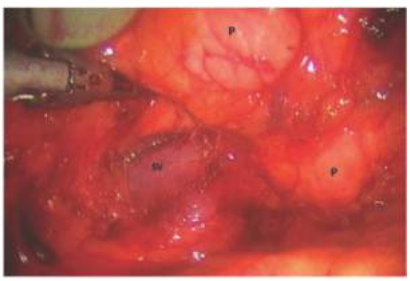
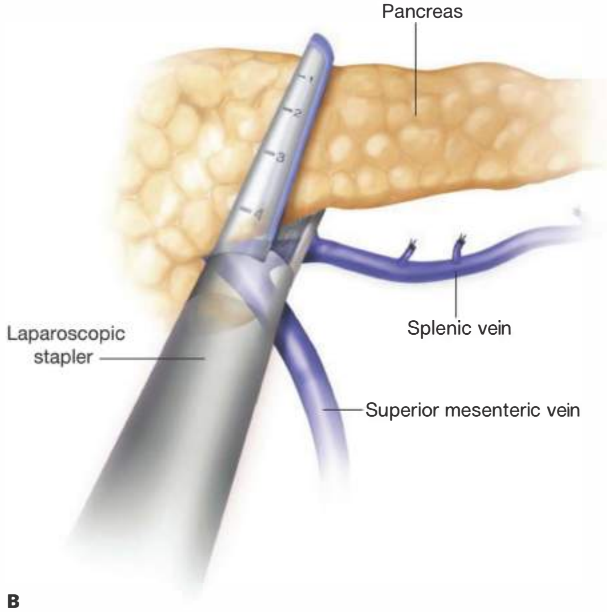
small bleeding veins can be controlled through direct pressure for a short time; however, persistent bleeding may require ligation with a Prolene suture.

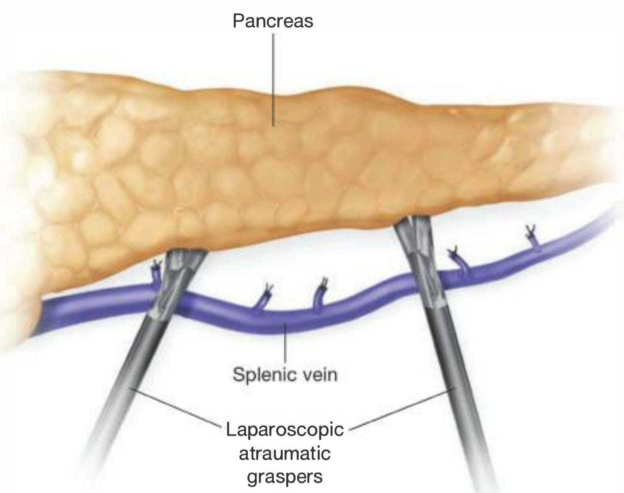
- Without splenic vessel preservation (Warshaw technique)
  - An additional fire of the laparoscopic stapler using a vascular load is needed to control the splenic vasculature at the splenic hilum.
  - Great care should be taken to avoid lacerating or puncturing the splenic parenchyma during control of the hilar vessels.
  - Once accomplished, the specimen can be removed from the abdomen using a specimen bag through the largest port site, leaving the spleen to obtain its vascular supply from the short gastric vessels.



A



B



C

FIG 7 ● **A.** Dissection of the pancreas *(P)* from the underlying splenic vein *(SV)* in a medial to lateral direction. Small venous branches are controlled with fine suture, clips, or staples. **B.** Medial to lateral dissection of the pancreas from underlying SV. **C.** The pancreas is transected to the right of the lesion using a laparoscopic Endo GIA stapler

Management of the Residual Gland

- Once the specimen is removed, careful attention should be paid to assuring meticulous hemostasis. The surgical bed should be irrigated with warm sterile saline and the SA and SV should be investigated to ensure hemostasis. Attention should also be directed to the spleen to ensure adequate perfusion and no evidence of ischemia or bleeding.
- Placement of a soft closed suction drain to monitor for pancreatic leaks in the postoperative period is indicated.

Closure

- Following specimen removal, the spleen should be inspected to assess perfusion and bleeding. When using the Warshaw technique, if a completely ischemic or partially ischemic spleen is identified, a splenectomy should be performed, as ongoing ischemia will often result in significant left upper quadrant abdominal pain and bleeding.
- The fascia is closed for 10-mm or larger port sites and the skin is closed with 4-0 dissolvable sutures. If a hand port is placed, the fascia is closed.

OPEN TECHNIQUE

Incision Choice

- The incision of choice for a DPSP depends on the patient's body habitus and previous abdominal surgery.
- Either an upper midline or left subcostal incision can be used. Patients with previous upper midline incisions can be used although in obese patients and those with a narrow subcostal angle, it may be difficult to reach the pancreatic tail with a midline incision. Additionally, locally advanced malignancies, large tumors, or those where oncologic endpoints may be compromised should be approached with the open technique.
- Once inside the peritoneal cavity, careful palpation of the abdominal cavity should be performed to ensure no evidence of metastatic disease. A self-retaining retractor (Bookwalter) can be placed with cephalad retraction of the left costal margin to allow for visualization.
- The remainder of the operative steps in the open technique are identical to those used for the laparoscopic technique, although sometimes it is easier to perform a left-to-right mobilization first, allowing the spleen to be elevated into the operative field. If performing the Warshaw technique, the SA and SV on the posterior aspect of the pancreas are transected, followed by pancreas transection. The transected edge of the pancreas should be investigated after the specimen is removed and the pancreatic duct ligated with a 2-0 or 3-0 polypropylene suture, or other techniques of pancreatic stump closure can be used, such as the stapler, ultrasonic dissector, or LigaSure.
- A soft closed suction drain should be placed along the cut edge of the pancreas and brought out through a separate stab incision on the abdominal wall. The fascia is then closed in several layers.

PEARLS AND PITFALLS

Preoperative considerations	■ A complete history and physical examination should be performed to ensure the patient is a candidate for surgery. ■ Evaluate for pancreatic insufficiency and malnutrition; consider preoperative nutritional support. ■ Vaccination against encapsulated organisms
Open vs. laparoscopic technique	■ Ability to tolerate pneumoperitoneum and previous foregut surgery ■ Laparoscopic is the preferred approach for lesions amenable to this technique. ■ Consider placement of hand port to assist with dissection or specimen removal. ■ Midline or left subcostal incision can be used for the open approach.
Management of short gastric arteries (Warshaw technique only)	■ Maintain short gastrics and avoid excessive traction.
Control of splenic artery and vein	■ Small branches of the SV should be controlled with direct pressure, clips, or suture ligation. ■ IMV should be ligated and divided if it enters the SV to the left of the target lesion and preserved if it enters the SV to the right of the lesion or enters the SMV. ■ If the lesion involves the SA, SV, or IMV—ligate and resect the vessels with the specimen (Warshaw technique). ■ Careful dissection of the thin-walled SV can avoid bleeding and postoperative SV thrombosis.
Splenectomy	■ Splenic preservation is an option except in cases of adenocarcinoma, unclear diagnosis, or direct involvement of the splenic hilum. ■ Unexpected bleeding or splenic ischemia may require unplanned splenectomy.
Management of the residual pancreas	■ Soft closed suction drain placed and output monitored for several days.

POSTOPERATIVE CARE

- Following an uncomplicated DPSP, the patient should be admitted to the general care floor. Routine nasogastric decompression is per surgeon's discretion but may not be needed.
- Assuming stable hemodynamics and hematocrits, patients may begin a clear liquid diet the following day and diet may be advanced as tolerated.
- On postoperative day 1, drain amylase should be checked to assess the risk for pancreatic fistula formation. Attention should be paid to the volume, consistency, and color of the soft closed suction drain and changes in any of the three should prompt further investigation for a developing pancreatic fistula.
- Patients are encouraged to ambulate often and discharged home 4 to 5 days following surgery.

OUTCOMES

- With adequate laparoscopic training and a solid anatomic understanding, this approach can be safely performed with similar rates of morbidity, mortality, and pancreatic fistula development. As with the majority of laparoscopic techniques, patients often experience less postoperative pain, narcotic use, shorter hospital stay, and nearly identical rates of operative blood loss. Several studies have indicated that when comparing splenic vessel ligation (Warshaw technique) to splenic vessel preservation, there was a greater incidence in splenectomy with splenic vessel ligation, although this technique is easier to perform with shorter operative times. Despite similar outcomes compared with the open technique, a DPSP should be performed by those surgeons with advanced laparoscopic skills after careful patient selection.[1–19]

COMPLICATIONS

- Hemorrhage
- Infection—often subdiaphragmatic
- Pancreatic leak/fistula
- Splenic vein thrombosis
- Thrombocytosis
- Hyperglycemia—potential to develop diabetes mellitus
- Pancreatic exocrine insufficiency
- Splenic ischemia (Warshaw technique)

Chapter 43 Central Pancreatectomy

Daniel J. Delitto Jose G. Trevino

DEFINITION

- Central pancreatectomy (occasionally referred to as median or middle pancreatectomy) is a conservative resection of the neck and body of the pancreas in order to conserve endocrine and exocrine pancreatic function. This segmental resection also preserves surrounding structures including the duodenum, spleen, biliary tract, and gallbladder. Central pancreatectomy has been described for benign, premalignant, and low malignant potential tumors located in the pancreatic neck and proximal portion of the pancreatic body.

DIFFERENTIAL DIAGNOSIS

- Pancreatic neuroendocrine tumors (PNETs) are most commonly nonfunctional, but approximately 15% of PNETs actively secrete insulin, glucagon, vasoactive intestinal peptide (VIP), pancreatic polypeptide (PP), somatostatin, or gastrin. Neuroendocrine tumors have known malignant potential and resection is indicated in appropriate surgical candidates. PNET is the most frequent diagnostic indication for central pancreatectomy.
- Mucinous cystadenomas (MCAs) account for 2% of all pancreatic neoplasms and approximately 25% of cystic neoplasms.[1,2] These tumors tend to be larger than SCAs, contain a mucin-secreting epithelial lining, and have no communication with the pancreatic ductal system. MCAs are considered dysplastic lesions with premalignant potential and resection is indicated in suitable surgical candidates.
- Pseudopapillary tumor (SPT) is a rare cystic-appearing neoplasm with malignant potential in approximately 5% of cases. The hypodense areas seen on imaging represent necrosis of solid papillary vascular stalks that slough as the tumor grows. Resection is indicated upon diagnosis. As these rare lesions are typically large at the time of diagnosis, central pancreatectomy as a viable surgical approach will be incredibly unusual.
- Serous cystadenomas (SCAs) represent approximately 1% of all pancreatic neoplasms and 33% of pancreatic cystic neoplasms.[2] These lesions contain a true epithelium and do not communicate with the pancreatic duct. Indications for surgical intervention for SCAs include symptomatic lesions or rapid growth with solid components. Otherwise, observation of SCAs is recommended. As with SPT, these lesions tend to be large at the time of diagnosis; central pancreatectomy will rarely be a viable option.
- Intraductal papillary mucinous neoplasms (IPMNs) are continuous with the pancreatic ductal system. These lesions may be classified as either branch-type or involving the main pancreatic duct. Main duct neoplasms may be invasive in up to 50% of cases and central pancreatectomy is not appropriate. Branch-type IPMNs should be resected if they are symptomatic, contain concerning radiographic findings (e.g., a mural nodule, thickened septae, or a ductal stricture), high-grade atypia, strong family history of pancreatic cancer, or size greater than 3 cm. As surgical therapy for IPMN includes reduction of malignant potential, the authors do not advocate central pancreatectomy for IPMN—the surgical goal for these patients is not parenchymal preservation.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Early symptoms of benign pancreatic lesions may include vague abdominal pain or bloating, nausea, and weight loss. More advanced lesions may present with gastric outlet obstruction, jaundice, or recurrent pancreatitis. However, most of these lesions are identified incidentally with cross-sectional imaging. In particular, lesions amenable to central pancreatectomy are typically small (~1 to 2 cm) and are generally asymptomatic.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Pancreatic protocol triple-phase (arterial, late arterial, and venous phase) contrast-enhanced, multiplanar, thin-slice computed tomography (CT) provides excellent imaging of pancreatic parenchymal and ductal anatomy and is typically the diagnostic method of choice for characterizing pancreatic tumors. Magnetic resonance imaging (MRI) or magnetic resonance cholangiopancreatography (MRCP) may further characterize the relationship of the lesion to the pancreatic duct (**FIG 1**). Endoscopic ultrasound (EUS) may allow for fine needle aspiration (FNA) biopsies. Diagnostic characteristics of each lesion are described.
- PNETs appear as hypervascular lesions on thin-slice CT or MRI scans. Somatostatin receptor scintigraphy (SRS) has a high sensitivity for most PNETs, with the exception of insulinomas. EUS may further characterize lesions near the pancreatic head, which typically have a hypoechoic appearance compared to normal pancreatic parenchyma. FNA or core needle biopsy sampling can confirm the presence of PNETs with immunohistochemical staining of cell block or tissue for chromogranin. Functional tumors are diagnosed on a biochemical basis.
- MCAs are typically seen in younger women and may contain loculated lesions with multiple septae. More commonly, however, these lesions are seen as larger unilocular cysts. EUS and FNA reveal viscous, mucinous fluid with high carcinoembryonic antigen (CEA) levels and low amylase.
- SCAs may contain a "starburst" or honeycomb pattern of central scarring on CT imaging. EUS reveals a characteristic thin-walled capsule with thin septae. If FNA is performed, it often yields serous fluid with low amounts of CEA and mucin.
- SPTs present in young females (mean age 25 to 30 years) typically as a large mass in the body or tail. These lesions contain hypodense areas representing sloughed, necrotic papillary stalks with internal calcifications. FNA with immunostaining may reveal neuron-specific enolase, vimentin, and α1-antitrypsinase expression. Aggressive surgical resection is

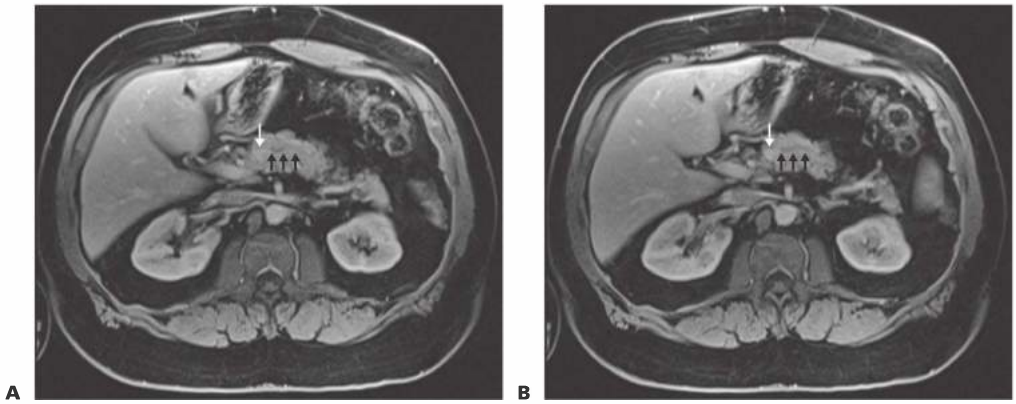

FIG 1 ● Contrast-enhanced MRCP of a PNET involving the pancreatic neck. The central location of the lesion and evidence of pancreatic duct (PD) involvement precludes safe enucleation; thus, central pancreatectomy was offered. **A,B.** The 1.2-cm lesion *(white arrows)* enhances as compared to the surrounding pancreatic parenchyma. The upstream PD is dilated *(black arrows)* and the surrounding parenchyma is edematous, consistent with inflammation.

warranted even in the presence of local invasion or metastatic disease.[3,4]

- IPMNs are diagnosed with CT or MRCP. EUS with FNA reveals high amylase and CEA levels. Additionally, K-*ras* mutation and loss of heterozygosity are malignant characteristics. Endoscopic retrograde cholangiopancreatography (ERCP) will show continuity with the main pancreatic duct.

SURGICAL MANAGEMENT

Preoperative Planning

- A complete history and physical of any patient undergoing central pancreatectomy is essential, paying close attention to signs of malignancy including weight loss or new-onset diabetes. A prior history of jaundice or pancreatitis should also be solicited. Basic blood chemistries should be obtained as well as a hepatic function panel, complete blood count, and coagulation studies. Serum tumor markers, including CEA, carbohydrate antigen (CA 19-9), and α-chromogranin should be obtained. When indicated, additional studies to characterize functional PNETs are warranted.
- Central pancreatectomy may be considered for lesions less than 3 cm located deep within the pancreatic neck or proximal body or situated near the main pancreatic duct; such lesions are not amenable for enucleation. The length of remnant distal pancreas should maximize functional endocrine tissue. To this effect, recommendations from Iacono et al.[5] include a minimum length of 5 cm for the distal pancreatic stump.
- Contraindications to resection include evidence of invasive malignancy and chronic or focal pancreatitis not involving the pancreatic neck or body. Importantly, central pancreatectomy is contraindicated when the tail of the pancreas receives its only blood supply from the transverse pancreatic artery, as this will be ligated during the operation.[5]

POSITIONING

- The patient is placed in supine position, with the table placed into slight reverse Trendelenburg. Two large-bore peripheral intravenous (IV) lines should be established and, if the patient has cardiovascular comorbidities, arterial blood pressure monitoring is advisable.

- Laparoscopic central pancreatectomy has been reported by experienced surgeons to be feasible and safe. Port site placement for a minimally invasive approach is shown in **FIG 2**. The minimally invasive operation proceeds in the order described in the following text.

FIG 2 ● Port placement for laparoscopic central pancreatectomy. The camera is placed through the umbilical port and a stomach/liver fixed retractor is placed through the left anterior axillary line port. During the dissection, the surgeon stands on the right side of the patient. For the pancreatic anastomosis, the surgeon moves to the left side of the patient and the fixed retractor is repositioned to the right anterior axillary line port.

EXPOSURE OF THE PANCREAS

- Obtain adequate exposure to the upper abdomen through a midline celiotomy or, alternatively, a bilateral subcostal incision. Thoroughly explore the abdomen to exclude metastatic or other disease.
- Divide the gastrocolic ligament to enter the lesser space. Preserve the gastroepiploic vasculature; this will lead you to the insertion of the right gastroepiploic artery into the superior mesenteric vein. Divide any congenital adhesions between the gastric antrum and the body of the pancreas. Continue this dissection working left to right until you reach the level of the gastroepiploic vein.
- Mobilize the proximal transverse mesocolon to fully expose the head of the pancreas (HOP) and the second and third portions of the duodenum. Then, establish the plane between the gastroepiploic vascular pedicle and the transverse mesocolon to expose the pancreatic neck and superior mesenteric vein (**FIG 3**).
- Dissect the superior border of the pancreas. Divide the hepatoduodenal ligament to expose the common hepatic artery (CHA) and the associated lymphatics. Sharply dissect down to the anterior adventitia of the CHA. Continue the dissection distally, establishing a plane between the CHA and the cephalad aspect of the pancreatic body and neck. The gastroduodenal artery is your landmark for the distal extent of the dissection. Beyond this landmark, pancreatic transaction risks injury to the intrapancreatic bile duct.

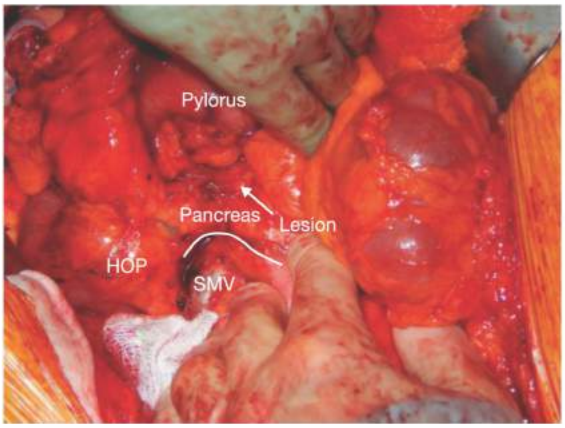

FIG 3 ● The HOP should be fully exposed by dividing the omentum and reflecting the antrum and pylorus toward the head. Dissect the inferior border of the pancreatic body and neck *(white line)*, and identify the anterior surface of the SMV. The lesion is readily palpable deep within the parenchyma of the pancreas and marked with an *arrow*—it is not readily visible on the surface of the gland.

PREPARING FOR RESECTION

- If the lesion is not visible or palpable, perform intraoperative ultrasound (IOUS) of the pancreas to localize the lesion. IOUS probes for liver imaging typically cannot visualize superficial structures and will not provide good imaging of the pancreas unless "stand-off" technique is applied. Fill the lesser space with saline as an ultrasonic conduit and position the transducer 2 to 3 cm away from the pancreatic parenchyma to visualize the superficial structures and lesion within the pancreas.
- Ligate and divide the gastroepiploic vein as it inserts into the superior mesenteric vein (SMV).
- Establish a plane between the pancreatic neck and the SMV/portal vein. Pass a vessel loop or umbilical tape to facilitate exposure of the posterior aspect of the pancreas. The authors do not perform extensive dissection of the pancreas off of the splenic vein until the pancreas is divided distally (toward the HOP). This dissection is straightforward once the distal (toward the HOP) pancreatic neck has been divided.
- At this point, identify the appropriate transection planes necessary to achieve appropriate margins and determine if central pancreatectomy is feasible or if pancreaticoduodenectomy or distal pancreatectomy are more appropriate (**FIG 4**).

Central Pancreatic Resection

- Transect the pancreatic neck to the side of the HOP. This margin can be stapled or the transaction may be performed with an energy device. For the latter, use 5-0 monofilament suture ligation for hemostatic control of the longitudinal pancreatic arteries (**FIG 5**).

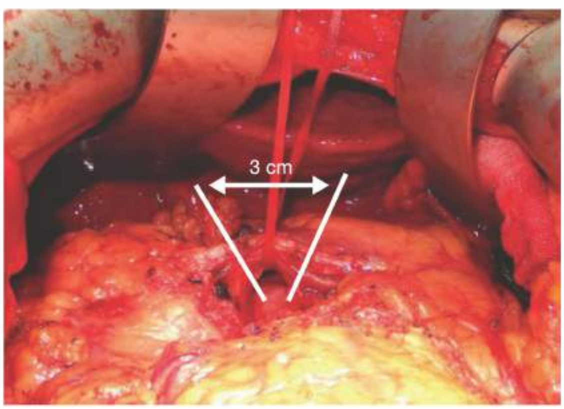

FIG 4 ● After dissecting the superior border of the pancreas to establish space between the hepatic artery and the pancreas, establish a broad plane between the pancreas and the splenic vein, SMV, and portal vein. A 1.5- to 2.0-cm space will allow for transections with adequate margins for most lesions amenable to central pancreatectomy (*white lines* represent planned transection planes).

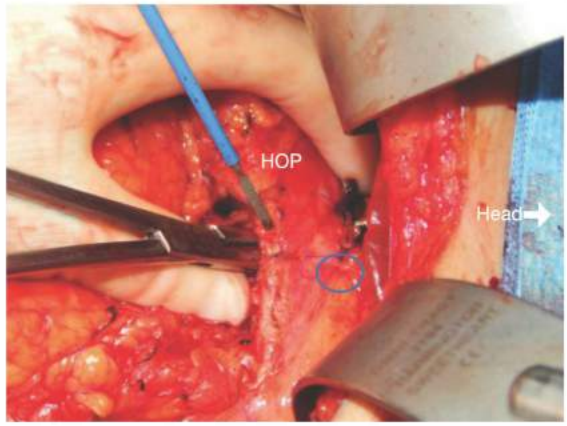

FIG 5 ● Transect the pancreas. Start to the HOP side of the lesion. A staple load can be used on this side. The authors prefer to divide the neck with electrocautery as it provides an excellent understanding of the margin. Use a clamp to protect the portal vein. Further mobilization of the body of the pancreas to take the proximal margin is facilitated once the distal margin has been taken. Do not deviate toward the HOP unless the margin mandates this; the smaller the transaction surface, the less likely the hemorrhage or the postoperative fistula. In this example, the distal margin could safely be taken at the surgical neck of the pancreas (*circle* marks the location of the palpable lesion). Note the placement of sutures to ligate the longitudinal pancreatic arteries.

- Dissect the body of the pancreas off the splenic vein as indicated to provide an adequate proximal margin and mobility for enteric reconstruction to the remnant pancreas.
- Place additional ligatures through the proximal pancreatic body (toward the spleen) for hemostasis and take the proximal margin with an energy device. When possible, divide the pancreatic duct sharply to minimize cautery artifact that can compromise pathologic assessment of the margin.
- When performing the procedure laparoscopically, retrieve the specimen through a separate incision (McBurney's incision is the author's preference) using a specimen retrieval bag. Personally assess the margins by visualization and palpation of the specimen.
- The specimen must then be transported to the pathologist for frozen section analysis to ensure clear margins and no evidence of invasive disease. In the case of malignancy or an involved margin, the operation of choice changes to a standard resection, either a pancreaticoduodenectomy or a distal pancreatectomy with splenectomy.
- The distal stump (HOP side) is then oversewn with 4-0 absorbable, monofilament sutures. If necessary, the distal pancreas (remnant) is then further mobilized anteriorly from the splenic vessels to ensure adequate space for anastomosis.

Reconstruction of Pancreatico-Intestinal Continuity

- Central pancreatectomy with pancreaticogastrostomy has gained popularity in the past decade as a means of

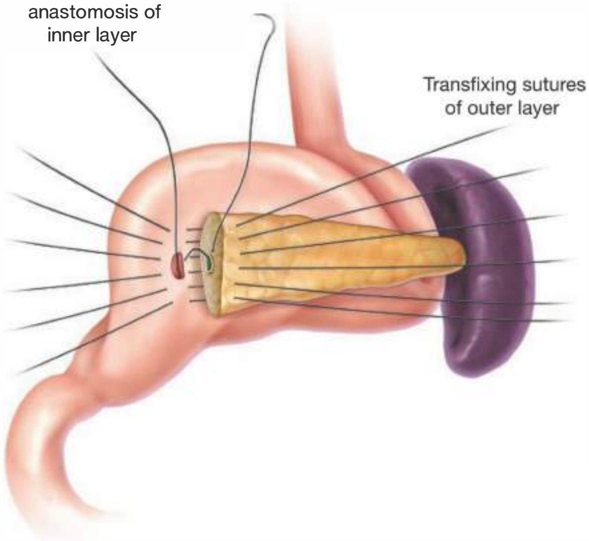

FIG 6 ● Reconstruction of pancreaticoenteric continuity via a pancreaticogastrostomy.

preserving pancreatic endocrine and exocrine function without disrupting intestinal continuity (**FIG 6**). This technique has been proven safe and effective in retrospective reviews in two major academic centers.[6–9] Major factors supporting this anastomosis include a generous blood supply to the posterior gastric wall and reduced anastomotic tension as the posterior gastric wall already lies in close proximity to the pancreatic tail. Critics note the inactivation of pancreatic enzymes by the low pH of the stomach potentially leading to reduced exocrine function. However, this result is not seen in studies evaluating central pancreatectomy.[1] Of note, a recent retrospective review showed a higher pancreatic leak rate with pancreaticogastric anastomosis.[9]

- Pancreaticogastrostomy is attractive as it eliminates the need to fashion a Roux limb; there is no separate jejunojejunostomy or the need for the creation of a tunnel through the colonic mesentery.
- Pancreaticogastrostomy is unattractive in that it requires additional mobilization of the pancreatic remnant and is rarely employed by most pancreatic surgeons.
- Alternatively, a Roux limb of jejunum is created by dividing the jejunum 15 to 30 cm distal to the ligament of Treitz. The mesentery is transected and the Roux limb is delivered to the pancreas in a retrocolic position. The pancreaticojejunal anastomosis may then be fashioned in an end-to-side or end-to-end manner to the distal pancreas (**FIG 7**).

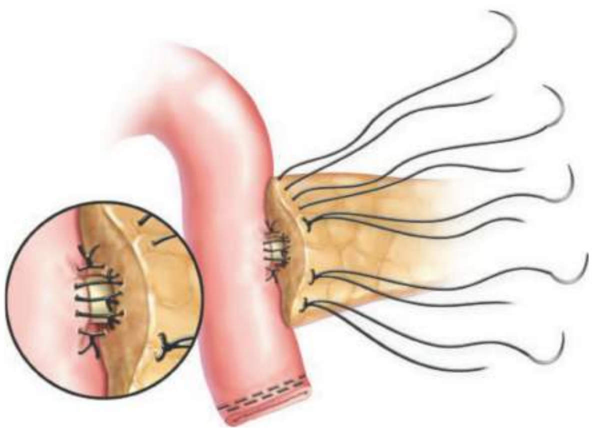

FIG 7 ● If the pancreatic remnant cannot be adequately mobilized (i.e., 3 cm) to provide a tension-free anastomosis to the posterior wall of the stomach or the surgical team is uncomfortable with the technique, Roux-en-Y pancreaticojejunostomy should be performed.

PEARLS AND PITFALLS

Patient selection	■ Rule out possibility of malignancy; central pancreatectomy is not an appropriate operation for malignant lesions especially adenocarcinoma. ■ Ensure adequate margins may be obtained. ■ Exclude chronic pancreatitis patients.
Head of pancreas margin	■ Ensure the main pancreatic ductal stump is visualized and suture ligated.
Pancreaticojejunostomy	■ Position the Roux limb retrocolic to the right of the middle colic vessels.
Pancreaticogastrostomy	■ Attractive option as it avoids the need to fashion a Roux limb. Ensure there is minimal tension on anastomosis; additional mobilization of the pancreatic remnant is necessary when compared to pancreaticojejunostomy.
Closure	■ Two closed suction drains placed in close proximity to anastomosis.

POSTOPERATIVE CARE AND COMPLICATIONS

- The patient should be admitted to a monitored setting for at least the first 24 hours postoperatively. Postoperative hemorrhage from central pancreatectomy is relatively uncommon but signs including unexplained tachycardia, hypotension, or oliguria must be explored.
- Pancreatic drain outputs are analyzed on postoperative day 3 for amylase content. Fistulas are identified based on these amylase levels and are graded based on the system from Bassi et al.[10] Drains with high amylase content remain in place until output is negligible or amylase content is low. Grade B fistulas include those with clinical impact and may include early signs of infection and radiographic findings. These fistulas typically require antibiotic treatment and further drainage procedures. Grade C fistulas have greater clinical impact, typically progressing to sepsis, and may be an indication for reoperation.
- Endocrine and exocrine function must be assessed prior to discharge. Exocrine function may be assessed on a symptomatic basis, looking for symptoms of malabsorptive diarrhea. Serial blood glucose measurements should be performed postoperatively, particularly in patients with preexisting hyperglycemia. If necessary, diabetic education and an appropriate regimen should be in place prior to discharge.
- Delayed gastric emptying is commonly seen after pancreatic resections and may be managed medically with promotility agents and slow diet advancement. Reoperation and gastroenterostomy for drainage are rarely required.

OUTCOMES

- Numerous retrospective studies have shown comparable results to standard resection techniques, namely pancreaticoduodenectomy and distal pancreatectomy. In fact, reduced endocrine insufficiency has been shown in one large retrospective review.[1]
- Postoperative pancreatic fistula rates are variable and have ranged from 8% to 63%, depending on the study.[1,11] Although pancreas-preserving resections provide an attractive alternative for benign lesions, a randomized, prospective trial is necessary to further delineate the role of central pancreatectomy.

Chapter 44

Ampullectomy and Transduodenal Sphincteroplasty

Bharath D. Nath   Tara S. Kent

DEFINITION

- Ampullectomy and transduodenal sphincteroplasty are defined as operative approaches to the resection of lesions of the ampulla of Vater and the palliative or therapeutic reconstruction of the sphincter of Oddi, respectively, performed via a duodenotomy to facilitate exposure of the ampulla within the duodenal lumen. Operation on the sphincter of Oddi consists of reconstruction of the lumen orifices of the pancreatic and/or biliary tree, which may include the following:
  - Incision of the sphincter alone, without reconstruction (sphincterotomy)
  - Incision of the sphincter and reapproximation of the duct to the duodenal mucosa (sphincteroplasty)
  - Incision of the sphincter, division of the septum between the pancreatic and common bile ducts, and their reapproximation with suture (septoplasty)
- These operations may be employed for the treatment of benign, functional, and premalignant disorders of the ampulla and sphincter complex. Though both ampullectomy and transduodenal sphincteroplasty may be incorporated as separate components of the same procedure, they effectively serve as the extirpative and the reconstructive phase, respectively, of an operation on the ampulla of Vater.
- The standard of care for malignant tumors of the ampulla or periampullary duodenum (as well as the head of the pancreas and distal bile duct) is a pancreaticoduodenectomy.
- Ampullectomy is a more limited operation with comparably less morbidity that thus has theoretical benefit for patients with benign or premalignant lesions of the ampulla of Vater.

DIFFERENTIAL DIAGNOSIS

- Transduodenal sphincteroplasty/ampullectomy (TSA) may be considered one of several treatment options for the patient with a mass or functional lesion at the ampulla of Vater. However, the caveat is that TSA is only indicated for a small minority of patients with ampullary lesions and careful consideration of the differential diagnosis is crucial, as it will often lead to other management strategies.
- The indications for transduodenal sphincteroplasty include the following:
  - Impacted common bile stones that are not amenable to extraction by endoscopic means or a "top-down" common bile duct (CBD) exploration
  - Therapy for sphincter of Oddi dysfunction leading to ongoing injury to the liver and/or pancreas that is refractory to endoscopic management
  - Management of benign ampullary adenomas
  - Pancreas divisum

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients may come to clinical attention due to obstructive symptoms of the pancreatic or common bile ducts and may initially present with symptoms of biliary or pancreatic obstruction, such as dark urine, jaundice, steatorrhea, abdominal pain, pruritus, cholangitis, or pancreatitis. Occasionally, melena or iron deficiency anemia may lead to the diagnosis.
- The majority of ampullary adenomas are sporadic; however, a significant second group of patients are those with familial adenomatous polyposis (FAP) syndrome.[1]
- Up to 90% of patients with FAP will develop duodenal adenomas, and ampullary adenocarcinoma is the leading cause of death in FAP patients who have undergone prophylactic colectomy.[1,2]
- Whether sporadic or associated with a polyposis syndrome, adenomas at the ampulla are considered precancerous lesions warranting resection.
- Various series have documented 25% to greater than 50% of adenomas contain occult malignant foci.[1–3]
- Adenomas have a 30% transformation rate to carcinoma.[4]
- In several published series, sampling error results in a falsely negative preoperative biopsy in 25% to 30% of cases harboring malignant disease.[2,5]
- As patients with benign ampullary lesions are now often initially managed with endoscopic resection, candidates for surgical ampullectomy comprise a very small group of patients who are neither candidates for endoscopic resection nor for pancreaticoduodenectomy.[6] Additionally, patients in whom endoscopic resection has been incomplete or unsuccessful for technically limitations (such as prior Roux-en-Y gastric bypass) may fall into this group.
- In one series of 157 patients with ampullary lesions, the presence of jaundice, steatorrhea, dark urine, or pruritus was associated with malignancy, whereas when the presenting symptom was gastrointestinal (GI) bleed, the diagnosis was more commonly benign.[7] Notably, patients with obstructive symptoms are highly unlikely to be candidates for ampullectomy because of the association with malignancy.
- Sphincter of Oddi dysfunction (SOD) is a well-characterized syndrome that in turn may be due to mechanical causes (e.g., fibrosis) or functional (e.g., dysmotility in the biliary tree, persistent spasm of the sphincter due to neurohormonal dysfunction).
- SOD often presents with recurrent biliary-type pain after a cholecystectomy. Other causes of biliary pain, such as retained CBD stone, pancreatitis, and cholangitis, are typically ruled out by extensive workup before the diagnosis of SOD is made.
- Additionally, SOD may occur in the setting of a prior Roux-en-Y gastric bypass performed for morbid obesity.[8]

- Patients who have undergone a prior gastric bypass operation or Roux-en-Y gastrojejunostomy for any other indication may have anatomy that renders endoscopic management of ampullary lesions, retained CBD stone, or SOD unfavorable, necessitating a transduodenal approach.
- Patients with pancreas divisum are thought to have pancreatitis secondary to minor papillary insufficiency. This group of patients should initially be managed conservatively, and replacement of pancreatic enzymes alone may decrease symptoms. Endoscopic therapy with minor papillotomy or surgical minor papillary sphincteroplasty is the next option.[9]
- A final category of patients who may require surgical intervention on the ampulla include those who have sustained a posterior duodenal perforation as a complication of endoscopic retrograde pancreatography. Most often, these injuries should be managed nonoperatively; however, when the injury is immediately recognized, emergent transduodenal sphincteroplasty may be considered in carefully selected patients.

FIG 2 ● **A.** EUS image of an adenoma at the ampulla of Vater. The CBD and pancreatic duct (PD) are both visible and there is an irregular density that is an adenoma visible toward the center of the field *(red arrow)*.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Noninvasive imaging modalities may include magnetic resonance cholangiopancreatography (MRCP) and computed tomography (CT) with pancreatobiliary contrast protocols (**FIG 1**).
- Invasive modalities include endoscopic retrograde pancreatography (ERCP) or endoscopic ultrasound (EUS) and are part of the initial workup for lesions of the ampulla.
- Imaging modalities can provide information on extent of local disease including depth of invasion, if applicable. CT scans are the usual initial diagnostic imaging studies performed, due to ready availability and ease of interpretation.
- CT scan has use for the detection of nodal disease or distant metastases, whereas EUS has a great deal of use in the detection of depth of invasion of ampullary adenoma and hence has a role in the workup of disease amenable to local resection (**FIG 2**). This point is not without controversy, as others have argued that CT scan is not superior to EUS in terms of nodal staging.
- When stricture at the ampulla is suspected, ERCP can be used to clarify the extension of the stricture into the pancreatic parenchyma or the distal CBD; this information is critical for operative planning.

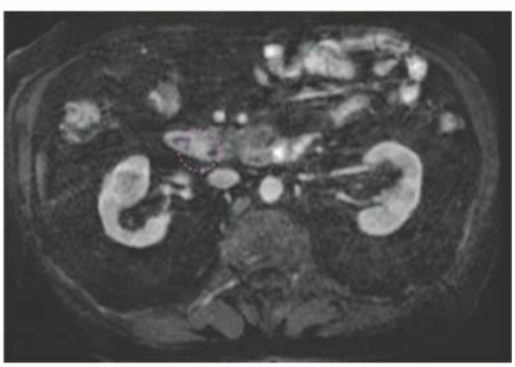

FIG 1 ● MRCP image demonstrating a 1.3-cm adenoma at the ampulla of Vater. The ampullary adenoma is outlined in a *dashed purple line* in this image.

- For strictures that extend beyond the ampulla itself, the operation of choice would be a pancreaticoduodenectomy or CBD reconstruction, that is, hepaticojejunostomy depending on the etiology.
- ERCP, hepatobiliary iminodiacetic acid (HIDA) scan, and MRCP with secretin stimulation or sphincter manometry may be used to make the diagnosis of SOD.
- Patients with delayed excretion of contrast after ERCP (>45 minutes), CBD dilatation greater than 1.2 cm, and elevated alkaline phosphatase or serum glutamic oxaloacetic transaminase (SGOT) (greater than two times the upper limit of normal) have excellent response to endoscopic sphincterotomy alone without other diagnostic maneuvers.
- Patients who meet some but not all of these criteria benefit from further diagnostic testing with manometry, and those patients in whom manometry is abnormal may benefit from sphincterotomy.
- Patient with biliary pain but without any of the aforementioned abnormalities may undergo manometry but have generally lower rates of success following sphincterotomy even in the presence of abnormal manometry.
- Although this has not been validated prospectively, one small study suggested that HIDA scan with morphine as an adjunct has the advantage of a noninvasive test that, when positive, correlates well with a positive surgical outcome.[10]
- MRCP with secretin stimulation is another modality that has been used to demonstrate SOD dysfunction in patients with prior Roux-en-Y gastric bypass for morbid obesity.[8]
- Sphincter manometry is performed via a miniaturized pressure catheter that is placed in the sphincter of Oddi using a side-viewing endoscope. Four categories of manometric abnormalities are defined and include the following:
  - Papillary stenosis, which is defined as persistently elevated resting pressures within the sphincter of Oddi that are unresponsive to pharmacologic means of sphincter relaxation
  - Dyskinesia, in which the response to pharmacologic relaxation is preserved within the context of elevated resting pressures

- Tachyoddia, in which there is an increased frequency of spontaneous contractions of the sphincter and physiologically abnormal (paradoxical) response to cholecystokinin.[11]
- Paradoxical sphincter response, in which an increase in sphincter tone is observed in response to cholecystokinin administration
- Endoscopy with secretin stimulation test may also be used in the stratification of patients with pancreas divisum who are likely to benefit from surgical sphincteroplasty. Briefly, EUS may be used to visualize the minor pancreatic duct. After administration of secretin, increase in ductal dilatation gives evidence to an obstructive papillary stenosis. The absence of this dilatation should prompt consideration of further trials of nonsurgical therapy.

SURGICAL MANAGEMENT

Preoperative Planning

- Biliary tract decompression, that is, by percutaneous transhepatic biliary drain placement or ERCP, may be required if the patient has presenting symptoms of biliary obstruction.
- Preoperative placement of an epidural catheter for pain control is a useful adjunct for a planned open operation and limits postoperative dependence on narcotic pain medication.
- General strategies to optimize patients for major surgery should be employed as indicated. These may include optimization of nutritional status as well as smoking and alcohol cessation.

Positioning

- The patient is positioned supine on the operating table. Sequential compression device boots are placed. Unless there is a contraindication to heparin administration, 5,000 units of unfractionated heparin are given in the preoperative holding area as deep venous thrombosis (DVT) prophylaxis.
- Preoperative antibiotics are administered within 1 hour of incision. Appropriate antibiotics should cover for skin flora as well as for gram-negative enterics and anaerobes.
- Our practice is to extend the left arm and tuck the right arm and place the Bookwalter (or similar) retractor on the patient's right side. A right subcostal (Kocher) incision with extension a short distance across the midline is used (**FIG 3**).

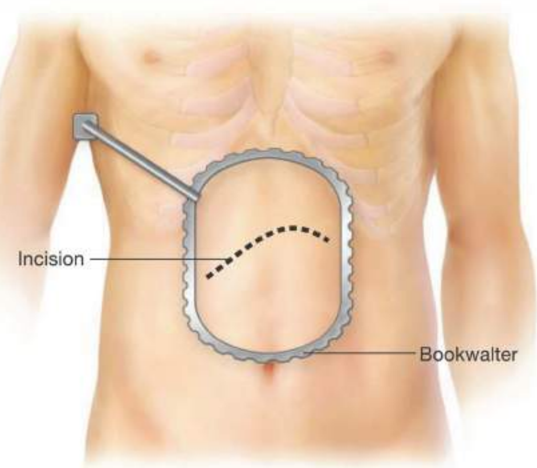

FIG 3 ● The patient is positioned in the supine position. The right arm is tucked and a Bookwalter retractor is typically placed on the right side. A right-sided subcostal incision with extension across the midline is used.

INCISION AND EXPOSURE

- A right subcostal (Kocher) incision is made with extension across the midline to facilitate exposure. The incision should be made approximately two fingerbreadths inferior to the costal margin. Adequate exposure is facilitated by the placement of a fixed retractor such as the Bookwalter or Thompson. If the gallbladder is present, a cholecystectomy is typically performed. We suggest leaving a long cystic duct stump to facilitate placement of transcystic duct stump biliary catheter to guide identification of the ampullary orifice. This maneuver can optimize the location of the subsequent duodenotomy. The liver is retracted superiorly and the hepatic flexure is completely mobilized such that it can be safely retracted inferiorly out of the operative field.

KOCHER MANEUVER

- The second portion of the duodenum is grasped and retracted medially so as to enable division of the peritoneum at its lateral border. An avascular plane is developed, with extension toward the midline to completely mobilize the duodenum through the third portion (**FIG 4**). The location of the ampulla is typically at the distal aspect of the second portion of the duodenum; hence, wide mobilization of the duodenum with a Kocher maneuver that extends inferiorly and medially toward the midline with full mobilization of the hepatic flexure to expose the third portion of the duodenum is essential to provide adequate exposure and a tension-free closure. This mobilization also allows the duodenum to be retracted up into the field where it may be maintained with stay sutures for subsequent steps of the operation. The placement of laparotomy pads posterior to the duodenum to further elevate it into the incision is recommended.

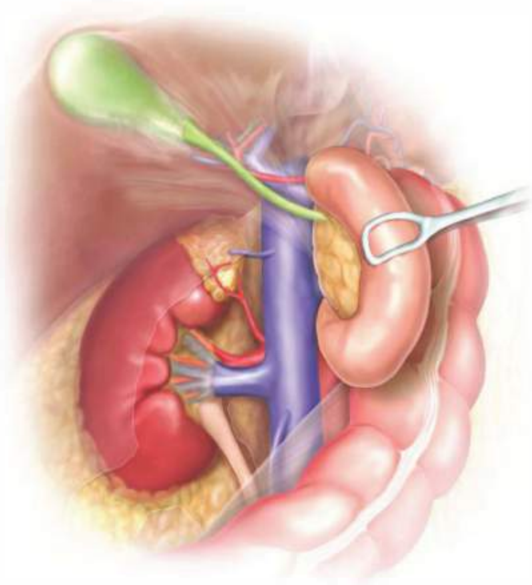

FIG 4 ● A Kocher maneuver is performed by incision of the lateral attachments of the duodenum and extension to the third portion of the duodenum, exposing the junction of the middle colic and the superior mesenteric vessels.

DUODENOTOMY AND EXPOSURE OF THE AMPULLA

- Bimanually palpate the second portion of the duodenum to identify the lesion. If it cannot be palpated, place a biliary catheter via the cystic duct stump, inflate the balloon, and withdraw it until you meet resistance—the balloon will be palpable at the ampulla. An antimesenteric duodenotomy is then made to expose the luminal orifice of the ampulla (**FIG 5**). The duodenotomy may be made either in a longitudinal or a so-called lazy S curvilinear incision. We typically favor a longitudinal incision, which allows for extension of the incision if a wider field of exposure is needed. Alternatively, if a wide exposure is required to remove a large adenoma, a curvilinear incision offers the broadest operative field. The duodenum will stretch, so use care not to make an unnecessarily large incision. A 5-cm longitudinal incision will usually facilitate adequate exposure. Stay sutures are placed around the edges of the duodenotomy to maintain the operative field, thus exposing the lumen of the duodenum.

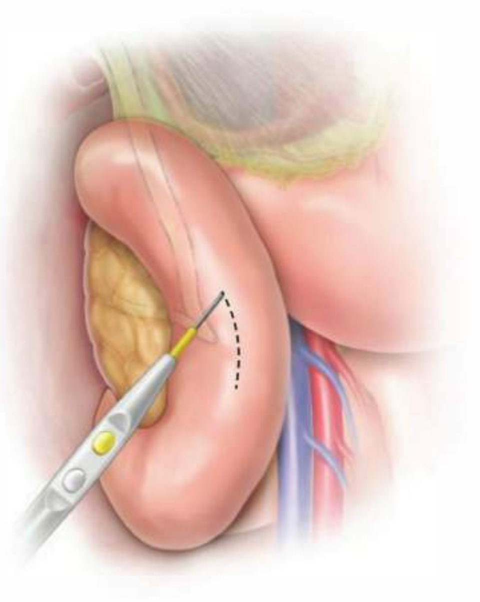

FIG 5 ● A duodenotomy is performed. The placement of the incision may be longitudinal or in a lazy S configuration. Palpation of the ampulla through the duodenal wall or palpation of a biliary catheter threaded through the cystic duct stump across the ampulla facilitates placement of the incision. The *dashed line* represents the approximated location of the ampullar structures. Palpation of the structures (and any preoperatively placed biliary stents) should guide the placement of the incision.

IDENTIFICATION OF THE MAJOR AND MINOR PAPILLA

- The major and minor (if present) papillae are identified. Adenomas are readily apparent. Alternatively, the biliary catheter will identify the major papilla.
- The minor papilla is typically located 2 cm cephalad to the major orifice. Its identification may be facilitated, if needed, by intraoperative secretin injection (75 U/kg) to stimulate pancreatic secretions.

PREPARATION FOR THE EXTIRPATIVE PHASE

- At this point, it is advantageous to prepare the field for excision of the ampulla (**FIG 6**). The maneuvers used will be dependent on the goals of the operation specific to the individual patient. If a mass is to be excised, placement of a traction suture (2-0 silk) into the mass allows it to be elevated, retracted, and excised.[3]
- From within the lumen of the duodenum, full-thickness, circumferential stay sutures are placed to demarcate 1.0-cm borders around the planned resection area (i.e., 1.0 cm from the ampulla or obvious borders of the mass itself), which will also facilitate delivery of the ampulla into an optimal position for resection. These sutures also stabilize the redundant duodenal mucosa.

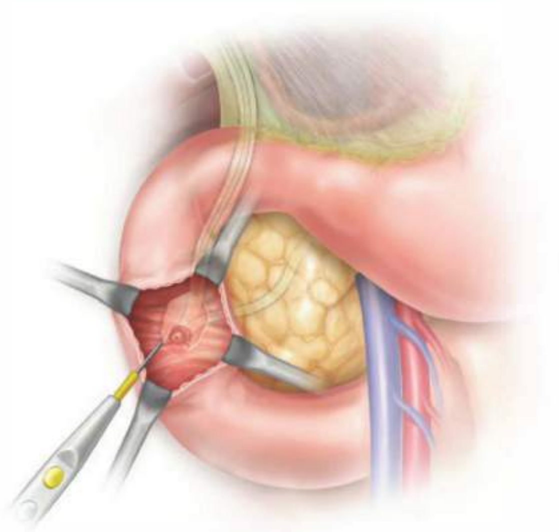

FIG 6 ● Circumferential cautery around the ampulla results in the exposure of the biliary and pancreatic ductal orifices. If difficulty is encountered identifying the pancreatic orifice, intraoperative secretin administration may be used, with a resultant clear effluent observed in the operative field from the pancreatic orifice. The localization of the biliary duct is enabled by the placement of a directed biliary catheter via the cystic duct stump.

PERFORMANCE OF THE EXTIRPATIVE PHASE

- Retracting the mass inferiorly, *needle tip* electrocautery is used to divide the posterior duodenal mucosa until the bile duct is reached. At that point, sutures are placed to approximate the (full-thickness) CBD and the medial duodenum (5-0 absorbable monofilament). The dissection then continues circumferentially in a cranial to caudal fashion.
- The biliary catheter, when present, is withdrawn. Needle-tipped electrocautery is used to incise the medial (deep) wall of the CBD. This transaction point can be up to 3 cm proximal to the duodenal orifice and still accommodate a ductoplasty.
- As the dissection progresses circumferentially, 4-0 or 5-0 absorbable monofilament sutures are placed full-thickness through the CBD and then the duodenal wall and tied. Hence, the reconstruction occurs as the dissection is performed. This approach provides optimal identification of the edge of the incised bile duct and prevents catastrophic retraction of the CBD out of the field of view.
- Alternatively, delaying reconstruction until both pancreatic ducts and CBDs have been excised serves two purposes. First, intraoperative frozen section of the completely excised specimen may be performed and additional ductal margins (up to 1 cm) taken as needed. Second, the reconstruction with orientation of the pancreatic and CBDs may be optimized.
- For this approach, sutures should be placed in the bile and pancreatic ducts as the dissection proceeds and the needles left in place. Opposing bites of duodenum will be taken later to approximate these structures after the resection is complete.
- The pancreatic ductal orifice is encountered at about the 2 o'clock position. Similar to the CBD, stay sutures (5-0 polydioxanone [PDS] or similar) are placed full thickness through the pancreatic duct and ultimately are secured to the duodenum.
- The dissection is carried circumferentially with sutures placed through the duodenal wall until the entire ampullary complex has been excised.

TECHNIQUES

INTRAOPERATIVE FROZEN SECTION

- If the operation is performed for an adenomatous lesion, intraoperative frozen section should be used. Malignancy found on intraoperative frozen section should warrant consideration of conversion to pancreaticoduodenectomy.
- Between 25% and 45% of patients with pathologic T1 periampullary lesions will have positive lymph node metastases. Thus, pancreaticoduodenectomy is the preferred management strategy for malignancy. Intraoperative analysis of the resected adenoma is essential.[4,10,12]

RECONSTRUCTIVE PHASE

- Reconstruction proceeds with creation of a septum by apposition of the CBD and pancreatic ducts. Full-thickness interrupted sutures using 5-0 monofilament, absorbable sutures are placed through each duct such that they can be tied on the lumen side (**FIG 7**).
- The pancreatic ducts and CBDs are then approximated to the duodenal wall by taking the previously placed sutures through the ducts and placing full-thickness suture bites through the duodenum, exiting in the duodenal mucosa. This is carried out in a circumferential fashion until a duodenal defect remains at the inferior portion of the reconstruction, which is then closed by reapproximation (**FIG 8**).
- Our practice is to close the duodenotomy in a transverse fashion when this can be accomplished in a tension-free manner (typically dependent on the size of the duodenotomy). Alternatively, we use a longitudinal closure using seromuscular 3-0 silk sutures. Oversewing is avoided in order to prevent stricture and to maintain maximal duodenal patency. In some cases, when a longitudinal closure provides a better primary closure but narrows the lumen, we also perform a gastrojejunostomy.
- A closed suction drain may be left in close proximity to the duodenotomy at the surgeon's discretion, and the abdomen is closed in a standard fashion.

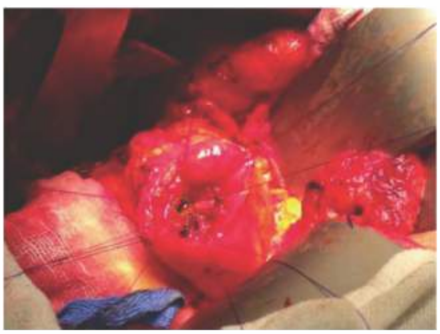

FIG 7 ● A completed reconstruction of the ampullary structures. The CBD is identified by the *dashed green line*, whereas the pancreatic duct is identified by the *dashed blue line*.

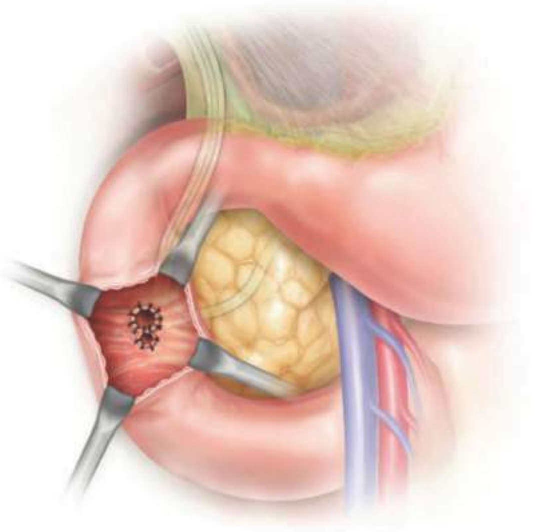

FIG 8 ● Reapproximation of the ductal structures. The reapproximated ducts are always smaller than the excised ampulla; hence, the additional defect may be closed with simple duodenal stitches.

PEARLS AND PITFALLS

Sphincter manometry	■ Avoid use of anticholinergics or opioids such as morphine, which alter sphincter of Oddi pressures.
Postoperative pneumobilia	■ Expected; indicative of patency of the repair
Delayed reconstruction of pancreatic and CBD	■ Facilitates optimization of the orientation of the ducts to the duodenum and enables additional margins to be taken if needed
Bariatric surgery patients with pancreatobiliary-type pain	■ SOD and ampullary stenosis should be in the differential and may be amenable to surgical intervention. ■ More recently, data has emerged questioning the value of endoscopic management of SOD. The extension of this finding to surgical management is unknown.

Preoperative ERCP and EUS	■ Both are crucial modalities to demonstrate the feasibility of ampullectomy.
Duodenotomy	■ The duodenotomy will stretch. Although it must be of sufficient size so as to afford appropriate exposure, start small and extend as needed.
Closure of the duodenotomy	■ If transverse closure is not possible to accomplish in a tension-free manner, a longitudinal closure may be used, with a gastrojejunostomy if concern exists that the duodenal lumen is thus narrowed.
Identification of the ampulla	■ A biliary Fogarty catheter may be passed via the cystic duct in order to facilitate identification of the ampulla.

POSTOPERATIVE CARE

- Routine postoperative care includes pain control, strict recording of urine output via a Foley catheter, gastric decompression via a nasogastric tube, and monitoring output of a closed suction drain.
- Patient-controlled analgesia or an epidural is typically used. Patients are transitioned to oral pain medication once tolerable of clear liquids.
- Our practice per the clinical pathway is to draw routine full set of labs on the first postoperative day and then the fourth postoperative day but otherwise only when clinical suspicion raises concern. In sphincteroplasty patients, it is prudent to include total bilirubin and serum amylase and lipase and to delay advancement of diet if pancreatic enzymes remain elevated postoperatively.
- Sequential compression stockings and unfractionated heparin (5,000 units three times a day) are used routinely. Additionally, pantoprazole (40 mg intravenously daily) is continued in the postoperative period.
- The nasogastric tube is typically discontinued on the third postoperative day.
- The epidural and Foley catheter are typically discontinued on the third postoperative day. In the absence of an epidural, the Foley catheter is removed once postoperative urine output is satisfactory, typically on postoperative day 1 or 2.
- The drain output is continuously monitored. The drain is left in place until the patient can tolerate a regular diet. The drain is then removed unless the character or volume of output is of concern for a leak at the duodenal closure site.

OUTCOMES

- When performed for SOD, patient satisfaction and symptom relief has been noted to vary with SOD subclass. In one series, patients with type I SOD reported good outcomes in nearly 100% of patients. However, results were not as favorable in type III and type II dysfunction with 58% and 61% favorable outcomes, respectively. In multivariate analysis, patients with good outcomes tended to be older (47 years old vs. 33 years old), whereas patients with poor outcomes tended to suffer from chronic pancreatitis.[9]
- Surgical sphincteroplasty is associated with a 30% complication rate. Complications after ampullectomy occur at half the frequency of complications of pancreaticoduodenectomy and with a lesser degree of severity.[10]
- When performed for minor papillary stenosis, success rates vary with patient characteristics. Success is lowest in patients with pancreatic-type pain without clinical evidence of pancreatitis, intermediate in patients with chronic pancreatitis, and highest (75% to 90%) when undertaken after a single episode of acute pancreatitis.
- When performed for SOD, a retrospective review indicated that the success rate of transduodenal sphincteroplasty was low in patients with concomitant chronic pancreatitis but relatively high in patients who had undergone prior bariatric surgery.[9]
- In patients who had undergone prior Roux-en-Y gastric bypass and subsequently underwent operation for SOD, one relatively small case series demonstrated that the majority of patients had pain improvement after surgery.[8]
- When performed for malignancy, retrospective analysis indicates significant disadvantages to transduodenal resection versus pancreaticoduodenectomy including increased incidence of local recurrence and decreased survival. However, the only prospective series comparing the two techniques is relatively small and demonstrates that in selected patients outcomes may be equivalent.[13]

COMPLICATIONS

- In one series of patients comparing surgical ampullectomy to endoscopic ampullectomy, a 42% morbidity rate was observed among the surgical ampullectomy group versus the 18% in the endoscopic ampullectomy group. Complications after endoscopic ampullectomy included hemorrhage, pancreatitis, and intractable nausea, in decreasing order of frequency. After surgical ampullectomy, the most frequent complications included dehydration, symptomatic pancreatitis, wound infection, and intraabdominal abscess.
- Major complications are rare but include leakage at the duodenotomy leading to pancreaticobiliary fistula or intraabdominal abscess and sepsis. Cholangitis is also reported with a frequency of 6% in one series.[14]

Chapter 45

Enucleation of Pancreatic Neuroendocrine Tumor

Megan B. Anderson   Christopher D. Raeburn   Barish H. Edil

DEFINITION

- Pancreatic neuroendocrine tumors (PNETs) are a diverse group of neoplasms that can arise from mature endocrine cells of the pancreas (α, β, δ, and γ cells) and multipotent cells, which have the ability to differentiate into endocrine and exocrine cells. PNETs were previously known as islet cell tumors.
- PNETs can be subdivided into functional and nonfunctional based on their production of specific pancreatic endocrine hormones. Functional PNETs can produce insulin, gastrin, glucagon, vasoactive intestinal polypeptide (VIP), and somatostatin.

DIFFERENTIAL DIAGNOSIS

- Functional PNETs amenable for enucleation are the following:
  - Insulinoma
  - Selected gastrinoma
  - Selected somatostatinoma
- Selected nonfunctional PNETs amenable for enucleation are typically less than 2 cm but this is an area of controversy.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history and physical must be obtained to assess for signs of functional tumors, symptoms of mass effect, or evidence of metastatic disease. Physical exam should focus on abdominal masses, organomegaly, signs of biliary obstruction or liver dysfunction, and lymphadenopathy.
- Although most PNETs are sporadic, 10% can be associated with predisposing syndromes such as multiple endocrine neoplasia type 1 (MEN-1), von Hippel-Lindau (VHL) disease, neurofibromatosis type 1 (NF1), and tuberous sclerosis complex (TSC).
- Nonfunctional PNETs are typically slow growing and occur in the head of the pancreas. These lesions usually present similarly to pancreatic adenocarcinoma due to the mass effect of the tumor: jaundice, abdominal pain, and weight loss.
- Functional PNETs
  - Insulinoma: Whipple's triad—symptoms of hypoglycemia, generally when fasting, at night, or during exercise; hypoglycemia documented at the time of symptoms; and symptom relief with glucose administration.
    - Supervised 72-hour fast with a plasma glucose of less than 45 mg/dL
    - Increased C peptide more than 100 pmol/L
    - Negative sulfonylurea screen in urine
    - Negative insulin antibodies
  - Gastrinoma: Zollinger-Ellison syndrome—refractory peptic ulcer disease and secretory diarrhea
    - Serum gastrin of more than 500 pg/mL
    - Gastric pH less than 3
    - Positive secretin or calcium stimulation test

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Imaging: Computerized tomography (CT), magnetic resonance imaging (MRI), endoscopic ultrasonograph with fine needle aspiration (EUS/FNA), somatostatin receptor scintigraphy (SRS), percutaneous transhepatic portal venous sampling (PTPVS), and arterial stimulation with venous sampling (ASVS) all may play a role in localization of a PNET and preoperative planning. **FIG 1** shows a CT scan of an insulinoma at the level of the head of the pancreas. These lesions are typically best visualized on arterial phase CT.
- CT scanning is unfortunately only 67% sensitive in localizing PNET and these other adjunctive measures may be required.
- As a part of EUS evaluation, tattoo small lesions or lesions that are deep within the parenchyma of the pancreas to make localization easier at the time of operation.
- Based on the data collected from laboratory tests and imaging studies, only select PNETs are amenable to enucleation. Low-grade tumors such as insulinomas are most amenable to enucleation.

SURGICAL MANAGEMENT

Preoperative Planning

- Because most (>90%) insulinomas are benign, enucleation is usually preferred. A formal pancreatic resection should be considered if there is evidence of invasion, lymphadenopathy, or if the tumor is in close proximity to the pancreatic

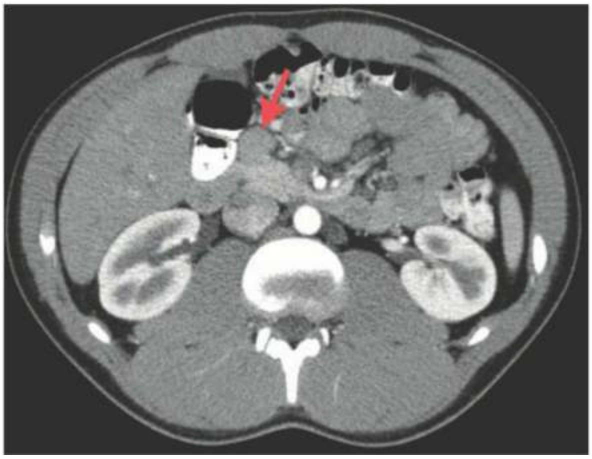

FIG 1 • CT scan of abdomen showing an insulinoma in the head of the pancreas. It is well circumscribed, consistent with a benign PNET. It is presented as it is unusual; it does not enhance on the arterial phase of imaging. *Arrow* points to an exophytic insulinoma at the head of the pancreas.

duct or major vessels. It is possible to perform an enucleation through traditional open technique or laparoscopically.

- For lesions where the pancreatic duct may be at risk for injury, some have advocated preoperative placement of a pancreatic duct stent. There is not clinical data that supports or condemns this approach.
- Contraindications would include recent pancreatitis, uncontrolled coagulopathy, comorbidities that would limit life expectancy, and signs of malignancy, which include enlarged lymph nodes or distant metastases.

Positioning

- The patient should be placed supine on the operating room table. The entire abdomen should be sterilely prepped and draped.

PLACEMENT OF INCISION

- Open: An upper midline incision should be made to enter the abdomen.
- Laparoscopic: An infraumbilical 10-mm port should be placed to gain access to the abdomen. From there, another two 10-mm ports will be placed in the left upper quadrant and right lower quadrant, and two 5-mm ports will be placed in the right upper quadrant and left lower quadrant as shown in FIG 2.

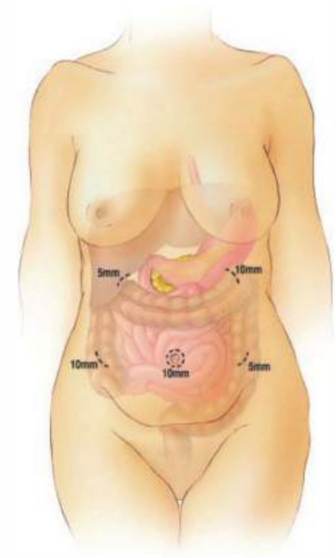

FIG 2 ● Illustration of port site placement for laparoscopic enucleation of PNET. It is best to bring the drain(s) out through the left upper quadrant and/or right upper quadrant port sites. Illustration by Frank Corl.

ABDOMINAL EXPLORATION

- A thorough examination of the abdomen should be performed prior to proceeding with enucleation to exclude advanced locoregional disease or metastatic disease. PNETs most commonly metastasize to the liver; thus, thorough examination of the liver is critical and intraoperative ultrasound (IOUS) is the most sensitive imaging modality for detecting metastases.

PANCREATIC DISSECTION

- If the lesion lies in the head of the pancreas, this area is mobilized by first dissecting the omentum from the hepatic flexure. A Kocher maneuver allows you to further mobilize the head of the pancreas. Division of the right gastroepiploic vessels on the anterior surface of the pancreatic head will allow for full exposure. While mobilizing medially, the superior mesenteric vein (SMV) will be encountered and care must be taken to avoid a vascular injury.
- The gastroepiploic vein may need to be divided to provide adequate exposure to the pancreatic neck.
- If the tumor is located in the neck, the plane below the neck and anterior to the portal vein/SMV might need to be developed.
- If the lesion is in the tail of the pancreas, mobilizing the splenic bed may expose this area. This requires division of the gastrosplenic ligament (containing gastroepiploic vessels) and also the short gastric vessels.
- Obtain access to the lesser sac by dividing the gastrocolic ligament from left to right. Retract the stomach more superiorly, along with the omentum to adequately visualize the pancreas.
- At this point, inspection of the pancreas is done. If the tumor is easily identified, further dissection may be

avoided unless patient has an inherited syndrome or if there are clinical concerns of multicentric disease.

- Dissecting out the superior and inferior borders of the pancreas using blunt and sharp technique may further help delineate the location of the lesion and allows access to the posterior pancreas if necessary for tumor identification.
- Once the pancreas is visible, palpate the mass using your finger or a laparoscopic instrument. In open cases, a wide Kocher maneuver and splenic mobilization facilitates bimanual palpation of the pancreatic head and body/neck, respectively. If the tumor is small, IOUS is also useful in localizing the mass as well as to better evaluate the proximity to the pancreatic duct and vascular structures.
- Once the mass is located, care must be taken to avoid any major surrounding vascular structures.
- Once the pancreas has been sufficiently mobilized and excellent exposure has been obtained, one should be able to visualize the mass using the aforementioned techniques. Please see **FIG 3** to appreciate how exposure of the pancreas provides visualization of the mass.

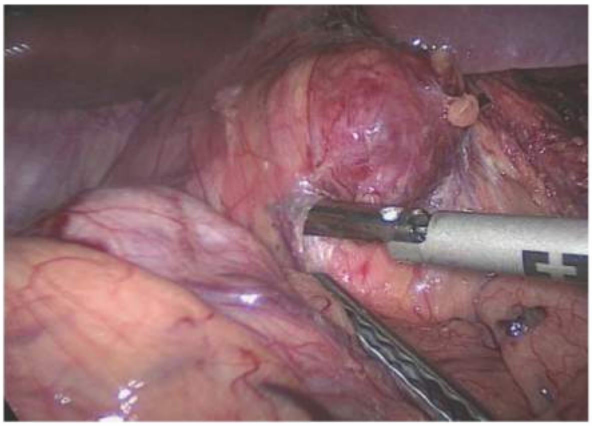

FIG 3 ● Intraoperative photograph of an insulinoma. This photo shows the well-encapsulated mass that extends outside the parenchyma of the pancreas being dissected using an ultrasonic energy device. This anatomic relationship of a PNET to the parenchyma of the pancreas, coupled with the pseudocapsule, make this lesion ideal for enucleation.

DISSECTING THE MASS

- PNETs, especially insulinomas, are typically well circumscribed and well encapsulated, and a dissection plane should be evident. **FIG 4** demonstrates a well-encapsulated insulinoma and a dissection plane, which can be followed with electrocautery.
- Once the appropriate tissue plane has been identified, it may be further dissected out using different type of energy devices. Constant gentle elevation and traction allows for visualization of the plane of dissection and feeding vessels.
- The authors advocate the use of surgical clips on any bridging structure greater than 1 mm.
- A figure-of-eight suture placed in the mass can serve as a valuable retraction point and facilitate development of the tissue plane along the pseudocapsule of a PNET.
- Once the mass is removed, care should be taken to ensure excellent hemostasis. In addition, IOUS can be used to demonstrate the integrity of the pancreatic duct.
- In the case of gastrinoma, some advocate for routine duodenotomy as there is a higher risk of multiple tumors, which can be small and otherwise difficult to detect.

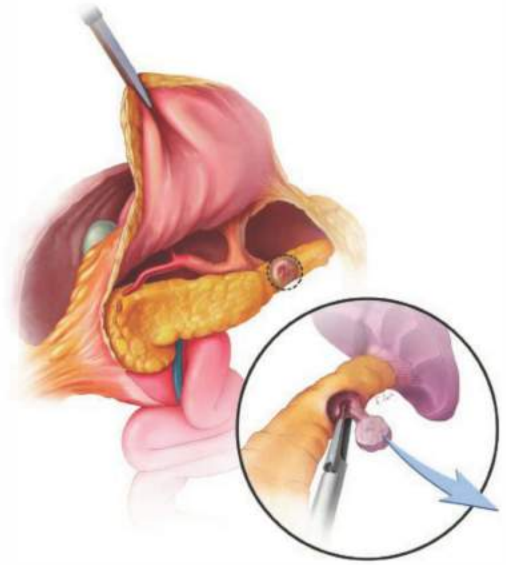

FIG 4 ● Schematic demonstration of adequate exposure of the pancreas. This figure emphasizes the importance of retracting the stomach on providing adequate exposure. The *inset* demonstrates how the lesion should be easily dissectible from the pancreatic parenchyma.

CLOSURE AND DRAIN PLACEMENT

- When closing the 10-mm ports, the fascia is ideally closed to prevent incisional hernia in the future.
- A drain should be placed along the area that has been enucleated; this will aid in monitoring for and controlling any postoperative leaks. The drains are most easily brought out through the left upper quadrant or right upper quadrant incisions, as demonstrated in **FIG 5**.

FIG 5 ● A photograph of the closed abdomen; the drains are most easily brought out through the right upper quadrant or left upper quadrant port sites.

PEARLS AND PITFALLS

EUS with tattooing of the lesion	■ A tattoo that localizes very small PNETs is invaluable to guide the operation. As most are now approached laparoscopically, this facilitates identification of the neoplasm without the ability of palpation.
Deep difficult PNETs	■ If enucleation is difficult for body/tail tumors or violation of the pancreatic duct is suspected, perform either laparoscopic or open distal pancreatectomy, with preservation of the spleen when possible.
Technique	■ Grasping a PNET will often lead to laceration. The neoplasm should not be grasped; rather, use an instrument to push the lesion to provide exposure. ■ A suture through the lesion serves as an excellent retraction tool when exposure is challenging.
IOUS	■ A very useful tool in determining duct relationship with tumor to plan enucleation versus resection early in the operation.
Drain	■ The vast majority of pancreatic surgeons place a drain following enucleation. The fistula rate is very high.

POSTOPERATIVE CARE

- Postoperatively, the patient may have their diet advanced as tolerated. If an insulinoma is removed, plasma glucose should be monitored every 15 minutes until stabilized. The drains should be monitored for the quantity and quality of the output. Once patient is taking adequate oral intake, the drains should be sent for amylase levels to rule out a leak before the drains are removed.

OUTCOMES

- If the PNET is an insulinoma, enucleation should be curative. If a nonfunctional PNET is elected for enucleation, the patient should be placed in a surveillance program and for PNETs that are large or potentially malignant, the operation should be a formal resection with lymphadenectomy.

COMPLICATIONS

- Early complications include the following:
  - Pancreatic leak
  - Acute pancreatitis
  - Wound or intraabdominal infection
  - Bleeding
- Late complications
  - Chronic pancreatic leak resulting in a cutaneous fistula, ascites, or pseudocyst
  - Recurrent PNET

Chapter 46 Operative Treatment of Gastrinoma

Jason A. Castellanos Nipun B. Merchant

DEFINITION

- Zollinger-Ellison syndrome is a rare etiology of ulcer disease that is caused by gastrin secretion of neuroendocrine tumors (gastrinomas) typically found in the duodenum and pancreas. These tumors may be sporadic or associated with multiple endocrine neoplasia type 1 (MEN-1). Although the gastrin-mediated gastric acid hypersecretion can be controlled with modern antacid and proton pump inhibitor medications, the potentially malignant nature of the gastrinoma is the main determinant of patient survival. Therefore, surgical management remains critical in the care of patients with gastrinomas.

DIFFERENTIAL DIAGNOSIS

- Table 1 summarizes the potential etiologies of hypergastrinemia.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with gastrinomas typically have nonspecific symptoms, and this has historically led to delayed diagnosis from 3 to 9 years after initial onset of symptoms. Although presentation may occur anytime from childhood to old age, patients typically present with a male predominance (3:2) in the fifth decade of life with sporadic gastrinomas and in the fourth decade of life with MEN-1–related gastrinomas.[1]
- The most common symptoms are abdominal pain, diarrhea, and gastroesophageal reflux disease (GERD) (Table 2). Typically, patients have a small, solitary ulcer (<1 cm in diameter) in the first portion of the duodenum, although they may also have a history of recurrent ulcers in atypical locations such as the jejunum (11%) and distal duodenum (14%).[2,3]
- The most common complications are due to ulcer perforation, although up to 20% of patients do not have an ulcer on presentation.
- Gastrinomas arise sporadically in a majority of cases (75% to 80%), whereas the remainder are due to MEN-1. It is important to differentiate the etiology as this dictates the clinical and surgical management of these patients. In addition to gastrinomas, patients with MEN-1 also develop parathyroid adenomas, pituitary adenomas, and other neuroendocrine tumors.[4]

Table 1: Differential Diagnosis of Hypergastrinemia

Elevated Gastric Acid Secretion	Normal/Decreased Gastric Acid Secretion
Helicobacter pylori infection	Pernicious anemia
Retained gastric antrum	Atrophic gastritis
Gastrinoma	Proton pump inhibitor or H_2 blocker use
Antral G-cell hyperplasia	Postvagotomy
Renal failure	
Short bowel syndrome	

IMAGING AND OTHER DIAGNOSTIC STUDIES

- If a gastrinoma is suspected, then a serum fasting gastrin level should be obtained. Prior to this test, the patient should be instructed to hold antacid medication (proton pump inhibitors held for 7 days; histamine receptor blockers held for at least 30 hours).
- An elevated gastrin level greater than 10 times the upper limit of normal (>1,000 pg/mL) should be followed by a gastric pH probe in order to rule out achlorhydria. A gastric pH of 4.0 or greater confirms the diagnosis of gastrinoma if other etiologies (e.g., retained antrum after Billroth II resection) have been ruled out.
- A gastrin level that is elevated but less than 10 times the upper limit of normal should be followed by a secretin stimulation test. Although normal G cell gastrin secretion is inhibited by secretin, gastrin release by gastrinoma cells is actually increased. Secretin is infused intravenously over 1 minute after baseline gastrin measurements are obtained; gastrin is then measured at 2, 5, 10, 15, and 20 minutes after infusion. A positive test, typically defined by a rise in serum gastrin of 200 pg/mL or greater, confirms diagnosis of gastrinoma.

Table 2: Signs and Symptoms of Gastrinoma

Abdominal pain (75%)
Diarrhea (73%)
Peptic ulcers (>90%)
Reflux esophagitis (44%)
Nausea (33%)
Emesis (25%)
Weight loss (17%)
Complications of hyperacidity
  Bleeding (25%)
  Perforation
  Obstruction
  Stricture (pylorus, duodenum, esophagus) (<10%)
Physical findings
  Hypertrophic gastric rugal folds (94%)
  Multiple ulcers
  Unusual ulcer locations
    Distal duodenum (14%)
    Jejunum (11%)
  Pancreatic mass

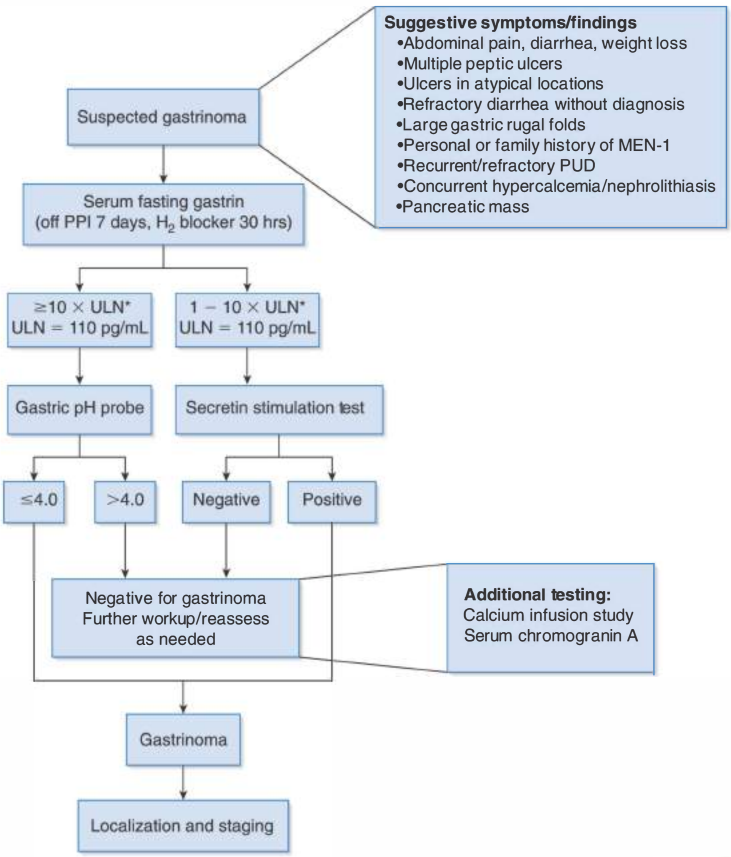

FIG 1 ● Diagnosis of suspected gastrinoma. ULN, upper limit of normal. PPI, proton pump inhibitor; MEN-1, multiple endocrine neoplasia; PUD, peptic ulcer disease.

- If these tests do not confirm the diagnosis but a high clinical suspicion remains, then additional tests may be used. The calcium infusion study consists of a continuous intravenous infusion of 5 mg/kg 10% calcium gluconate over a 3-hour period. Serum gastrin and calcium are measured prior at baseline and at 30-minute intervals for 3 hours after the test begins.[5] A positive result is typically defined as an elevation in serum gastrin by 395 pg/mL or greater, but multiple criteria exist.[6] Serum chromogranin A levels have also been found to be elevated in patients with gastrinomas, and this test may be used to confirm diagnosis in carefully selected cases[7] (**FIG 1**).
- After obtaining a biochemical diagnosis of gastrinoma, attention is turned to preoperative localization and staging. Up to 90% of gastrinomas can be located in the area bounded by the junctions of the cystic and common bile ducts, second and third portions of the duodenum, and neck and body of the pancreas—the so-called gastrinoma triangle (**FIG 2**).
- Initial localization studies include contrast-enhanced triple-phase protocol computed tomography (CT) or magnetic resonance imaging (MRI), and endoscopic ultrasonography (EUS). The decision to use CT versus MRI should be determined by the clinician based on institutional expertise and availability. Although the accuracy of these modalities continues to improve, the sensitivity for detection of tumors less

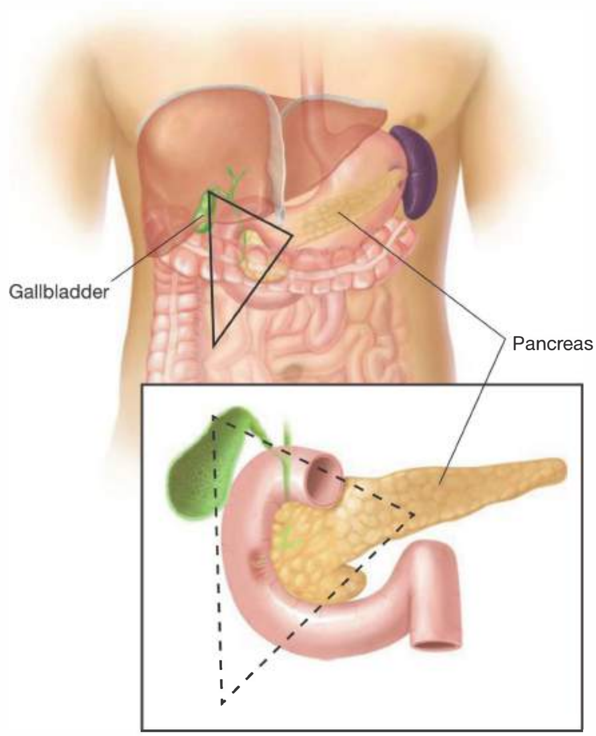

FIG 2 ● The gastrinoma triangle. Up to 90% of gastrinomas are located in this region.

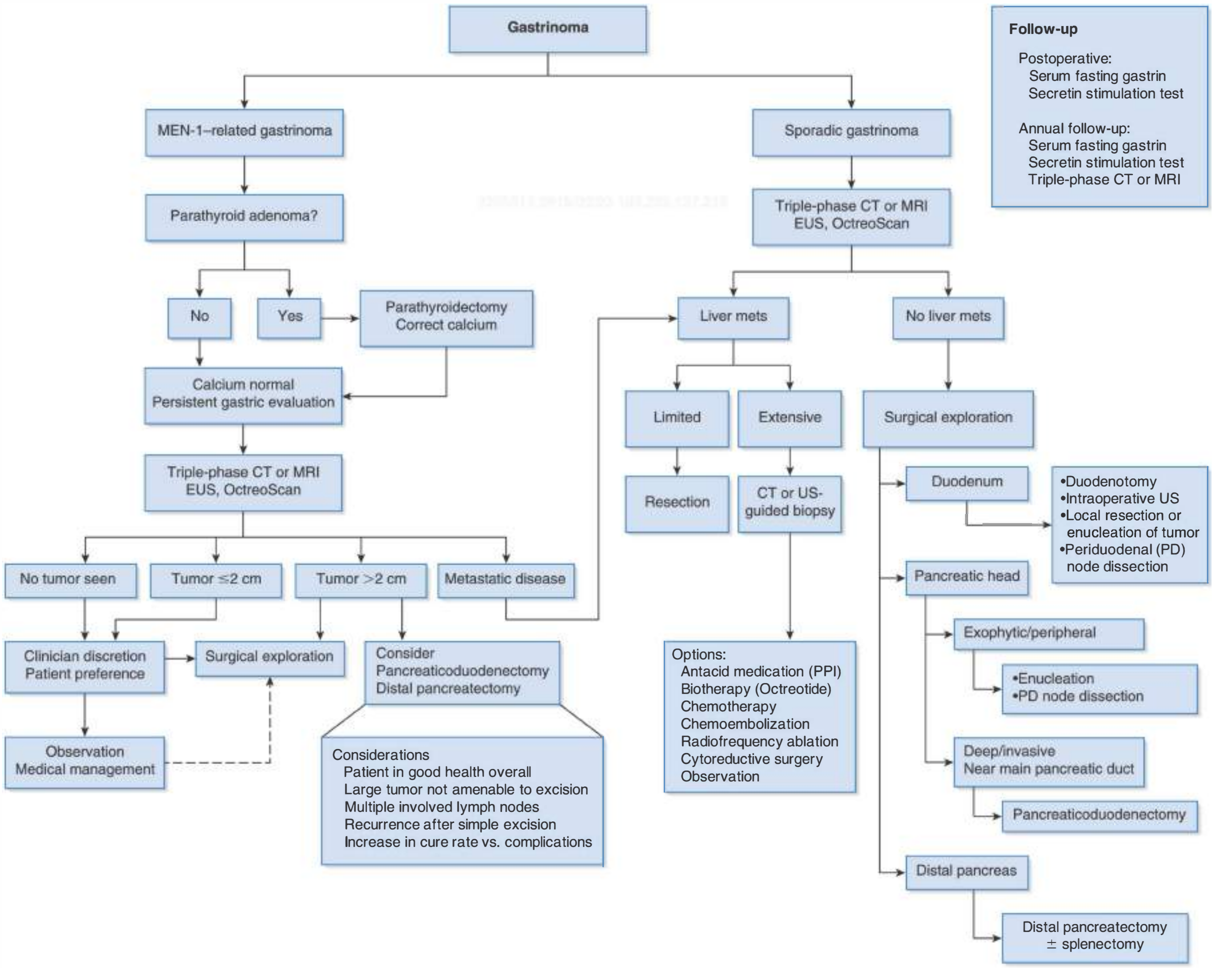

FIG 3 ● Localization and treatment of gastrinoma.

than 2 cm in diameter is decreased, although lesions as small as 4 mm have been detected.[8] EUS can detect smaller lesions (up to 2 to 3 mm, depending on operator experience) and also has the advantage of being able to obtain a cytologic specimen.

- Somatostatin receptor scintigraphy (SRS), also known as OctreoScan, takes advantage of the high level of somatostatin receptor expression in gastrinomas by using radiolabeled 111-indium pentetreotide to detect both primary tumors and hepatic metastases. Although the accuracy of other imaging modalities is improving, SRS continues to have a place in tumor localization and staging as it remains highly sensitive for detection of metastatic disease.[9]
- Patients determined to have MEN-1–related gastrinoma should be evaluated for hyperparathyroidism. If a primary hyperparathyroidism is present, it should be addressed prior to further surgical treatment as hypercalcemia may increase anesthetic risk and also elevates gastrin and acid production.
- If the etiology is sporadic and no metastases are detected, then surgical exploration is indicated even if a tumor is not localized by preoperative imaging as these tumors can often be found with careful intraoperative exploration.
- The risk of liver metastases is increased when tumors are larger than 2 cm.[10]
- Patients who present with metastatic disease should undergo resection, if possible, as chemotherapy has limited efficacy in the treatment of gastrinomas. Other modalities, such as radiofrequency ablation, hepatic artery embolization, liver transplantation, and radiolabeled somatostatin therapy, may be considered when anatomic resection is not possible (**FIG 3**).

SURGICAL MANAGEMENT

Positioning

- Patients should be placed in the supine position for exploratory laparotomy to identify gastrinomas.

TECHNIQUES

PLACEMENT OF INCISION

- Either a bilateral subcostal incision or an upper midline incision may be used to approach the duodenum and pancreas for exploration (FIG 4).

Exploration and Kocher Maneuver

- After incision and entry into the peritoneal cavity and initial exploration, the hepatic flexure and ascending colon are mobilized (FIG 5A), the peritoneal reflection

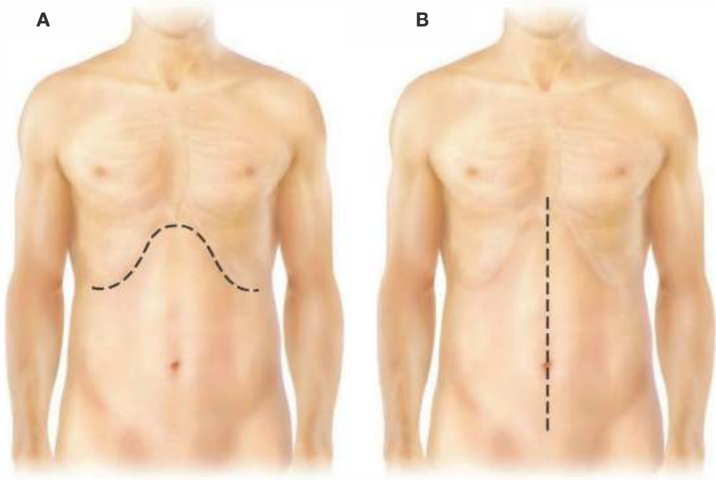

FIG 4 ● Potential incisions for exploration. Bilateral subcostal incisions **(A)** or upper midline incision **(B)** may be used.

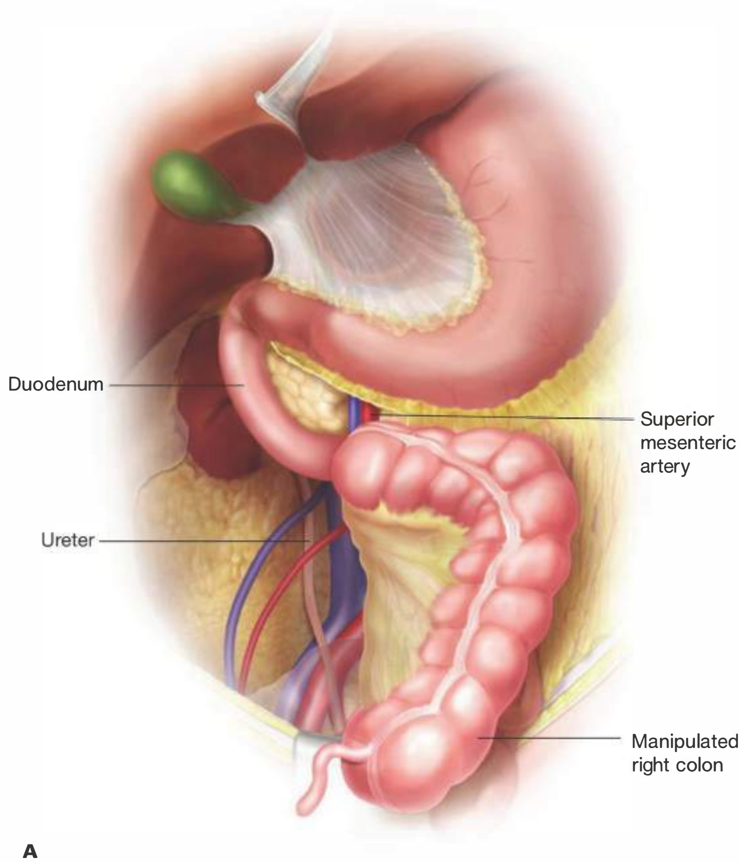

FIG 5 ● Kocher maneuver. An extended Kocher maneuver allows lifting of the pancreatic head out of the retroperitoneum for palpation **(C)** after mobilization of the right colon **(A)** and incision of the peritoneal reflection along the duodenum **(B)**. Separation from the transverse mesocolon allows for complete mobilization of the pancreas and palpation of the pancreatic body and tail **(D)**. *(continued)*

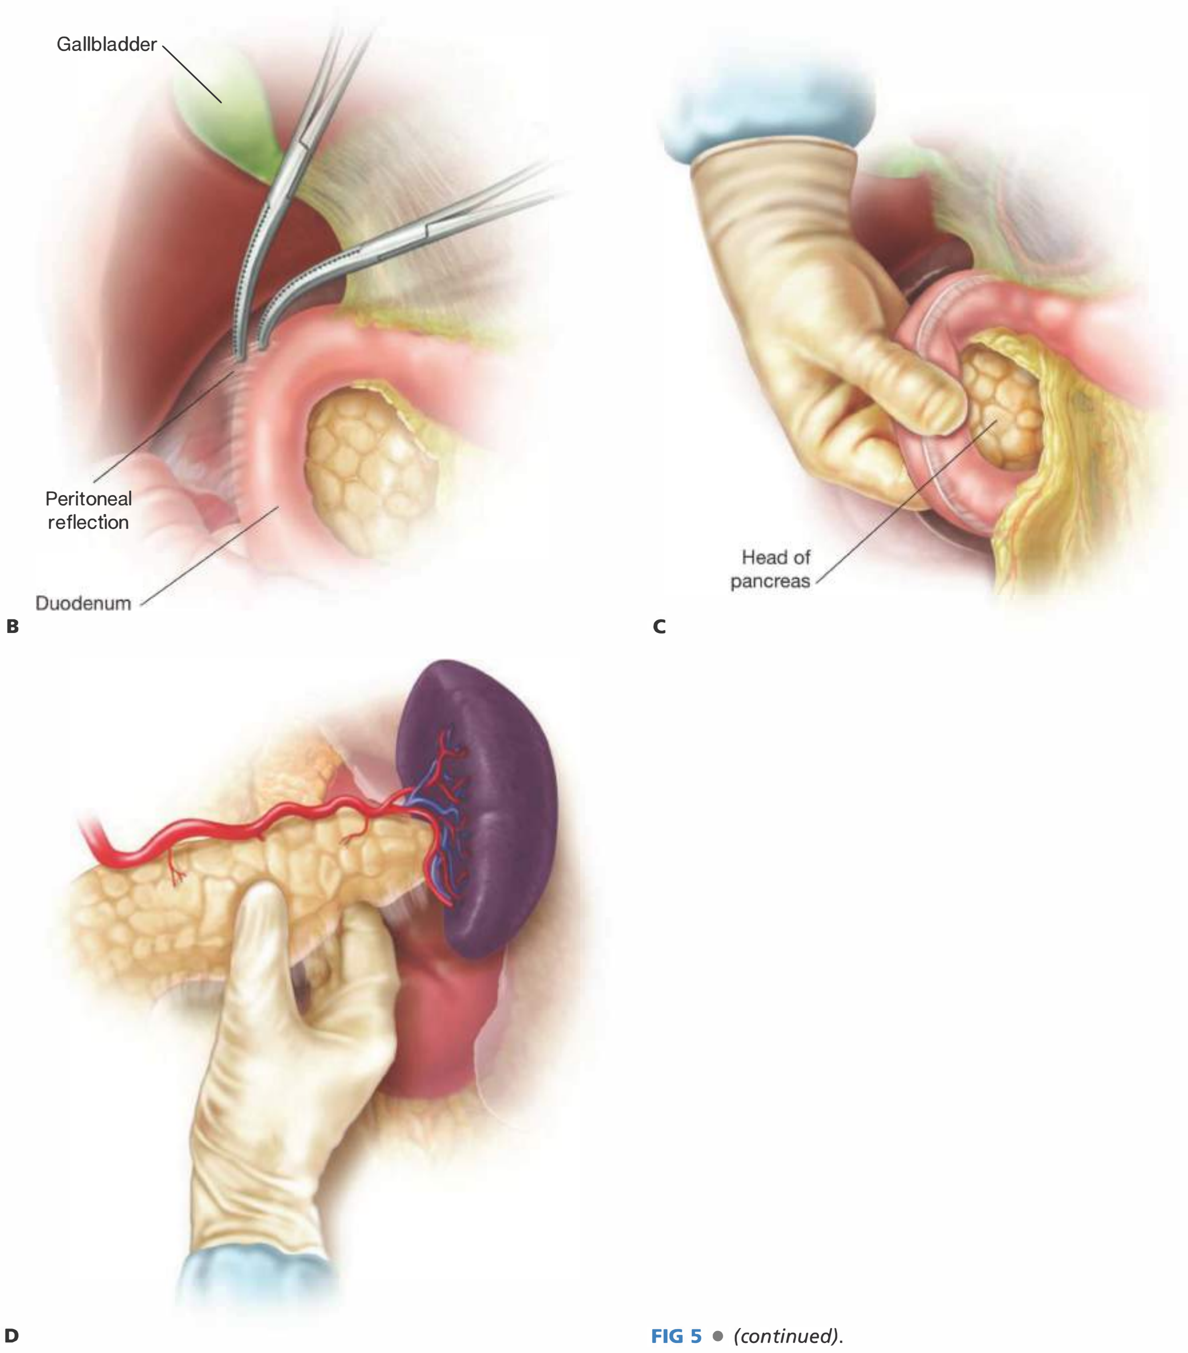

FIG 5 ● *(continued)*.

of the duodenum is incised along the second and third portion of the duodenum, and an extended Kocher maneuver is performed in order to expose and mobilize the duodenum and head of the pancreas (**FIG 5B**).

- After exposure is obtained, the surgeon may palpate the duodenum and pancreatic head. (**FIG 5C**).
- It is important to also palpate the pancreatic body and tail. To accomplish this, the lesser sac is opened and the avascular inferior pancreatic border incised; this can be aided by mobilizing the splenic flexure if necessary. Once exposed, the pancreatic body and tail may be carefully palpated to detect any additional tumors (**FIG 5D**).

Intraoperative Ultrasound

- After mobilization of the duodenum and pancreas and detection of visible and palpable tumors, an ultrasound probe is used to visualize small tumors in the duodenum

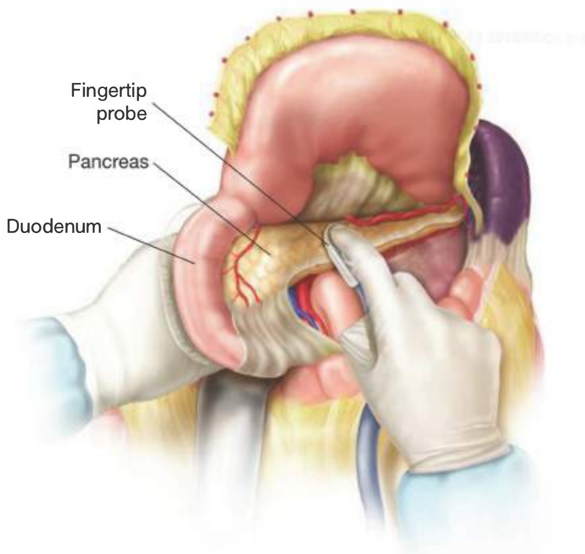

FIG 6 ● Ultrasound examination of the duodenum and pancreas.

and pancreas. The relationship of any tumor to the pancreatic duct should be noted if an enucleation will be performed (**FIG 6**).

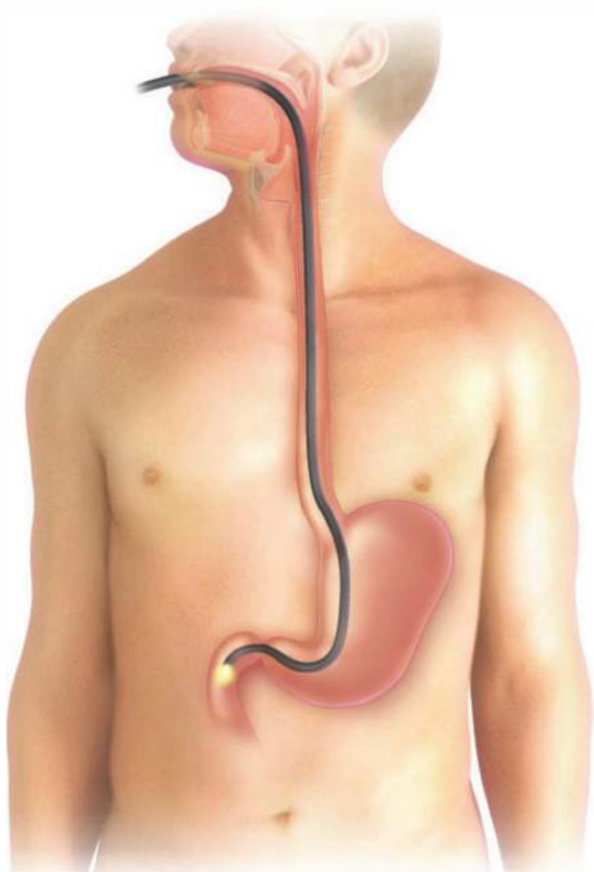
- The type of probe used should be dictated by surgeon experience and preference. We prefer a fingertip transducer in our institution.
- During ultrasound examination, the surgeon's left hand is generally placed posterior to the duodenum and pancreas, while the right hand handles the probe.
- At this time, the liver is also examined for any possible metastatic lesions, and suspicious lesions should be biopsied.

Intraoperative Endoscopy

- Next, a gastroscope is used to perform intraoperative endoscopy. The gastroscope is advanced orally into the stomach and then duodenum where transillumination is used to identify any remaining gastrinomas. These lesions, located in the submucosa of the duodenum, will appear as shadows upon transillumination (**FIG 7**).

Duodenotomy

- A 2- to 3-cm longitudinal duodenotomy is created on the antimesenteric aspect of the second portion of the



A

FIG 7 ● Intraoperative endoscopy. The endoscope is advanced into the duodenum **(A)** where submucosal tumors may be visualized directly **(B)** or through transillumination **(C)**. *(continued)*

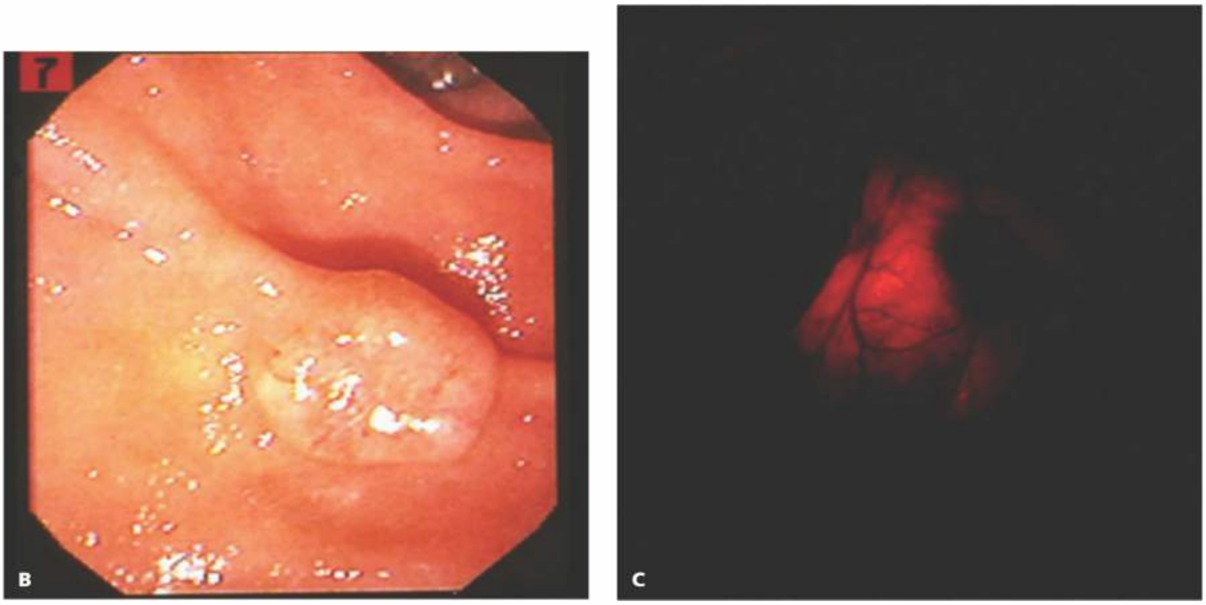


FIG 7 ● *(continued)*.

duodenum. If duodenal lesions were identified during exploration prior to this, then the duodenotomy may be relocated to enable excision of the lesion.

- Once the duodenotomy is made, the duodenal wall is palpated carefully with the index finger and thumb (**FIG 8**).
- The third and fourth portions of the duodenum may be difficult to examine, and so the mucosa can be everted into the duodenotomy using the index finger. This enables direct visualization of all portions of the duodenum (**FIG 9**).
- A full-thickness excision is performed for any duodenal lesion found, and a margin of at least 2 mm should be obtained.
- Lesions found on the medial wall of the duodenum should not be excised until the pancreatic duct and

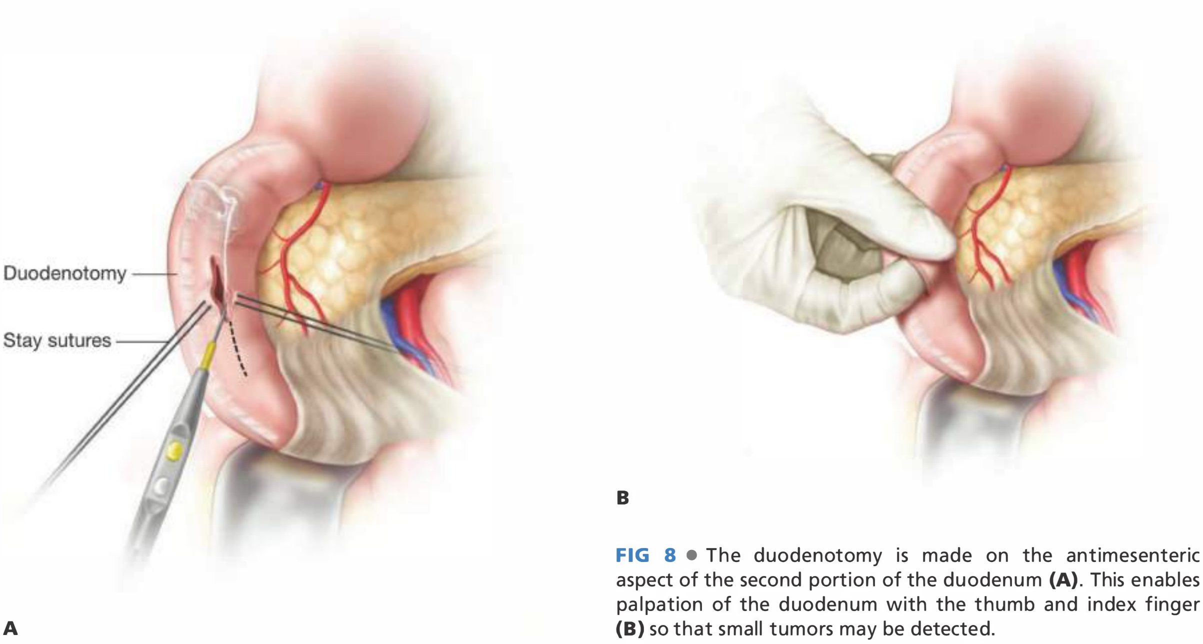

FIG 8 ● The duodenotomy is made on the antimesenteric aspect of the second portion of the duodenum **(A)**. This enables palpation of the duodenum with the thumb and index finger **(B)** so that small tumors may be detected.

ampulla of Vater are identified. This may be aided with use of a small catheter passed through the ampulla.

Excision of Pancreatic Tumors

- Tumors found in the pancreas are managed based on size and location. Tumors found in the head of the pancreas may be enucleated if they are exophytic, but if they are invasive or near the main pancreatic duct, a pancreatico-duodenectomy may be required.
- Tumors found in the distal pancreas require distal pancreatectomy. Splenectomy is not mandated; need for splenectomy is based on the tumor location and suspicion of lymph node metastases. (See Part 3, Chapters 33 to 41 for details of pancreaticoduodenectomy and Part 3, Chapters 40 to 42 for details of distal pancreatectomy.)

Periduodenal Lymph Node Dissection

- A lymph node dissection encompassing the periduodenal and peripancreatic nodes is important as they may contain microscopic metastases or actually represent primary tumors.
- Lymphatic tissues are identified and excised from around the pancreatic head, celiac axis, common hepatic artery, superior mesenteric artery, common bile duct, and portal vein. Lymphadenectomy should begin in the hepatoduodenal ligament and proceed from porta hepatis to celiac axis, followed by excision of all lymph nodes from the anterior and posterior aspects of the pancreatic head (**FIG 10**).
- If a primary tumor is identified, then that region should be paid specific attention as positive lymph nodes are most likely to be found close to the primary tumor.[11]

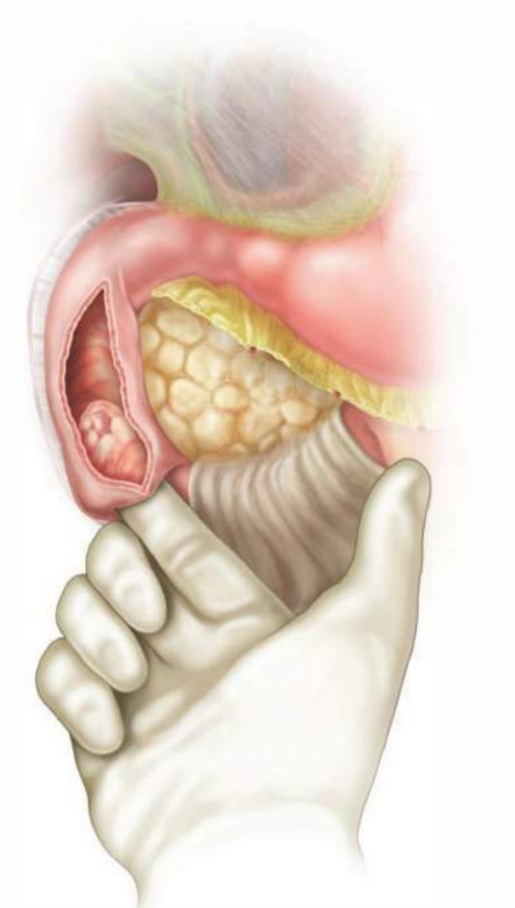

FIG 9 ● Eversion of the mucosa of the third and fourth portions of the duodenum into the duodenotomy.

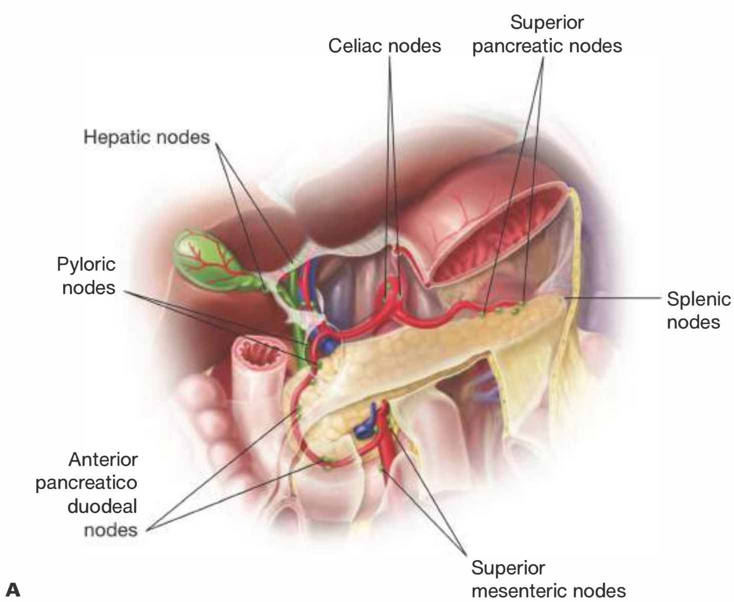

FIG 10 ● Lymphadenectomy for gastrinoma should encompass nodes in the hepatoduodenal ligament, celiac axis and anterior **(A)** as well as posterior **(B)** pancreatic head. *(continued)*

B

FIG 10 ● *(continued)*

Closure of Duodenotomy

- After completion of exploration and excision of gastrinomas, the duodenotomy is closed transversely if possible in order to prevent narrowing of the lumen.
- This is not always possible when a long duodenotomy was required. If this is the case, then a careful longitudinal closure may be used (**FIG 11**).
- The duodenum is closed in two layers. Either interrupted or a running closure may be performed based on surgeon's preference.
- We place a Jackson-Pratt (JP) drain adjacent to the closed duodenotomy in order to monitor output in the postoperative setting. If pancreatic tumors have been enucleated, then an additional drain may be placed overlying the resected lesion.

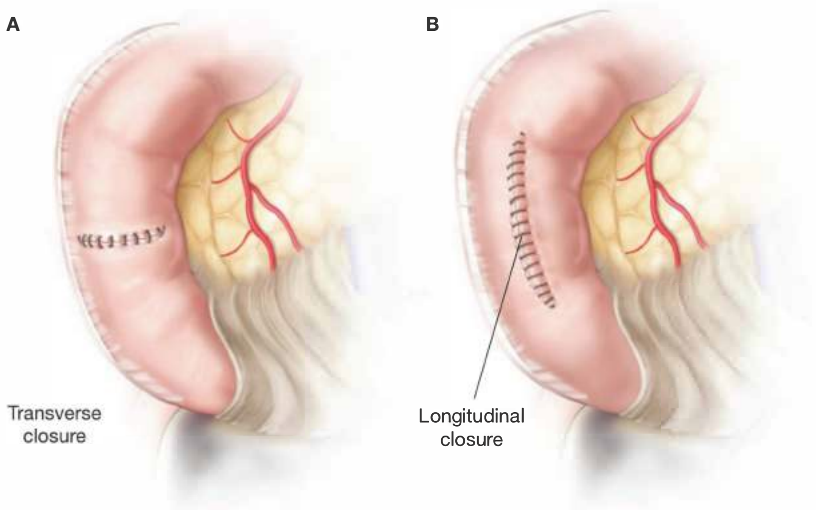

FIG 11 ● A transverse closure of the duodenotomy **(A)** is preferable, but the incision length may make a careful longitudinal closure **(B)** necessary.

PEARLS AND PITFALLS

Operative indications	■ Biochemical diagnosis of sporadic gastrinoma ■ Gastrinoma >2 cm in MEN-1 patients ■ No evidence of unresectable or extensive metastatic disease ■ Reasonable surgical candidate
Surgical exploration	■ Intraoperative ultrasound and endoscopy with transillumination greatly aid detection of tumors. ■ Duodenotomy should be performed in all patients as duodenal tumors are the most frequently missed. ■ Tumors require full-thickness excision with a 2-mm margin. ■ Avoid enucleation of pancreatic tumors if invasive or near main duct; resection is indicated.
Lymphadenectomy	■ Exploration and excision of lymph nodes is crucial.
Closure	■ Close duodenotomy transversely, if possible.

POSTOPERATIVE CARE

- After exploration, the patient should be placed on a surgical floor and be kept NPO until return of bowel function. Drain output should be monitored closely for character and volume until PO intake is resumed. If there is clinical concern of a leak, then a Gastrografin swallow study should be obtained for confirmation. We remove the JP drain when output is less than 50 mL per day and serosanguineous once patient is eating normally.
- Three and 6 months after discharge, patients should return to clinic for history and physical, CT or MRI, and serum fasting gastrin and secretin stimulation tests. Subsequent follow-up should occur every 6 months until 3 years postoperation and should include these same studies. OctreoScan is not recommended for routine surveillance by current National Comprehensive Cancer Network (NCCN) guidelines.[12]

OUTCOMES

- Mortality from this disease is due to metastasis, and it is thought that at least 60% of gastrinomas are malignant. Patients who present with liver metastases have a 10-year overall survival of 30%, whereas patients without liver metastases have a 15-year overall survival of 83%.[13]
- Sporadic disease is potentially curable by surgical exploration. A large series comparing surgical versus medical treatment demonstrated a 41% cure rate at 12 years as well as significantly fewer liver metastases (5% vs. 29%). Disease-related survival at 15 years was 98% with surgical intervention versus 74% with medical treatment.[14]
- Patients with MEN-1 are not typically curable, as only 1% to 6% are disease-free at 5 years.[15] Long-term survival is still possible despite the lack of biochemical cure, and 5-year survival rates of 98% have been reported.[16]

COMPLICATIONS

- Recurrence
- Residual tumor left after exploration
- Duodenal leak
- Pancreatic leak
- Infection (intraabdominal abscess)
- Duodenal stricture

Chapter 47

Lateral Pancreaticojejunostomy with (Frey) or without (Puestow) Resection of the Pancreatic Head

Kevin E. Behrns Jose G. Trevino

DEFINITION

- Chronic pancreatitis is an inflammatory disease that encompasses a spectrum of morphologic, histologic, and clinical features, which range from subclinical inflammatory changes evident only in histologic specimens to marked morphologic gland destruction accompanied by acinar cell dropout, prominent deposition of fibrous extracellular matrix, and pancreatic duct strictures.

DIFFERENTIAL DIAGNOSIS

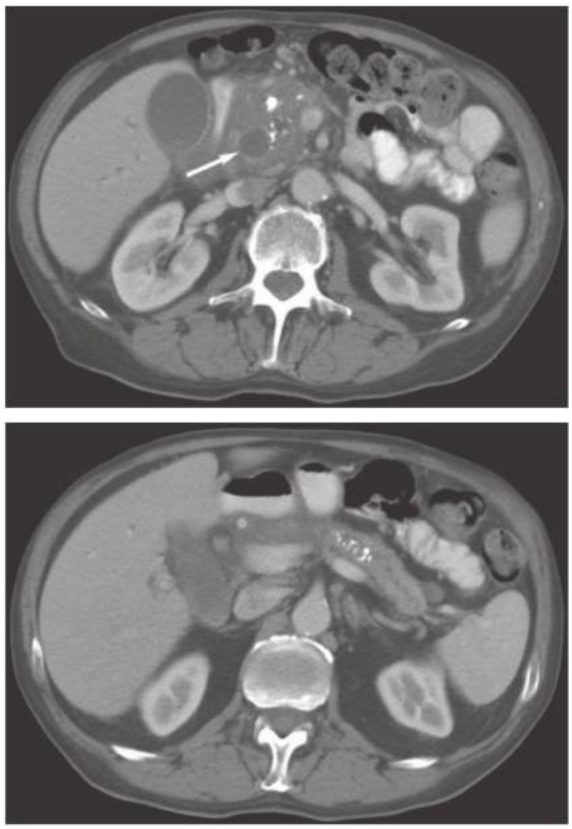
- Acute pancreatitis
- Autoimmune pancreatitis
- Pancreatic adenocarcinoma
- Intraductal papillary mucinous neoplasm (IPMN)

PATIENT HISTORY AND PHYSICAL FINDINGS

- Advanced stages of chronic pancreatitis manifest clinically by disabling pain and pancreatic exocrine and endocrine insufficiency.[1,2] The most prominent etiology of chronic pancreatitis is excess consumption of alcohol.
- Other forms of chronic pancreatitis including autoimmune pancreatitis, paraduodenal pancreatitis, and familial pancreatitis are attributed to genetic mutations.[2–5]
- Differentiating alcoholic chronic pancreatitis from autoimmune pancreatitis, especially focal autoimmune pancreatitis,[6] and adenocarcinoma of the pancreas may require extensive evaluation and prove challenging.[7]
- Important risk factors that exacerbate the development of chronic pancreatitis include alcohol use and smoking cigarettes.[8,9]
- A detailed history of alcohol consumption should be obtained; heavy alcohol use (>5 drinks per day) is present in the majority of patients with chronic pancreatitis.[8,9]
- The pain associated with chronic pancreatitis may be either episodic or persistent.[2] Episodic abdominal pain has a duration of 1 to 2 weeks and is interrupted by pain-free periods of a few months. Persistent pain occurs daily but on occasion may spontaneously resolve for a period of a month or more.[10]
- The weight loss seen in chronic pancreatitis typically occurs over months to years, but it may be more rapid if morphologic changes such as pseudocyst formation induce gastroduodenal obstruction.
- Other complications of chronic pancreatitis include jaundice from biliary obstruction and upper gastrointestinal bleeding from gastric varices secondary to splenic vein obstruction.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Computed tomography (CT) is the imaging procedure of choice. Intravenous contrast-enhanced, multiplanar, thin-slice CT provides excellent imaging of pancreatic parenchymal and ductal anatomy.[11] CT characteristics of chronic pancreatitis include an enlarged pancreatic head with multiple calcifications and a dilated pancreatic duct distally (**FIG 1**).
- Detection of early-stage disease may be enhanced by magnetic resonance (MR) with cholangiopancreatography (MRCP) with or without secretin administration. Morphologic changes



A

B

FIG 1 ● **A.** CT of the abdomen demonstrating an enlarged head of the pancreas with multiple calcifications indicative of alcoholic chronic pancreatitis. A small pseudocyst is also noted in the head *(arrow)*. **B.** The distal pancreas contains calcifications and a dilated pancreatic duct.

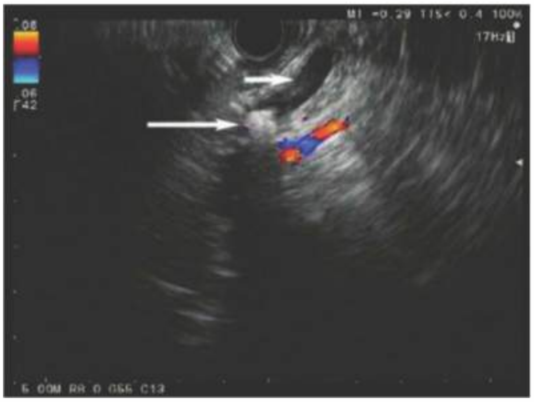


FIG 2 ● Endoscopic ultrasound demonstrating a dilated pancreatic duct *(short arrow)* with a calculus *(long arrow)* in a patient with chronic pancreatitis.

in the pancreatic duct and hydrodynamic-significant strictures may be evident on these images.[12]

- Endoscopic ultrasound (EUS) with or without functional testing by administration of secretin may aid in the diagnosis of early fibrosis in chronic pancreatitis (**FIG 2**). EUS has a sensitivity of 84% and a specificity of 100%, correlating with histology for chronic pancreatitis.[13] Furthermore, EUS is advantageous when mass lesions are present in chronic pancreatitis because EUS-guided biopsy is the most reliable method of confirming malignancy.
- Imaging of the pancreatic duct prior to surgical intervention is essential because all strictures and intraductal calculi must be addressed by the operative approach. Ductal anatomy can be delineated by MRCP or endoscopic retrograde cholangiopancreatography (ERCP). ERCP is often performed in the context of pancreatic duct stenting as endotherapy often precedes operative management.

SURGICAL MANAGEMENT

- Operative management of chronic pancreatitis by lateral pancreaticojejunostomy with or without pancreatic head resection is indicated in patients with disabling abdominal pain, weight loss, and evidence of pancreatic duct obstruction.[14] Morphologic characteristics are associated with outcomes. An excellent response to pancreatic head resection with pancreaticojejunostomy is most likely in the setting of an enlarged head of the pancreas and a distally dilated pancreatic duct.[15]

Table 1: Preoperative Checklist for Patients Undergoing a Frey Procedure

Parameter	Assessment
Alcohol abstinence	Enrollment in substance abuse program with aftercare
Failed medical or endoscopic management	Detailed review of previous medical history
Laboratory evaluation	Blood chemistries, hematologic assessment, liver function tests including coagulation profile, pancreatic function test (fecal fat)
Assessment of pancreatic parenchyma for fluid collections or mass lesions	CT or MRI
Assessment of pancreatic duct	MRCP or ERCP
Assessment of biliary obstruction	Liver chemistries, cholangiogram

CT, computed tomography; MRI, magnetic resonance imaging; MRCP, magnetic resonance with cholangiopancreatography; ERCP, endoscopic retrograde cholangiopancreatography.

Preoperative Planning

- These patients are often afflicted with a chronic disease and have lacked regular medical care, thus a thorough evaluation of the patient prior to pancreatic head resection and duct drainage is essential.
- Patients should be alcohol-free for at least 6 months and enrolled in an alcohol cessation program with aftercare. Ideally, cigarette smoking would also be stopped prior to an operation, although this is difficult for most patients.
- Specific attention should be paid to the nutritional status of patients with chronic pancreatitis because they often meet criteria for severe protein and caloric malnutrition. Fat-soluble vitamin deficiency should also be considered. If malnutrition is evident, a nasojejunal feeding tube should be placed with the delivery of enteral feeds with pancreatic enzyme supplementation prior to operative intervention. Additional protein supplementation may also be necessary. Generally, 2 to 4 weeks of enteral nutrition prior to an operation will place the patient in an anabolic state.
- Table 1 highlights the preoperative checklist of patients who are candidates for a Frey procedure with longitudinal drainage of the pancreatic duct.

Positioning

- The patient is placed on the operating room table in a supine position. Because the risk for blood loss is moderately high, at least two large-bore intravenous cannulas should be established or a central line should be placed. Arterial monitoring is recommended for patients with comorbidities.

TECHNIQUES

EXPOSURE OF THE PANCREAS

- A midline celiotomy is created to allow adequate exposure of the upper abdomen. After a thorough exploration of the abdomen, the pancreas is exposed by elevating the omentum off the transverse colon and pancreatic head back to the origin on the stomach. The hepatic flexure is mobilized as necessary and the duodenum is widely Kocherized. Frequently, the posterior wall of the stomach is adherent to the pancreas and must be dissected free. At the inferior border of the pancreatic neck, the right gastroepiploic vein is circumferentially dissected and divided at the insertion into the superior mesenteric vein (SMV). The distal stomach and proximal duodenum are mobilized from the head of the pancreas to allow adequate exposure for resection of the pancreatic head. The SMV should not be dissected free from the posterior surface of the pancreas for fear of venous injury. These maneuvers should provide wide exposure of the pancreas from the duodenum to the tail of the pancreas (**FIG 3**).

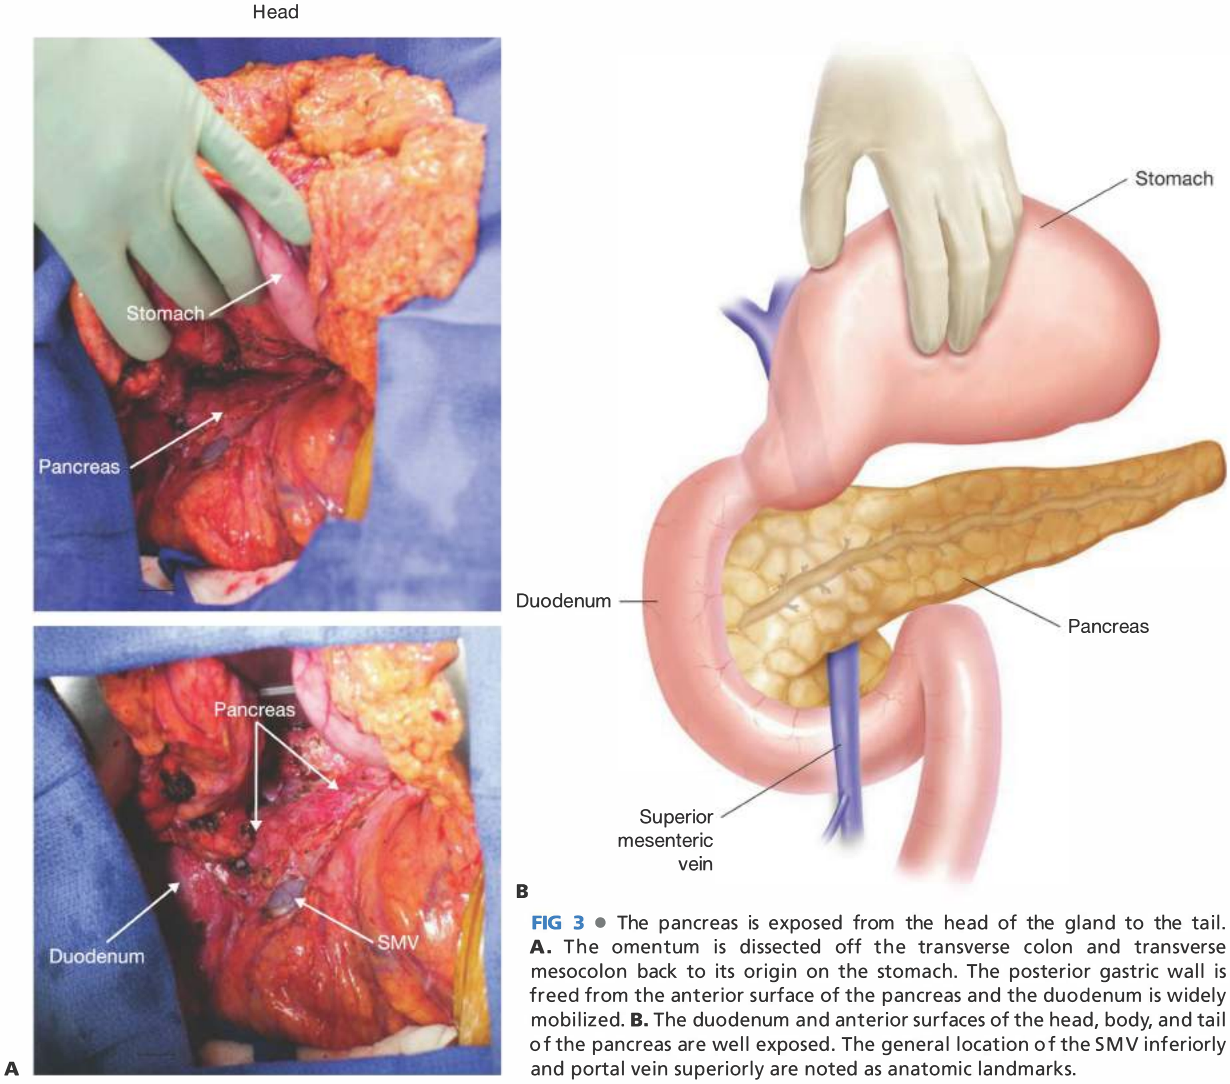

FIG 3 ● The pancreas is exposed from the head of the gland to the tail. **A.** The omentum is dissected off the transverse colon and transverse mesocolon back to its origin on the stomach. The posterior gastric wall is freed from the anterior surface of the pancreas and the duodenum is widely mobilized. **B.** The duodenum and anterior surfaces of the head, body, and tail of the pancreas are well exposed. The general location of the SMV inferiorly and portal vein superiorly are noted as anatomic landmarks.

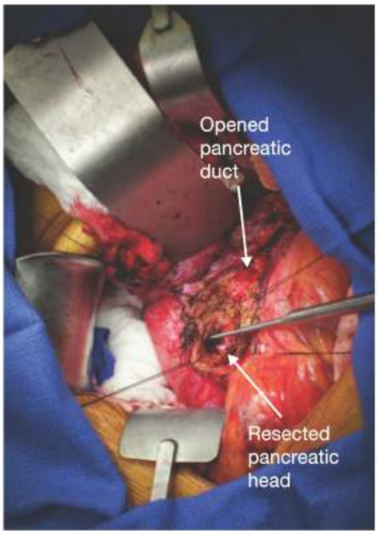
PANCREATIC HEAD RESECTION

- The gastroduodenal artery is identified at the superior border of the pancreas and ligated with a figure-of-eight 4-0 Prolene suture. The resection of the pancreatic head should be mapped with care to avoid injury to the SMV. The pancreatic head is generously resected, leaving only a thin rim (3 to 5 mm) of tissue along the duodenal wall and posteriorly (**FIG 4**). Usually, the pancreatic duct is evident with excavation of the head, and the duct may be followed distally. Resection of the pancreatic head should not be deeper than the posterior surface of the pancreatic duct. If this plane is not readily apparent, the duct should be identified in the body of the gland (described in the following text) and its course followed proximally to the head of the gland. Bleeding during the pancreatic head resection may be brisk and requires meticulous ligation with 5-0 Prolene sutures. The use of electrocautery to control arterial bleeding should be avoided because this often leads to temporary sealing of the vessel.

A



B

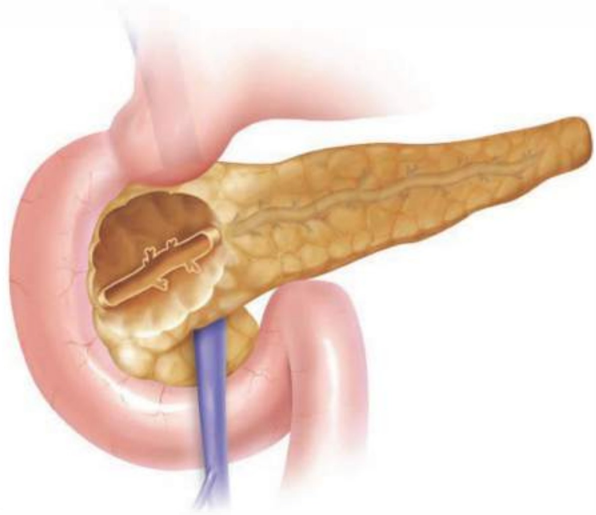


FIG 4 ● The enlarged head of the pancreas is resected, taking care to identify safety landmarks including the SMV, portal vein, and the posterior surface of the pancreatic duct. **A.** The head of the pancreas is resected by outlining the resection bed to the right of the SMV and portal vein. The head is resected deeper in increments such that the pancreatic duct is identified. The resection should not go deeper than the posterior surface of the pancreatic duct. Bleeding should be controlled by suture ligation. All stone material should be removed. The probe identifies the pancreatic duct entering the duodenum. **B.** The drawing demonstrated excavation of the head of the pancreas with important landmarks.

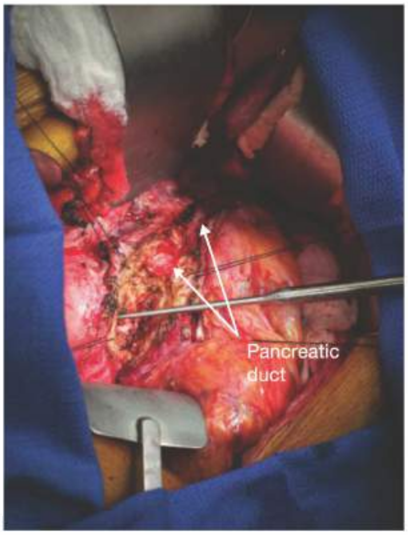
LONGITUDINAL PANCREATIC DUCTOTOMY

- If the pancreatic duct is identified during the pancreatic head resection, it can be followed distally by inserting a probe into the duct and cutting down on the probe with cautery. However, extensive fibrosis with ductal strictures may prevent identification of the duct in the head of the gland or preclude proximal tracing of the duct. If the duct cannot be identified or traced, it can often be accessed well to the left of the SMV. Care should be taken not to identify the duct over the SMV–splenic vein confluence. Once the duct is identified distally, it should be opened from the tail of the pancreas to the junction of the pancreatic head and duodenum (**FIG 5**). All pancreatic stones should be removed unless extraction of the stone would cause substantial parenchymal damage.

A



B

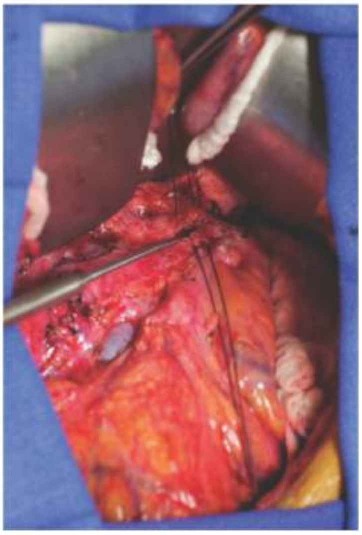


FIG 5 ● The pancreatic duct is opened from the head of the pancreas to the tail. **A.** Once the pancreatic head is resected, the pancreatic duct can be followed distally and opened over a probe until the duct is opened out to the tail of the gland. **B.** If the pancreatic duct cannot be identified in the head of the gland, a dilated duct can be opened to the left of the SMV in the tail of the gland and followed distally to the pancreatic head resection. *(continued)*

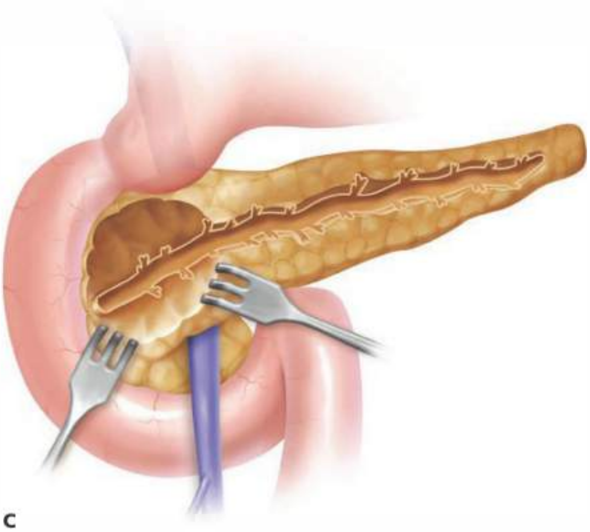

C

FIG 5 ● *(continued)* **C.** The drawing demonstrates the pancreatic duct opened from the duodenum to the head of the gland.

INTRAPANCREATIC BILIARY SPHINCTEROPLASTY

- Patients with biliary stricture are candidates for an intrapancreatic biliary sphincteroplasty, which is accomplished by identifying the bile duct along the duodenal wall in the depths of the excavated pancreatic head. This portion of the procedure is markedly aided by preoperative biliary stent placement. The intrapancreatic bile duct can be palpated by transduodenal compression on the biliary stent. The bile duct is opened over the stent with the longitudinal bile ductotomy extending up to the entrance of the bile duct into the pancreas. The stent is removed and not replaced. Once opened, the bile duct should accept at least a 6- to 8-mm probe. The bile duct is then circumferentially sewn with interrupted 6-0 polydioxanone (PDS) sutures to the surrounding pancreatic parenchyma such that the bile duct is widely opened (**FIG 6**).

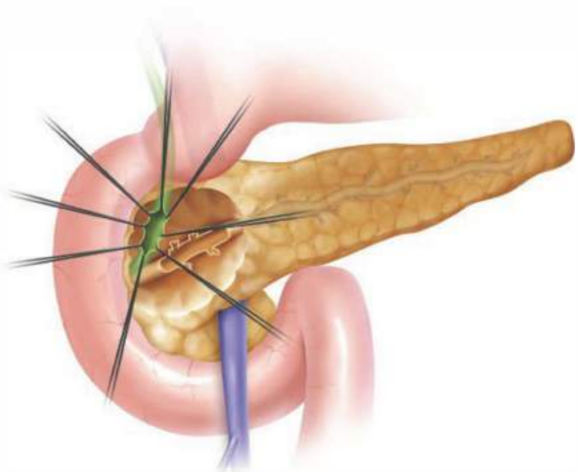

FIG 6 ● An intrapancreatic biliary sphincteroplasty may be performed in patients with a bile duct stricture. A longitudinal bile ductotomy is performed. The bile duct should be opened superiorly to its entrance in the pancreas. The bile is secured circumferentially to the pancreas with interrupted 6-0 PDS sutures. The bile duct should accept a probe of 6 to 8 mm in diameter.

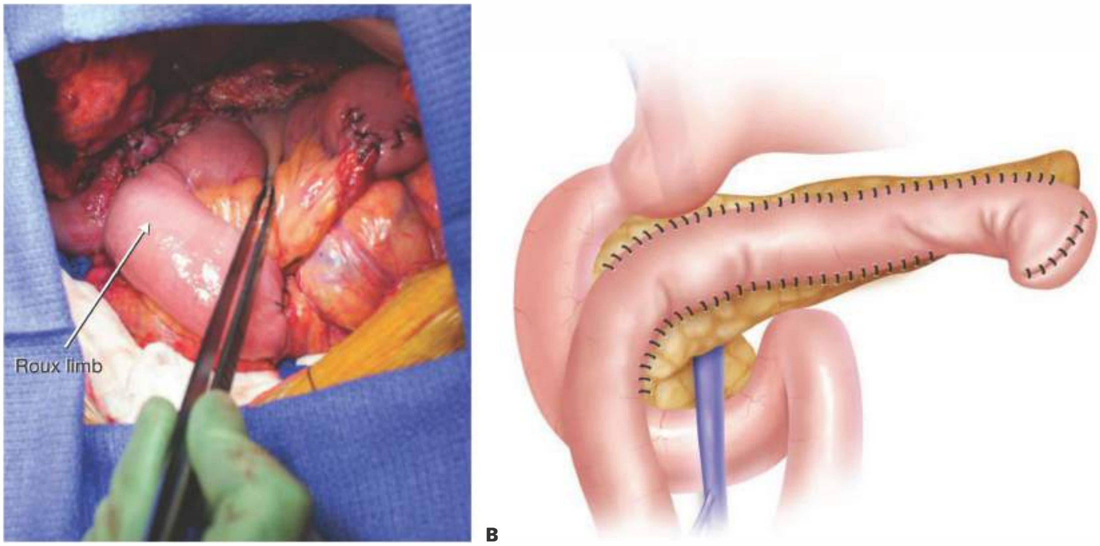
TECHNIQUES

ROUX-EN-Y PANCREATICOJEJUNOSTOMY

- A Roux-en-Y limb of jejunum is prepared by dividing the jejunum 15 to 30 cm distal to the ligament of Treitz. The mesentery is transected back toward its origin by dividing bridging vessels. The Roux-en-Y limb is delivered to the pancreas in a retrocolic position to the right of the middle colic vasculature. The divided end of the jejunum is oriented to the tail of the pancreas, and a two-layer side-to-side pancreaticojejunostomy is created with running 4-0 Prolene sutures (FIG 7). The epithelium of the pancreatic duct need not be incorporated with the inner layer of suturing. The jejunum should be opened in increments to avoid the creation of an overly long jejunotomy. A jejunojejunostomy is created 40 to 50 cm distal to the pancreaticojejunostomy to reestablish intestinal continuity.



A B

FIG 7 ● **A.** A Roux-en-Y limb is delivered to the pancreas in retrocolic fashion to the right of the middle colic vein. The limb is sewn to the pancreas in two layers with running 4-0 Prolene. **B.** The drawing demonstrates the completed side-to-side pancreatojejunostomy.

PLACEMENT OF A FEEDING JEJUNOSTOMY

- A feeding jejunostomy is appropriate in malnourished patients. A red rubber catheter or alternative device is placed approximately 30 cm distal to the jejunojejunostomy. The tube may be placed by imbricating the tube to create a tunnel, and the tube should be tacked to the abdominal wall in four-quadrant fashion. Two closed suction drains are placed at the superior and inferior aspects of the pancreaticojejunostomy, and the abdomen is closed.

PEARLS AND PITFALLS

Patient selection	■ Alcohol abstinence, chronic pain management ■ Optimum outcomes are observed in patients with an enlarged head of the pancreas and dilated pancreatic duct.
Pancreatic head resection	■ Ligate the gastroduodenal artery first. ■ Perform a generous resection leaving only thin (3–5 mm) rim of pancreatic tissue. ■ Dissection of the superior mesenteric vein should be avoided. ■ Suture ligation, not cauterization, of bleeding vessels
Pancreatic ductotomy	■ Ductotomy should extend from duodenum to the far tail of pancreas.
Intrapancreatic biliary sphincteroplasty	■ Assess biliary obstruction; place a biliary stent preoperatively if intrapancreatic biliary sphincteroplasty is anticipated.
Pancreaticojejunostomy	■ Open the jejunum incrementally to avoid an overly large jejunotomy.

POSTOPERATIVE CARE

- Because of the risk of postoperative bleeding, the patient should be admitted to a monitored setting. The initial 24 to 48 hours require close observation for hemorrhage. If hemorrhage occurs, a CT arteriogram should be obtained to look for blood in the gastrointestinal lumen versus intraabdominal hemorrhage. Bleeding into the gastrointestinal tract will require an operative approach, whereas intraabdominal bleeding may be treated by angioembolization.
- Oftentimes the exposure of the pancreas requires dissection of chronically inflamed adhesions and, therefore, the fluid requirements postoperatively may be high; close monitoring of the urine output is required.
- Early initiation of postoperative enteral nutrition is necessary because most of these patients are malnourished with low protein stores.

OUTCOMES

- A randomized trial comparing endoscopic therapy with stents to surgical drainage confirmed superior results for surgical treatment.[16] Patients treated with pancreatic drainage procedures had better pain control, and 47% of patients initially managed by endoscopic therapy ultimately required surgery.
- Operative treatment of chronic pancreatitis may include resection with standard or pylorus-preserving pancreatoduodenectomy or a drainage procedure such as the Frey procedure. The merits of each of these operations have been debated, but a randomized, prospective trial demonstrated that the Frey operation was associated with better short-term outcomes, although the procedures were equivalent in terms of pain control and pancreatic function in long-term analysis.[17]
- Table 2 summarizes the results of patients undergoing the Frey procedure.

COMPLICATIONS

- Postoperative hemorrhage
- Pancreatic fistula is distinctly uncommon.
- Delayed gastric emptying

Table 2: Outcomes following Local Pancreatic Head Resection with Longitudinal Pancreaticojejunostomy

Parameter	Frequency (%)
Reintervention required	8
Exocrine insufficiency	86
Endocrine insufficiency	61
Return to work	42
Continued alcohol consumption	21

Chapter 48

Enteric Drainage of Pancreatic Pseudocysts: Pancreatic Cyst Gastrostomy and Cyst Jejunostomy

Kenneth K. W. Lee

DEFINITIONS

- Collections of fluid or solid material may arise from episodes of acute pancreatitis. Although frequently referred to collectively as pancreatic pseudocysts, the 2012 revision of the Atlanta classification of acute pancreatitis distinguishes among several types of local collections that arise in acute pancreatitis based on their pathogenesis and imaging characteristics.[1] An understanding of these different collections is important as their management differs.
  - **Acute peripancreatic fluid collections** (APFCs) (**FIG 1A,B**) arise early in the course of interstitial edematous acute pancreatitis. APFCs lack a wall, are confined by fascial planes, and rarely require intervention as the risk of complications such as infection is very low and they usually resolve spontaneously (**FIG 2A,B**).
  - APFCs that fail to resolve may become **pancreatic pseudocysts** with well-defined walls. **Pancreatic pseudocysts** (**FIG 3A**) are encapsulated, well-defined peripancreatic or intrapancreatic fluid collections that arise from focal disruption of the pancreatic ductal system in the setting of acute or chronic pancreatitis or trauma. In contrast to cystic neoplasms of the pancreas, pseudocysts lack true epithelial walls and instead have walls composed of fibrous tissue containing histiocytes, giant cells, granulation tissue, and rarely eosinophils. The fluid within a pseudocyst is characteristically amylase rich as it arises from disruption of the pancreatic ductal system. The 2012 revision of the Atlanta classification of acute pancreatitis also emphasizes that pseudocysts are not associated with detectable amounts of pancreatic or peripancreatic necrosis and do not contain a solid component. Magnetic resonance imaging (**FIG 3B**) or ultrasound may be useful for identification of solid material not distinguishable on computed tomography.

A

B

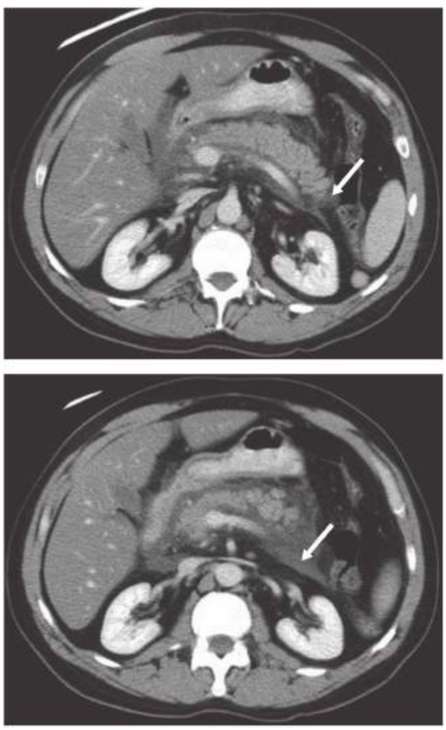

FIG 1 ● Acute peripancreatic fluid collection. **A.** The pancreas appears edematous with small amounts of fluid surrounding it. **B.** Peripancreatic fluid tracks laterally anterior to the kidney but remains confined by fascial planes.

A

B

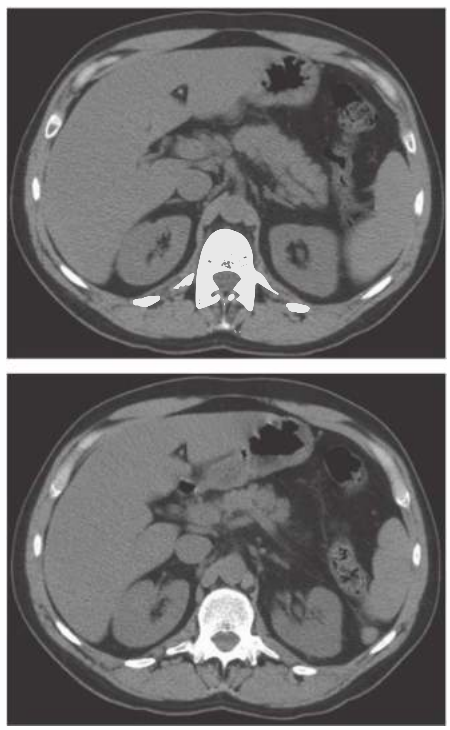

FIG 2 ● **A,B.** Acute peripancreatic fluid collection. The acute fluid collections are resolved 3 weeks later.

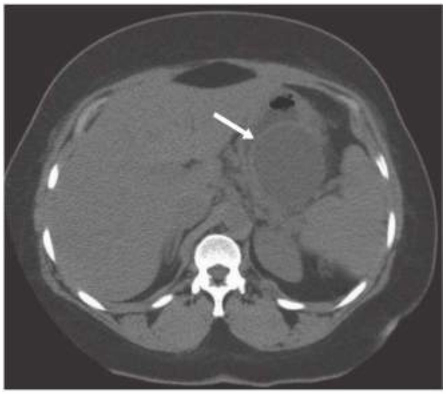
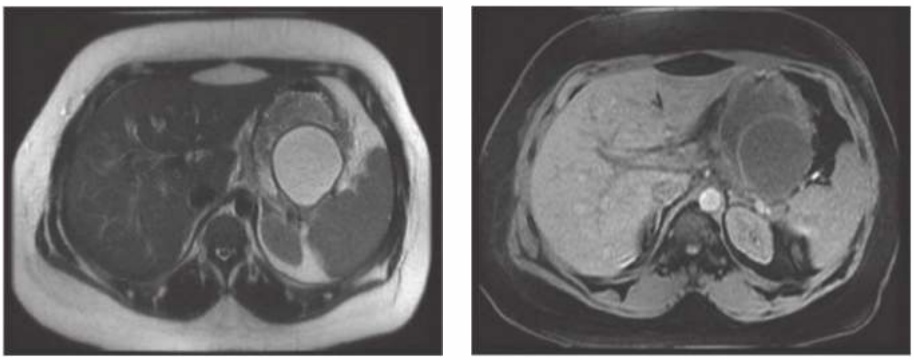


A

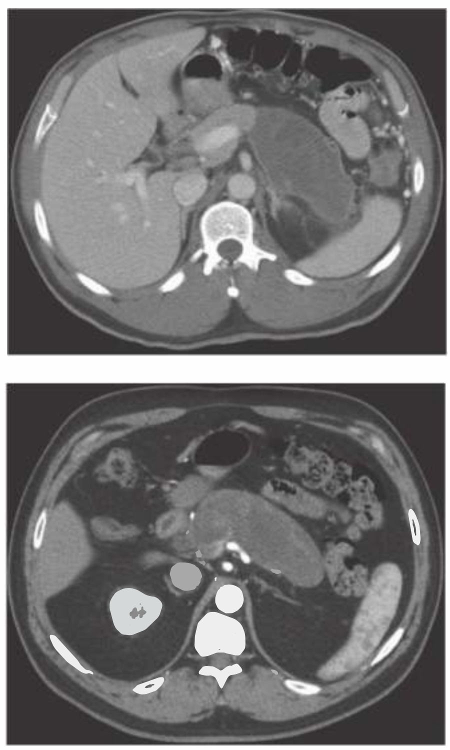


B

FIG 3 ● Pancreatic pseudocyst. **A.** A homogeneous fluid collection is surrounded by a discrete wall that is apparent despite the absence of intravenous contrast. **B.** Magnetic resonance imaging confirms the absence of solid material (necrotic debris) within the pseudocyst.

- In contrast to APFCs and pancreatic pseudocysts, acute necrotizing pancreatitis is defined by the presence of pancreatic and/or peripancreatic tissue necrosis. In the early stages of acute necrotizing pancreatitis, the necrotic tissue is described as an **acute necrotic collection** (ANC) (**FIG 4**). Such collections may additionally contain fluid leaking from the pancreatic duct or resulting from liquefaction of necrotic tissue. The natural history of ANCs is variable. Such collections may persist or absorb, remain solid or liquefy, remain sterile or become infected.
- Fibrous walls form around necrotic collections that are not reabsorbed or do not require early surgical debridement. As with acute necrotic collections, areas of **walled-off necrosis** (WON) (**FIG 5**) may contain fluid in addition to solid material.

FIG 4 ● Acute necrotic collection. Areas of pancreatic and peripancreatic necrosis surround portions of viable (enhancing) pancreas.



A

B

FIG 5 ● **A,B.** Walled-off necrosis.

- Although the pathogenesis and contents of WON differ from pancreatic pseudocysts, their management is similar to pseudocysts, particularly if communication with the pancreatic ductal system is suspected.

DIFFERENTIAL DIAGNOSIS

- **Pancreatic pseudocyst**
- **Walled-off necrosis**
- **Pancreatic cystic neoplasms** possess a true epithelial lining and thereby differ from pseudocysts that are lined by fibrous tissue (see earlier discussion). Cystic neoplasms primarily fall into two categories. **Microcystic cystadenomas** contain serous fluid and carry minimal if any risk of malignant transformation. Treatment by means of surgical resection is reserved for those that are symptomatic. **Macrocystic cystadenomas** contain mucinous material, are characterized by the presence of ovarian stroma, and have the potential for malignant transformation. Surgical resection is therefore usually recommended for such lesions.
- **Neoplasms with cystic morphology. Adenocarcinomas** of the pancreas may have cystic components. Areas of tumor necrosis, for example, may liquefy and appear cystic on imaging studies. Pancreatic ductal adenocarcinomas may also cause proximal ductal obstruction that may resemble cysts in the pancreas. **Pancreatic endocrine tumors** may also occasionally be predominantly cystic.
- **Intraductal papillary mucinous neoplasms** may arise in the main pancreatic duct or in side branch ducts and on imaging appear as solitary or multiple pancreatic cysts.
- Other benign cystic abnormalities include **lymphoepithelial cysts** and **inclusion cysts**. If diagnosed, treatment is reserved for those that are symptomatic. **Mucinous cysts** that do not contain ovarian stroma and do not appear to have potential for malignant transformation may also occur in the pancreas. Differentiation of such benign mucinous cysts from mucinous cystadenomas may be difficult.

EVALUATION

History and Physical Examination

- A thorough medical history must be taken to confirm **a history of acute pancreatitis**, or less commonly, pancreatic trauma. In the absence of such a history, the diagnosis of a pancreatic pseudocyst should be questioned, and the diagnosis of a neoplasm should be considered. As several weeks are required for a pseudocyst to form, the diagnosis of a pseudocyst should also be questioned if the clinical history of acute pancreatitis or pancreatic trauma is very recent and a cystic abnormality with an already well-formed wall is seen.
- The history should also attempt to identify the etiology of the patient's pancreatitis, as treatment of the etiology (e.g., cholecystectomy, lipid- and triglyceride-lowering medications, abstinence from alcohol consumption) should be considered.
- Symptoms potentially attributable to a pseudocyst should be elicited. Most frequently, these will include abdominal or back pain, abdominal pressure or fullness, early satiety, nausea, vomiting, or obstructive symptoms. If a complication of the pseudocyst such as infection, bleeding, or rupture has occurred, symptoms relating to the complication such as fever, light-headedness, or diffuse abdominal pain may also be present.
- The general medical history and overall health of the patient are important in determining the manner of treatment appropriate for the patient. Past surgical history should be reviewed with particular emphasis on prior operations on the stomach or small intestine and incisions that may impact on laparoscopic or open access to the abdomen.
- An abdominal mass or fullness should be sought on physical exam, and if found, its location should be noted in planning subsequent surgical procedures. Abdominal surgical scars should also be noted.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- The presence and location of cystic changes of the pancreas are best determined by means of contrast-enhanced **computer tomography** (CT) or **magnetic resonance imaging** (MRI). The imaging characteristics on these studies may help to differentiate among the various types of cystic pancreatic abnormalities listed earlier. Cross-sectional imaging also demonstrates the relationship of the cyst to the stomach and other structures as well as the thickness of the cyst wall and thereby aids in treatment planning.
- Pancreatic ductal abnormalities that may influence treatment decisions can be identified by means of **magnetic resonance cholangiopancreatography** (MRCP) or **endoscopic retrograde pancreatography** (ERP). MRCP is preferred as it is noninvasive, usually does not require patient sedation, and avoids the risks of procedure-induced pancreatitis or infection of fluid collections in communication with the pancreatic duct.
- If the clinical history and imaging findings are not sufficient to determine the specific type of cystic abnormality and in particular to exclude the diagnosis of a neoplastic cyst with potential for malignant transformation, further imaging by means of **endoscopic ultrasound** (EUS) can be performed. Under EUS guidance, fine needle aspiration of the cyst contents and cyst wall can be performed to obtain samples for biochemical and pathologic analysis. EUS can also identify solid material within the cyst and assess the thickness of the cyst wall.
- ERP is not routinely performed for evaluation of pseudocysts, but in selected cases may be performed to evaluate ductal anatomy when MRCP cannot be performed or is inconclusive. Because of the potential for introducing infection into a sterile pseudocyst, ERP should be limited to patients selected for treatment (see the following text) and should be performed shortly before treatment.
- Although the pathogenesis and pathology of pancreatic pseudocysts and WON differ, their management is similar and therefore differentiating between pseudocysts and WON is not always required. In the discussion that follows, the term pseudocyst is used to describe both pseudocysts and WON as defined in the 2012 revision of the Atlanta classification of acute pancreatitis.

SURGICAL MANAGEMENT

Indications for Treatment

- Treatment should be considered for symptomatic pseudocysts or enlarging pseudocysts.
- Emergency treatment of complications such as infection, rupture, or bleeding into the pseudocyst may be required.

- Small, asymptomatic, nonenlarging pseudocysts do not require treatment as the risk of developing acute complications is low. However, as the risk of complications arising in large asymptomatic, nonenlarging pseudocysts is uncertain and may be larger, treatment of such large pseudocysts can be considered.
- Treatment should be considered if the diagnosis of a neoplasm with malignant potential cannot be excluded.

Treatment Options

- Surgical resection can be performed for removal of a pseudocyst.
- External drainage may be achieved by percutaneous or surgical means.
- Internal drainage of a pseudocyst creates a communication between the pseudocyst and the gastrointestinal tract.
  - Drainage into the stomach is achieved by creating a communication between the posterior wall of the stomach and a pseudocyst known as a **cyst gastrostomy**. This may be achieved by endoscopic means, surgical means, or a hybrid combination of these methods. The anastomosis can be fashioned within the stomach via an anterior gastrotomy, outside the stomach via the lesser sac, or within the stomach via endolaparoscopic means.
  - Drainage into the small intestine is achieved by surgical creation of an anastomosis between a defunctionalized segment of the small intestine (Roux limb) and a pseudocyst known as **a cyst jejunostomy**.
  - Pseudocysts arising in the head of the pancreas are infrequently drained by creation of an anastomosis between the descending duodenum and the pseudocyst known as a **cyst duodenostomy**.

Choice of Procedure

- Surgical resection should be considered when the diagnosis of a cystic-appearing neoplasm such as a mucinous cystadenoma cannot be excluded or selectively by means of a distal (left) pancreatectomy for a pseudocyst or WON involving the tail of the pancreas. Distal (left) pancreatectomy is discussed elsewhere in this text. Because of the greater morbidity and mortality of a pancreaticoduodenectomy (Whipple procedure), resection should not be considered for pseudocysts in the head of the pancreas.
- As pseudocysts arise as a result of disruption of the pancreatic ductal system and WON is also commonly associated with pancreatic duct disruption, external (percutaneous) drainage of pseudocysts or WON may give rise to a pancreatic fistula. Therefore, when treatment is necessary, internal drainage into the gastrointestinal tract is preferred. However, external drainage may be preferred if treatment of the pseudocyst is required before a wall suitable for construction of an anastomosis has formed. Temporary relief of symptoms may be achieved by large volume fine needle aspiration. Infection of an evolving pseudocyst is treated by placement of a drainage catheter. External drainage may also be considered if internal drainage does not appear safe for treatment of acute complications such as pseudocyst rupture or infection that arise in mature pseudocysts.
- Surgical drainage is most commonly performed into either the stomach or the small intestine. Cystojejunostomies have a lower incidence of pseudocyst recurrence and perioperative bleeding compared to cystogastrostomies but require creation of a Roux limb and an intestinal anastomosis (see below). Additionally, pseudocyst recurrence after creation of a cyst gastrostomy may be amenable to endoscopic treatment. Therefore, if the stomach suitably abuts the pseudocyst, a cyst gastrostomy is usually created. Otherwise, a Roux-en-Y cyst jejunostomy is created.
- Endoscopic cyst gastrostomy (discussed in detail elsewhere in this text) is especially well suited for treatment of true pseudocysts containing only fluid and no necrotic tissue.
- Open and minimally invasive (laparoscopic or robot-assisted) techniques of creating cystogastrostomies and Roux-en-Y cystojejunostomies are fundamentally identical.

Preoperative Preparation

- Patients should be prepared in routine fashion for major abdominal surgery.
- Comorbidities such as hypertension and cardiopulmonary disease should be optimized.
- Patients should be evaluated and treated for pancreatic endocrine and exocrine insufficiency.
- Coagulation disorders if present should be corrected.
- Routine antibiotic and thromboembolic prophylaxis should be administered.
- In malnourished patients, surgery should be delayed and preoperative nutritional support should be given when possible. Enteral nutrition is preferred but may not be possible due to the mass effects of the pseudocyst.

Positioning

- For either open or minimally invasive procedures, the patient is placed in a supine position. Arms may either be tucked or extended outward.
- Table-mounted retractors are used as needed for open procedures.

DESCRIPTION OF PROCEDURES

- Gastric drainage procedures
  - Transgastric cyst gastrostomy
  - Extragastric cyst gastrostomy
  - Intragastric cyst gastrostomy
- Jejunal drainage procedure
  - Roux-en-Y cyst jejunostomy

TECHNIQUES

TRANSGASTRIC CYST GASTROSTOMY

- A midline incision provides excellent exposure for **open transgastric cyst gastrostomies**. Palpation of the abdomen after induction of anesthesia and review of the patient's preoperative imaging studies will guide placement of the incision.
- A wound protector is placed, thorough exploration of the abdomen is performed, and the fullness posterior to the stomach caused by the pseudocyst is palpated and localized. If necessary, the pseudocyst can be further localized using ultrasound (**FIG 6**).
- Port placement for **minimally invasive transgastric cyst gastrostomy** will vary according to the size and position of the pseudocyst. In general, however, one midabdominal 5-mm port, two right upper abdominal 5-mm ports, and two left upper abdominal 5-mm ports will suffice. These ports are upsized as necessary for insertion of staplers and ultrasound probes.
- Stay sutures are placed over the epicenter of this fullness (**FIG 7**), and a longitudinal anterior gastrotomy is made using electrocautery (**FIG 8**). This incision should be centered between the lesser and greater curvatures of the stomach to facilitate subsequent closure of the anterior gastrotomy. The anterior gastric wall is usually mobile and, consequently, the anterior gastrotomy can usually be made short. The longitudinal orientation of the gastrotomy allows it to be lengthened proximally or distally, if needed.
- Through the posterior wall of the stomach, the pseudocyst is palpated. The location of the pseudocyst can be confirmed by means of intraoperative ultrasound (**FIG 9**) or passage of a needle through the posterior wall of the stomach into the pseudocyst and aspiration of fluid from the pseudocyst (**FIG 10**). Both measures also provide an estimate of the distance between the stomach and the pseudocyst cavity. Fluid obtained by aspiration can be sent for biochemical, microbiologic, cytologic, and pathologic studies as indicated.
- The pseudocyst is entered through the posterior wall of the stomach using electrocautery at the site determined

FIG 6 ● Ultrasound can be used to localize the pseudocyst and assist in positioning of the anterior gastrostomy (laparoscopic cyst gastrostomy).

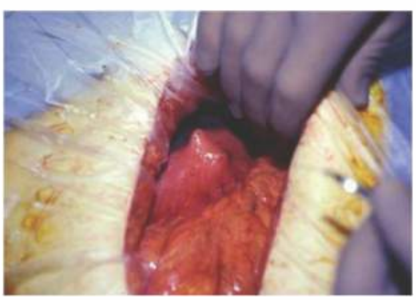


FIG 7 ● Stay sutures placed into the anterior wall of the stomach may facilitate creation of the anterior gastrostomy (open cyst gastrostomy).

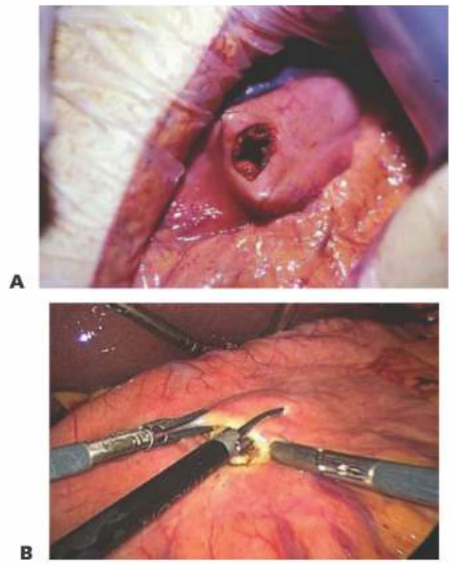

FIG 8 ● A longitudinal anterior gastrotomy is made. **A.** Open cyst gastrostomy. **B.** Laparoscopic cyst gastrostomy.

FIG 9 ● Ultrasound examination through the posterior wall of the stomach assists in localization of pseudocyst and positioning of the cyst gastrostomy incision (laparoscopic cyst gastrostomy).

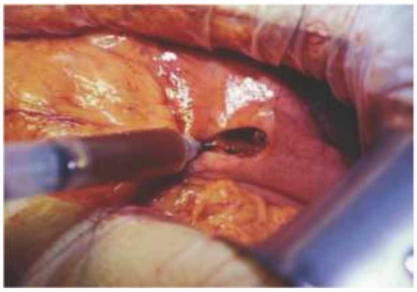

FIG 10 ● Transgastric aspiration of the pseudocyst confirms the location of the pseudocyst and distance from the gastric wall and assists in positioning of the cyst gastrostomy incision (open cyst gastrostomy).

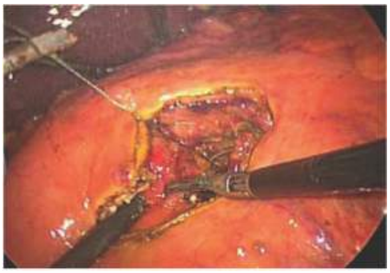

FIG 12 ● A portion of the cyst wall is excised and sent for frozen section examination to confirm the presence of a fibrous wall consistent with a pseudocyst and absence of an epithelial lining suggestive of a cystic neoplasm (laparoscopic cyst gastrostomy).

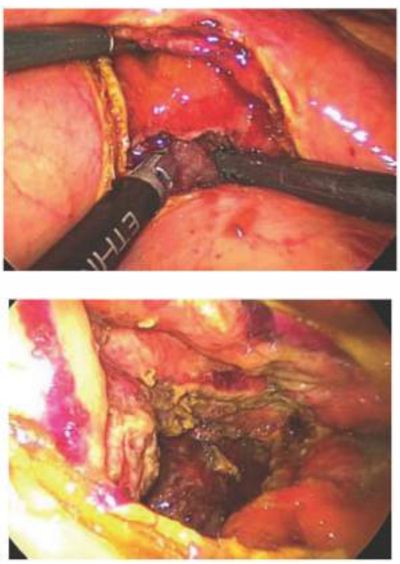
by ultrasound or aspiration and the contents of the pseudocyst are evacuated (**FIG 11**). Any necrotic debris within the cavity is removed. A portion of the pseudocyst wall is excised and sent for frozen section evaluation to confirm the presence of a fibrous wall and to exclude the presence of an epithelial lining (**FIG 12**).

- The opening into the pseudocyst is enlarged using electrocautery or another type of energized device. A finger or ultrasound probe placed into the pseudocyst helps to define the extent to which the posterior wall of the stomach is adherent to the anterior wall of the pseudocyst. A cyst gastrostomy of 5 cm or more is desirable when possible. The pseudocyst cavity is explored and any loculations within it are opened.
- Absorbable 2-0 sutures are placed circumferentially that approximate the posterior gastric wall to the pseudocyst wall (**FIG 13**). These sutures reinforce the adherence of the pseudocyst to the stomach and promote hemostasis along the cyst gastrostomy.
- After the initial entry into the pseudocyst, the cyst gastrostomy can also be enlarged using a linear surgical stapler. However, it remains mandatory to excise a portion of the pseudocyst wall for histologic evaluation.
- After ensuring that hemostasis is satisfactory, a nasogastric tube is positioned in the stomach and the anterior gastrotomy is closed using sutures or staplers. Depending on the length and position of the gastrotomy and the size of the stomach, the closure is oriented longitudinally or transversely.
- A final exploration of the abdomen is performed, and the midline incision is closed. Drains are not routinely placed.



A

B

FIG 13 ● **A,B.** Sutures are placed circumferentially along cyst gastrostomy to reinforce the adherence of the stomach to the pseudocyst wall and to ensure satisfactory hemostasis along the cyst gastrostomy. **A.** Open cyst gastrostomy. **B.** Laparoscopic cyst gastrostomy.

EXTRAGASTRIC CYST GASTROSTOMY

- Lesser sac pseudocysts in proximity to the posterior wall of the stomach can be anastomosed in side-to-side fashion to the stomach without entering the stomach through an anterior gastrostomy.
- The lesser sac is widely entered through the gastrocolic omentum.
- The posterior wall of the stomach and the anterior wall of the pseudocyst are identified where they lie in close proximity but are not adherent to one another.
- Small openings are made in the posterior wall of the stomach and the anterior wall of the pseudocyst where they lie in close proximity to one another, and a linear stapler is inserted into these openings and fired. Additional applications of the stapler are used as necessary to create an adequate anastomosis. The common opening is then closed using staplers or sutures.
- Alternatively, parallel incisions are made in the posterior wall of the stomach and the anterior wall of the pseudocyst and a hand-sewn anastomosis is fashioned.
- This technique of anastomosis between the stomach and pseudocyst can be performed as either an open or minimally invasive procedure.
- With this technique, the anastomosis between the stomach and the pseudocyst is not limited by the extent of their adherence to one another. Complications arising from the anterior gastrotomy are also eliminated.
- However, a leak at the cyst gastrostomy will result in extraluminal extravasation of gastrointestinal contents and a gastric fistula. Placement of a drain adjacent to the cyst gastrostomy should be considered.

ENDOLAPAROSCOPIC INTRAGASTRIC CYST GASTROSTOMY

- Laparoscopic access into the peritoneal cavity is achieved in the usual manner. Three right-sided 5-mm ports are initially placed. The mobility of the anterior wall of the body of the stomach is assessed to determine if it will reach to the abdominal wall. To do so, the pneumoperitoneum may need to be decreased. Once confirmed, traction sutures are placed into the stomach at this location, and passed out through the abdominal wall at the previously determined site.
- The jejunum is followed from the duodenojejunal junction to a site where the jejunum is mobile. A noncrushing bowel clamp is applied across the jejunum to prevent distention of the intestine during subsequent insufflation of the stomach.
- A 12-mm port is inserted at the previously determined site. A small gastrotomy is made at the center of the traction sutures, and the 12-mm port is advanced through this opening into the stomach. The traction sutures are used to hold the stomach upward against the abdominal wall. This is facilitated by also using a cuffed 12-mm port (**FIG 14**).
- The stomach is insufflated through the intragastric port, and laparoscopic examination of the inside of the stomach is performed. The bulge in the posterior wall of the stomach caused by the retrogastric pseudocyst is visible (**FIG 15**).
- An endoscope is the passed via the mouth into the stomach, providing intragastric visualization and allowing for laparoscopic instrumentation to be passed into the stomach through the single intragastric port (**FIG 16**).
- After localization of the pseudocyst by means of aspiration or ultrasound evaluation, an incision is made through the posterior wall of the stomach into the pseudocyst using electrocautery or other types of energy devices (**FIG 17**).
- A small portion of the pseudocyst wall is excised for frozen section evaluation, and the cyst gastrostomy is

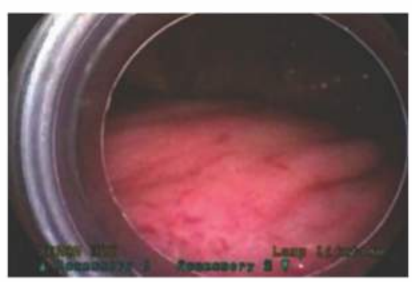

FIG 15 ● After passage of a laparoscope into the stomach through the intragastric port, a bulge in the posterior wall of the stomach caused by the retrogastric pseudocyst is visible.

FIG 16 ● An endoscope passed through the mouth into the stomach provides intragastric visualization and permits passage of laparoscopic instruments through the single intragastric port.

enlarged using either stapling or energy devices. Particular attention is given to ensuring satisfactory hemostasis. Through the cyst gastrostomy drainage and debridement of the cyst cavity are completed (**FIG 18**). Small amounts of residual debris will subsequently pass through the cyst gastrostomy. A nasogastric tube is positioned in the stomach, the port is removed from the stomach, and the gastrotomy is closed using either sutures or staplers. The bowel clamp is removed from the intestine and the remaining laparoscopic ports are removed. A drain is not routinely placed.

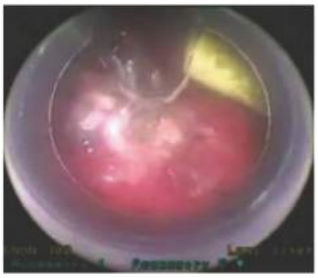

FIG 17 ● Under endoscopic visualization and after localization of the retrogastric pseudocyst, a small incision is made in the posterior wall of the stomach and the pseudocyst is entered.

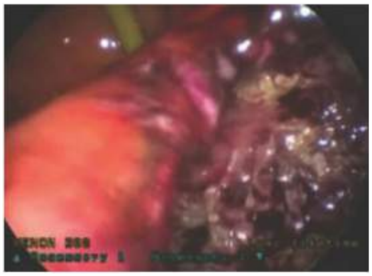

FIG 18 ● The cyst gastrostomy is enlarged using staplers or energy devices, and drainage and debridement of the pseudocyst are completed.

ROUX-EN-Y CYST JEJUNOSTOMY

- A midline incision provides excellent exposure for **open Roux-en-Y cyst jejunostomies**. Palpation of the abdomen after induction of anesthesia and review of the patient's preoperative imaging studies will guide placement of the incision. As the operation is performed predominantly below the transverse mesocolon, the incision is usually slightly more inferior than the incision used for creation of a cyst gastrostomy.
- A wound protector is placed and thorough exploration of the abdomen is performed. The pseudocyst typically presents as fullness bulging into the transverse mesocolon, and the fullness caused by the pseudocyst is palpated and localized.
- Port placement for **minimally invasive Roux-en-Y cyst jejunostomy** will vary according to the size and position of the pseudocyst. In general, however, ports are positioned lower in the abdomen than for creation of a minimally invasive cyst gastrostomy. Port placement is selected not only for creation of the cyst jejunostomy but also for creation of the Roux limb and subsequent enteroenterostomy.
- The transverse colon is elevated upward, allowing visualization of the transverse mesocolon and the bulging resulting from the pseudocyst. The location of the pseudocyst can be confirmed by aspiration. If the location of the pseudocyst is not readily apparent, intraoperative ultrasound can be used with reference to the patient's preoperative imaging studies (**FIG 19**). Ultrasound evaluation may also assist in identifying mesenteric vessels overlying the pseudocyst that should be avoided in fash-

FIG 19 ● Intraoperative ultrasound localization of pancreatic pseudocyst bulging through the transverse mesentery.

FIG 20 ● Dissection and exposure of pseudocyst bulging through the transverse mesentery.

FIG 21 ● Creation of Roux limb using a linear stapler to divide the jejunum and its mesentery.

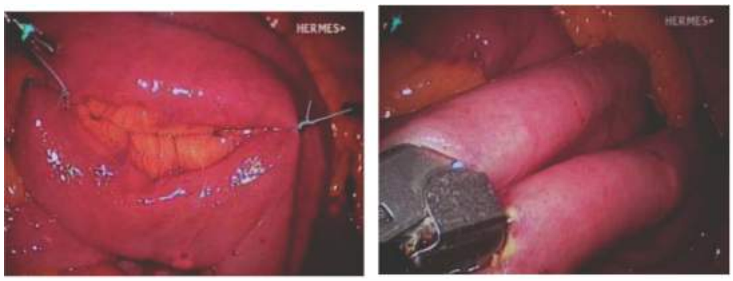

FIG 22 ● Creation of side-to-side enteroenterostomy using a linear stapler.

ioning the cyst jejunostomy. Adhesions overlying the pseudocyst are then taken down using sharp and blunt dissection (**FIG 20**).

- With the pseudocyst identified and exposed, a defunctionalized Roux limb is then prepared. The consequences of a leak subsequently occurring at the cyst jejunostomy are mitigated by use of a Roux limb rather than a functional loop of jejunum. The jejunum is followed from the duodenojejunal junction to a site where the mobility of the jejunum and the configuration of its vascular arcades are suitable. As the cyst jejunostomy is positioned below the mesocolon, mobility of the Roux limb is rarely an issue. However, occasionally, the jejunal mesentery may be very foreshortened or thickened as a result of the prior episode(s) of pancreatitis. The intestine is divided using a linear stapler, and the mesentery is divided, taking care to ensure that hemostasis is meticulous and that the blood supply to both ends of the jejunum is satisfactory (**FIG 21**).
- Gastrointestinal continuity can be reestablished before or after creating the cyst jejunostomy and can be performed using staplers, sutures, or a combination of both (**FIG 22**). The anastomosis can be performed in either a side-to-side or end-to-side fashion. A Roux limb measuring 40 to 50 cm should be created. In some instances, a longer Roux limb may be created if the patient's history or imaging results suggest the possible need for an additional cyst jejunostomy or biliary reconstruction in the future. In this case, the manner in which the enteroenterostomy is made and the positioning of the Roux limb should be carefully considered. After completing the enteroenterostomy, the resulting mesenteric defect is closed with sutures to prevent hernias.
- The Roux limb is positioned next to the pseudocyst and a side-to-side anastomosis measuring 3 to 5 cm in length is then created between the pseudocyst and the Roux limb. As with the extragastric cyst gastrostomy, this anastomosis can be performed using staplers (**FIG 23**) and/or sutures (**FIG 24**). Stapler and suture choice is determined by the thickness of the pseudocyst wall.
- A drain is placed adjacent to the anastomosis, and after confirming that hemostasis is satisfactory, the incision or ports are closed.

FIG 23 ● Creation of side-to-side Roux-en-Y cyst jejunostomy using a linear stapler. The jaws of the stapler are positioned in the Roux limb *(right)* and pseudocyst *(left)*.

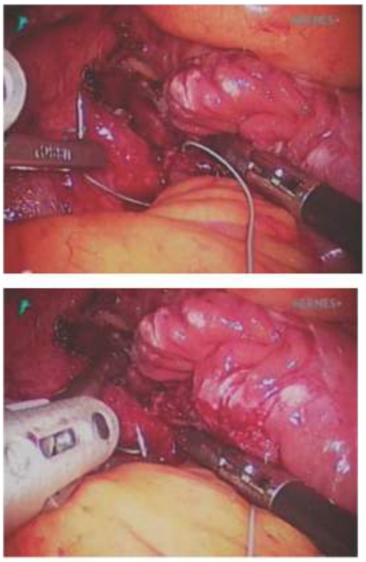

FIG 24 ● Creation of side-to-side Roux-en-Y cyst jejunostomy using sutures. Suture has been passed through the Roux limb **(top)** and is now being passed through the pseudocyst **(bottom)**.

PEARLS AND PITFALLS

Differential diagnosis	▪ Cystic neoplasm must always be considered.
Imaging and other diagnostic studies	▪ Management is driven by high-quality imaging. The anatomic relationships, presence of necrotic debris, and involvement of pancreatic duct must be well-determined to implement appropriate therapy. ▪ Be mindful of a potential disconnected pancreatic duct.

Preoperative planning	▪ Timing of intervention is key. The goal is to allow the process to adequately mature while minimizing the duration of disability.
	▪ Anatomic relationships drive management.
	  ▪ Cyst gastrostomy is technically least demanding but associated with higher recurrence rates.
	  ▪ Approach the pseudocyst from the transverse mesocolon for cyst jejunostomy.
	  ▪ Consider laparoscopic approach or endoscopic assistance.
	▪ Look for venous thrombosis and varices.

Surgical management	▪ Debride all necrotic material. ▪ Respect varices. Be liberal with ligation. ▪ Running or locking sutures to fashion the anastomosis are advised to minimize the risk of postoperative bleeding.

POSTOPERATIVE CARE

- A nasogastric tube is routinely placed in patients who undergo creation of a cyst gastrostomy and left in place until gastric emptying appears satisfactory.
- Drain output is evaluated for the presence of amylase and lipase. If present, the drain is left in place until output has ceased.
- Routine antibiotic and thromboembolic prophylaxis are administered. Other aspects of routine postoperative care are followed.
- Patients are evaluated for resolution of symptoms previously attributed to the pseudocyst. If symptoms persist, follow-up imaging (CT or MRI) is performed. Otherwise, routine follow-up imaging is obtained after 3 months to confirm resolution of the pseudocyst. Thereafter, further evaluations are dictated by the development of new symptoms.
- If symptoms persist after a cyst gastrostomy and imaging confirms the presence of a residual pseudocyst, endoscopy should be performed to evaluate the patency of the cyst gastrostomy. If narrowed, the cyst gastrostomy can be endoscopically dilated. The residual pseudocyst can be accessed, debrided, and drained endoscopically. Additionally, a nasocystic catheter can be placed for irrigation of the cavity.
- If symptoms persist after a Roux-en-Y cyst jejunostomy and imaging confirms the presence of a residual pseudocyst, the cyst jejunostomy can occasionally be evaluated and if

necessary be dilated endoscopically. However, the Roux construction often prevents this from being accomplished. Although revision of the cyst jejunostomy may need to be considered, if imaging studies demonstrate evidence of patency of the cyst jejunostomy (e.g., air in the pseudocyst), consideration should be given to allowing additional time for resolution of the pseudocyst before proceeding with surgery. Additionally, careful evaluation of the patient's symptoms should be performed to ensure that they are caused by the residual pseudocyst before embarking on further surgery.

COMPLICATIONS

- In addition to intraperitoneal bleeding, bleeding may occur from gastrotomies used to access the stomach and from any of the anastomotic sites. The cyst gastrostomy is particularly prone to bleeding because of the inherently rich blood supply of the stomach and the inflammation associated with the episode of pancreatitis and pseudocyst formation. Endoscopy is useful for not only evaluating the cyst gastrostomy but also for evaluating for bleeding within the pseudocyst cavity. However, accumulation of blood, fluid, and debris within the cavity may hinder thorough evaluation and consideration should be given to early angiography. Angiography should also be strongly considered for evaluation of bleeding from a Roux-en-Y cyst jejunostomy, as this anastomosis cannot be readily evaluated endoscopically.
- Leakage can occur at anastomotic and gastric closure sites. Leakage from an anterior gastrotomy closure or enteroenterostomy is managed as with any gastrointestinal leak. Leakage from a Roux-en-Y cyst jejunostomy can be managed nonoperatively if controlled satisfactorily by the drains placed at the time of surgery. Additional drains can be inserted percutaneously if needed. As the Roux limb is defunctionalized, surgical exploration is not required if adequate drainage is established. If leakage occurs from an extragastric cyst gastrostomy, the patient should initially be made nil per os (NPO). With adequate drainage from the surgically placed drains, leaks from either type of anastomosis will usually heal spontaneously.

Chapter 49

Pancreatic Debridement

Nicholas J. Zyromski

DEFINITION

- Two hundred and seventy thousand patients are admitted to U.S. hospitals yearly with the primary diagnosis of acute pancreatitis. Among these patients, 10% to 15% will develop severe acute pancreatitis with variable necrosis of the peripancreatic soft tissue and pancreatic parenchyma.
- Necrotizing pancreatitis (NP) is a serious problem with attendant mortality of approximately 20%.
- Once pancreatic and peripancreatic necrosis have been established, one of the three outcomes will present itself. **FIG 1** illustrates these potential outcomes. A small percentage of patients will resolve their necrosis with no intervention. Another portion of patients will develop infection in the necrosis; this typically demands treatment. A third group of patients will have persistent necrosis. If the necrosis causes no symptoms, no intervention is necessary. However, symptomatic necrosis remains an indication for intervention. Symptoms may include fullness/early satiety, general malaise, and back pain. These symptoms are related to mass effect of the necrosis as well as to the inflammatory response.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The etiology of pancreatitis should be investigated. Patients with biliary pancreatitis should be considered for cholecystectomy with cholangiography at the time of pancreatic debridement. A significant number of patients will have idiopathic cause; current data implicates microlithiasis and/or sludge in many of these cases. Therefore, strong consideration should be given to cholecystectomy if technically possible and safe at the time of debridement.
- NP patients have widely variable physiologic condition prior to necrosectomy. On two ends of the spectrum, a patient may be acutely ill with systemic sepsis and require debridement urgently for infectious control. On the other hand, many patients may be "walking wounded"—that is to say, they are home from the hospital managing some oral alimentation and are in reasonable physical health; however, they remain moderately to profoundly symptomatic.
- All efforts should be made to optimize nutritional and physical condition prior to pancreatic debridement. The clinician should understand that objective nutritional values will never normalize with a volume of necrotic tissue in the retroperitoneum generating a persistent inflammatory response. Enteral alimentation is ideal; parenteral nutrition may be necessary to supplement caloric and protein intake.
- It must be emphasized that multiple approaches are available to treat NP patients. The disease is extremely heterogeneous and no one intervention fits all patients. Ideally, a multidisciplinary team consisting of surgeons, interventional endoscopists, and interventional radiologists are invested in evaluating these patients. One doctor must be responsible for the long-term care of these patients as the recuperation typically encompasses 6 to 12 months or longer.

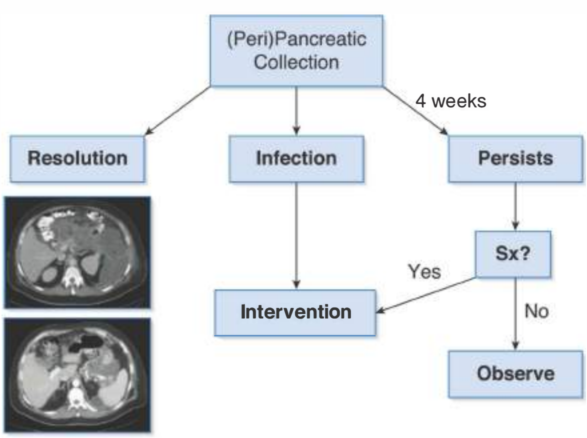

FIG 1 ● Necrosis outcomes. *Sx*, symptoms.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- A current cross-sectional image—that is, computed tomography (CT) or magnetic resonance imaging (MRI) scan—of the abdomen and pelvis is critically important to use as a road map guiding debridement.
- An important diagnostic consideration involves estimating the volume of solid material (as opposed to fluid) in the peripancreatic collection. MRI is more accurate than CT in making this estimation. Ultrasound may be most accurate; however, transabdominal ultrasound is plagued by artifact from hollow viscus. Endoscopic ultrasound (EUS) is an excellent modality; however, it requires sedation and is moderately invasive. **FIG 2** illustrates MRI and ultrasound images.
- Endoscopic retrograde pancreatography (ERP) is most accurate in defining pancreatic ductal anatomy and, specifically, the presence of disrupted main pancreatic duct. If ERP is undertaken in the setting of NP, it should be done a short time before planned debridement, as ERP has a high chance of contaminating what otherwise may be sterile necrosis. Fine needle aspiration of the pancreatic and peripancreatic necrosis is relatively sensitive in diagnosing infection. This modality is not commonly necessary or used in contemporary practice.
- Transabdominal ultrasound of the gallbladder should be performed to diagnose stones or sludge and inform the need for cholecystectomy.
- Broad-spectrum empiric antibiotic treatment is not recommended currently. Antibiotic therapy should be reserved for documented infections with a discrete endpoint in treatment.
- NP patients have an extremely high (56%) incidence of venous thromboembolic events. Screening duplex ultrasonography should be considered in all NP patients.

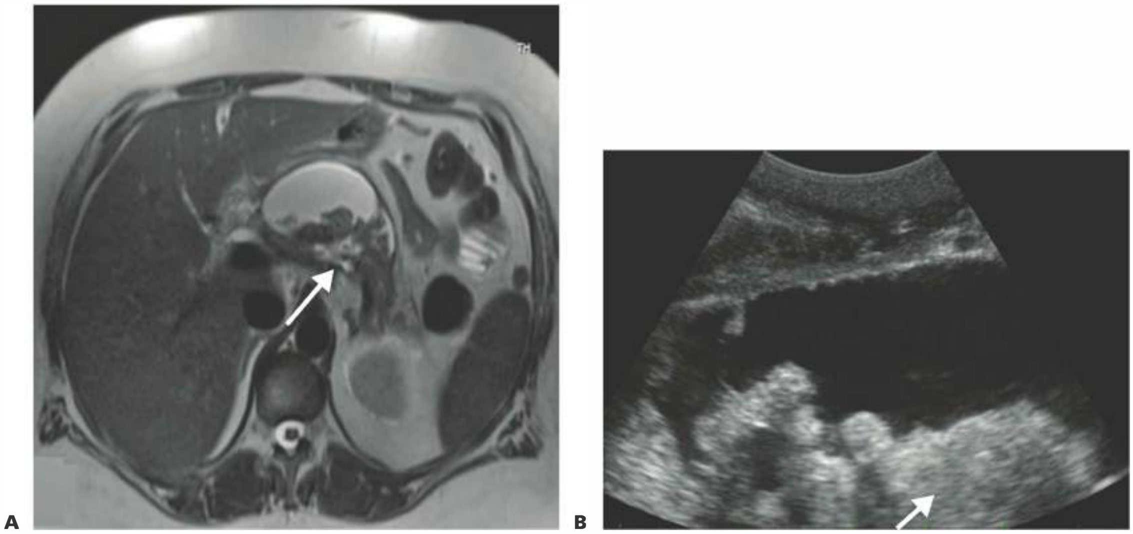

FIG 2 ● **A.** MRI showing solid and fluid components *(arrow)* of peripancreatic collections. **B.** IOUS image of the same collection. Solid necrosis is highlighted with *arrow*.

SURGICAL MANAGEMENT

- Perhaps the most important concept regarding NP is that this disease is extremely heterogeneous. The intervention/operative approach is dictated primarily by anatomic distribution of necrosis, involvement of the pancreatic parenchyma by necrosis, and specific individual clinical situation.
- Treatment approaches include percutaneous drainage, endoscopic drainage, a combination of percutaneous and endoscopic approaches, retroperitoneal debridement (videoscopic-assisted retroperitoneal debridement [VARD] or sinus tract necrosectomy), surgical transgastric approach, or traditional open operative debridement with external drainage.
- **FIG 3** illustrates typical patterns of necrosis. The image on the left with necrosis confined to the lesser sac may be approached through the posterior stomach either endoscopically or surgically. The middle image with necrosis extending down the left paracolic gutter may be best approached from the retroperitoneum (VARD). The image on the right with necrosis extending down both paracolic gutters and/or the small bowel mesentery root poses a challenging problem. This group also includes patients with pancreatic head involvement. These patients may be best approached by open operative debridement.
- Definitive intervention should not be undertaken earlier than 4 weeks from the incident episode of pancreatitis.

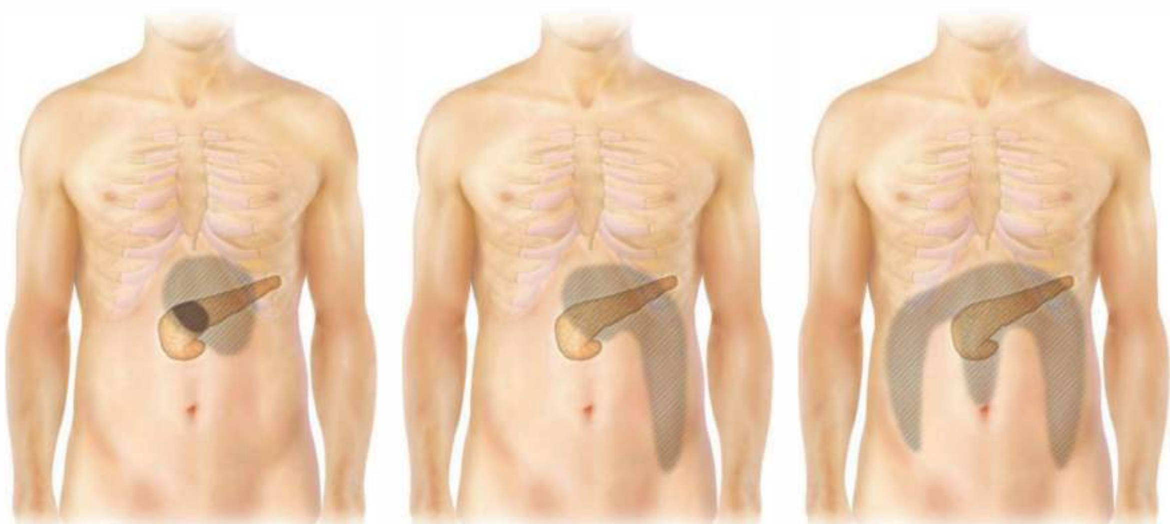

FIG 3 ● Necrosis patterns.

Goals of pancreatic debridement are shown in Table 1.

Table 1: Goals of Debridement

1	Debride as much solid necrotic tissue as possible safely.
2	Provide wide drainage of the pancreas (externally or into the alimentary tract if possible).
3	Establish enteral access.
4	Perform cholecystectomy and cholangiography if indicated.
5	Perform all the above with as little physiologic derangement as possible.

OPEN NECROSECTOMY

Exposure

- The patient may be approached through the midline or a low transverse incision, which provides superb access to the upper abdomen.
- Intraoperative ultrasound (IOUS) should be performed prior to disrupting any of the collections. IOUS provides important information about volume of solid necrosis.
- The surgeon should review recent cross-sectional image immediately before operating; this is a good "road map" directing debridement as well as to refresh memory of danger spots. Specific attention should be paid to the relationship of necrosis to the superior mesenteric and portal veins.
- A moderate amount of oozing from the diffuse inflammatory process is common. Infracolic adhesions, particularly to the undersurface of the transverse mesocolon, are quite common; these should be divided with careful blunt dissection as well as sharp dissection.
- The gastrocolic ligament should be divided. The inflammatory response commonly foreshortens the gastrocolic ligament and attention should be paid not to injure either the gastroepiploic vessels or the transverse colon wall.
- Lesser sac necrosis is always more cranial than it may seem.
- If necrosis extends down the paracolic gutters, these provide a reasonable and safe point of entry into the retroperitoneum. Debridement should progress from lateral to medial, paying special care to the known position of the superior mesenteric vein and portal vein around the pancreatic head (**FIG 4**).
- Catastrophic hemorrhage may occur from inadvertent vigorous debridement in the area of the superior mesenteric vein/portal vein (SMV/PV). The wall of the vein is weak from the inflammatory process. Proximal and distal vascular control is challenging because of the inflammatory process and in a desperate circumstance, applying a long straight vascular clamp across the porta hepatis and root of the small bowel mesentery may be a life-saving maneuver, allowing time to ligate the SMV/PV.
- It is important to release the colic flexures to provide full exposure of the upper retroperitoneum.
- Samples of the peripancreatic collection are commonly sent for Gram stain, aerobic, anaerobic, and fungal cultures.

Debridement

- The best tool for debriding pancreatic necrosis is the experienced surgeon's "educated finger." A ring forcep also is an excellent instrument.
- It is critical to only take the necrosis that is freely mobile. Vigorous debridement of immature necrosis, particularly along the area of major veins, is fraught with hazard.
- A reasonable approach is to debride one field at a time and to pack that area before moving onto the next area of debridement. For example, debride the left paracolic gutter, then pack this area with laparotomy sponges, and then move into the lesser sac or other areas in a stepwise fashion. Oozing from the retroperitoneum is very common; however, the vast majority of this bleeding will stop with a short period of tamponade.

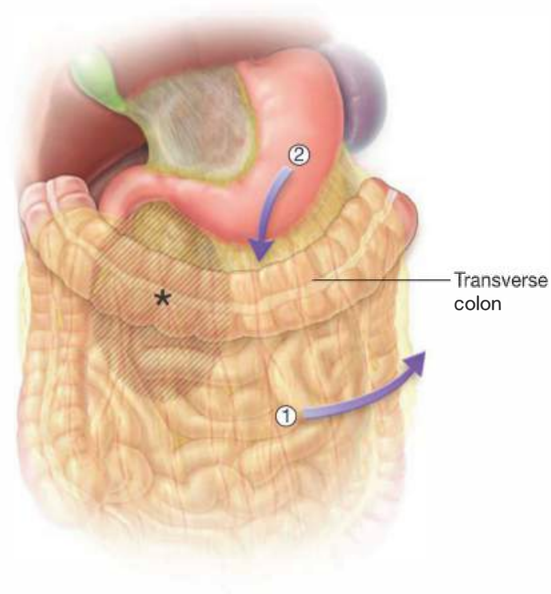

FIG 4 ● If necrosis extends down the right paracolic gutter, *(1)* this route provides safe access to the retroperitoneum. When dividing the gastrocolic ligament *(2)*, attention should be focused to preserving the gastroepiploic vessels and avoiding transverse colon injury. The *asterisk* highlights the danger zone with underlying SMV/PV.

FIG 5 ● Intraoperative photograph of right transverse mesocolon vessels skeletonized by adjacent necrosis *(arrow)*. The transverse colon is reflected cranially in the surgeon's hand.

- Vigorous irrigation of the retroperitoneum helps dislodge small volume necrosis.
- It is common to see skeletonized vessels both in the mesocolon as well as the retroperitoneum. These are quite friable; it is preferable to ligate these vessels if any question about their integrity exists. Many of these are already thrombosed (**FIG 5**).

Cholecystectomy

- Cholecystectomy may be performed at this point in the procedure if indicated and if the patient is physiologically stable. Obviously, the decision to perform cholecystectomy is a judgment call. A patient who is septic, requiring vasopressor support during debridement, is not the ideal candidate for a cholecystectomy, which is typically not a straightforward procedure and may involve substantial hemorrhage.
- Cholecystectomy is typically performed in the retrograde fashion. If the inflammatory process is too dense, cholecystectomy may be deferred, although it should not be abandoned and completely forgotten as a significant number of patients (35%) will have recurrent biliary symptoms (either cholecystitis or pancreatitis) if cholecystectomy is not performed within the next several months.
- In the setting of a densely inflamed right upper quadrant, subtotal cholecystectomy (Thorek's procedure) is acceptable (**FIG 6**).
- Cholangiography should be performed for all patients with biliary pancreatitis. Common bile duct exploration is potentially quite hazardous in this situation and experienced judgment should be sought before undertaking common duct exploration in the setting of NP. However, documenting the presence of common bile duct stones is important to direct further management.

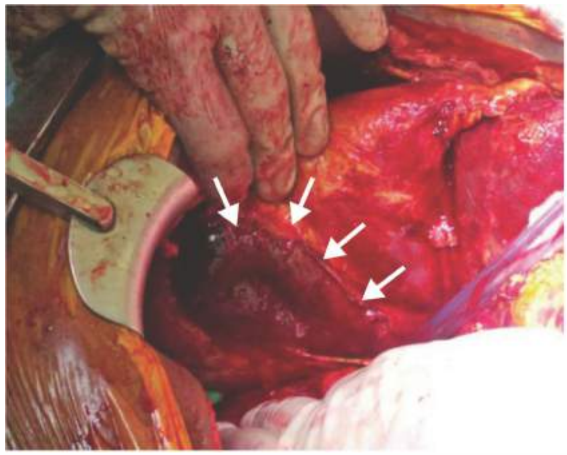

FIG 6 ● Intraoperative photograph showing densely inflamed gallbladder/right upper quadrant *(arrows)* in the setting of biliary acute NP.

Enteral Access

- Many patients with retroperitoneal necrosis have gastric ileus and/or small bowel ileus. Our preference is to place gastrojejunostomy feeding tubes liberally (**FIG 7**). This tube is easy to place and permits decompression of the stomach and feeding distal to the ligament of Treitz to provide enteral nutrition in the immediate postoperative period. The tube is then easily removed in the office once the patient has recuperated completely.
- The gastrostomy tube is placed in the anterior body in the fashion of Stamm.
- The stomach should be tacked securely to the anterior abdominal wall with heavy suture to permit replacement of the gastrojejunostomy tube should dislodgement occur.

FIG 7 ● Gastrojejunostomy feeding tube permits feeding downstream of ligament of Treitz while simultaneously decompressing the stomach.

Drains

- Debridement beds are drained widely.
- Our preference is to use closed suction large-caliber (19 mm) drains (**FIG 8**). Three-way drains, although attractive in theory, are extremely challenging to manage in the intensive care unit and on the hospital ward.
- If disconnected pancreatic duct is suspected and external drainage employed, it is critical to maintain this drain, which controls the fistula externally.

Abdominal Closure

- The fascia is most often able to be closed primarily, although the operator should pay close attention to the peak airway pressures at the time of closure.
- The need for true retention sutures is unusual; however, a combination of running and interrupted slowly reabsorbable monofilament sutures seems prudent.
- The incidence of ventral hernia after open pancreatic debridement is substantial (42%).
- The skin is typically left open to close by secondary intention.

FIG 8 ● Large-caliber closed suction drains typically provide adequate drainage of necrosis bed if thorough debridement is achieved. Drains are placed above the transverse colon; stomach is retracted cranially.

TRANSGASTRIC NECROSECTOMY

- Transgastric necrosectomy may be approached laparoscopically or through a short upper midline incision (**FIG 9**). This technique is selectively applied to patients with necrosis isolated in the lesser sac; it may be particularly effective for patients with a disconnected pancreatic tail. Clinicians should be aware that necrosis extending down the small bowel mesenteric root or paracolic gutter may not be appropriate for this technique.
- IOUS is a critical adjunct, especially if the majority of the necrosis is solid as opposed to liquid. Ultrasound should be applied through the front wall of the stomach and particularly through the back wall of the stomach to help localize posterior gastrotomy (**FIG 10**).
- The surgeon should be aware of the potential for hemorrhage from varices in the gastric wall in the setting of left-sided (sinistral) portal hypertension.
- Stay sutures in the posterior gastric wall are extremely helpful in the laparoscopic approach, delivering this

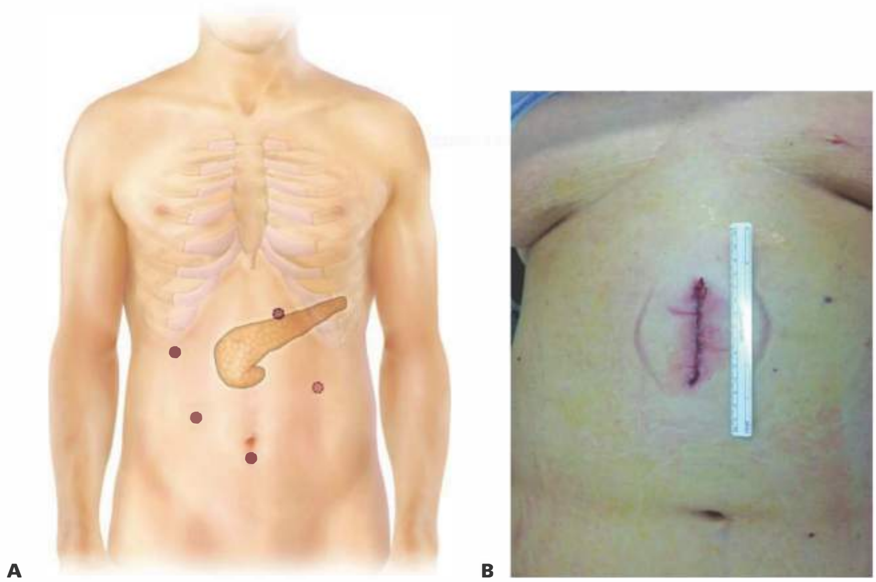

FIG 9 ● **A.** Diagram showing port placement for laparoscopic transgastric debridement. **B.** Postoperative photograph: even with heavy body habitus, open transgastric debridement may be achieved through a short (6 cm) upper midline incision.

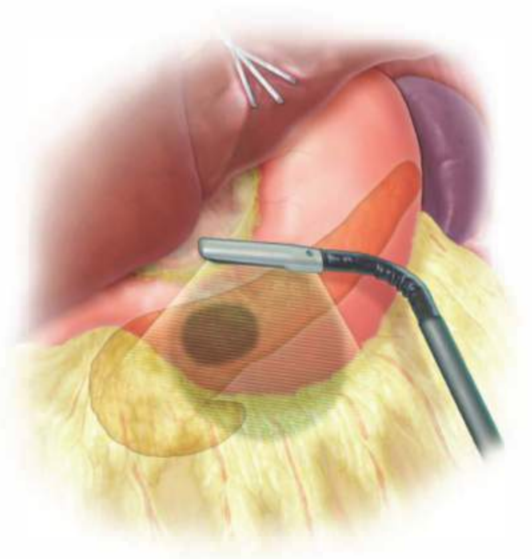

FIG 10 ● IOUS is critical, particularly in the laparoscopic approach.

opening into the operative field (**FIG 11**). Wide posterior gastrotomy is created either with cautery or a linear stapling device. The posterior gastrotomy is sutured to the cyst with permanent suture. This aids in hemostasis as well as in durably maintaining this ostomy. Gentle debridement and copious irrigation are applied. The conduct of debridement is similar to that in the open situation (**FIG 12**).

- Anterior gastrotomy is closed with suture or stapler (**FIG 13**). Often, the stomach is thick and suturing provides a more secure closure.

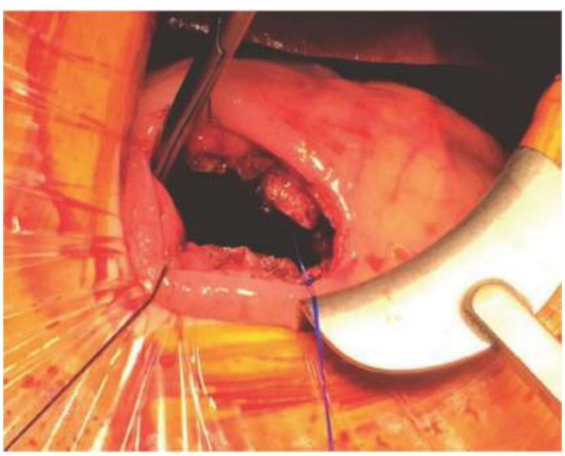

FIG 11 ● Intraoperative photograph showing anterior gastrotomy and large posterior cystogastrostomy. Note stay sutures on posterior gastric wall.

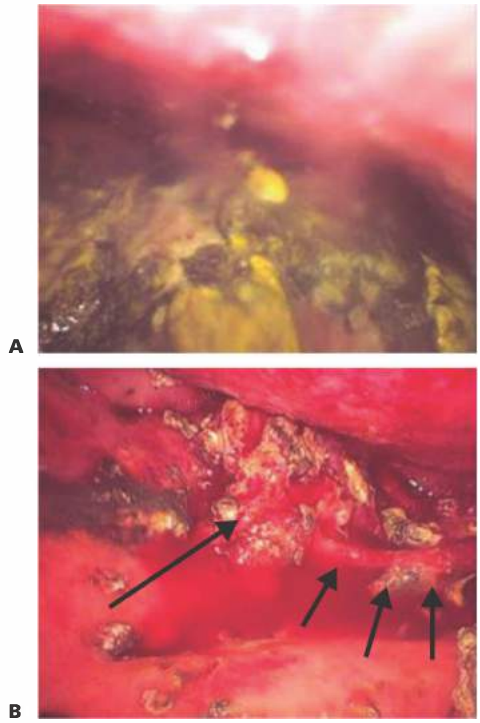

FIG 12 ● Intraoperative photographs of laparoscopic transgastric debridement. **A.** Camera is in necrosis cavity. **B.** After debridement. *Long arrow* shows disconnected pancreatitis tail; *short arrows* show splenic artery.

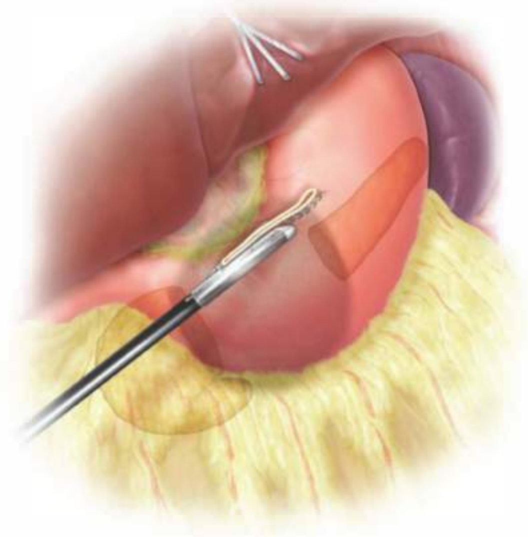

FIG 13 ● Anterior gastrotomy may be closed with suture or stapler (shown).

- If gastrostomy or gastrojejunostomy feeding tube is indicated, placing this prior to closing the anterior gastrotomy affords visualization of the tube passing through the duodenum. Care should be taken to place the gastrostomy at a distance away from the gastrotomy closure site.
- No drains are necessary with transgastric necrosectomy.
- Cholecystectomy and cholangiography may be performed if indicated.

Distal Pancreatectomy +/− Splenectomy

- In the setting of major body necrosis with a very small amount of viable pancreatic tail, the surgeon may consider distal pancreatectomy at the time of operative debridement. This should be reserved for highly select cases. It is almost always necessary to perform splenectomy in this setting due to the significant inflammatory response and frequent incidence of gastric varices.
- Preoperative embolization of the splenic artery should be considered in this clinical scenario.

PEARLS AND PITFALLS

Surgical decision making	■ NP is an extremely heterogeneous disease. Appropriate treatment must be based on the underlying necrosis anatomy as well as the patient's general condition. Ideally, treatment decisions are made in the context of multidisciplinary review. ■ Definitive intervention should not be applied before 4 weeks' time. ■ Should infection occur before 4 weeks' time, percutaneous drainage is the most appropriate intervention. ■ Keep in mind the potential for colon ischemia at any point in the course of this disease.
Operative technique	■ If forced to operate (to prove or exclude colon ischemia) prior to 4 weeks, wide drainage of immature necrosis is preferred to attempts at debriding immature necrosis. ■ In the setting of disconnected pancreatic tail, the transgastric approach may be most appropriate. Alternatively, distal pancreatectomy plus splenectomy may be considered in highly select patients. ■ Be aware of the potential for visceral arterial pseudoaneurysm. ■ When manually debriding pancreatic necrosis, only take the necrosis that comes easily. ■ In biliary pancreatitis, cholecystectomy and cholangiography should be performed if technically possible at time of debridement. Cholecystectomy may be hazardous and clinical judgment regarding extent of operation is important here.
Postoperative care	■ Do not be afraid to reoperate if the patient is not following the expected course. It is important to regain control of a poorly controlled or uncontrolled pancreatic fistula. It is also important to exclude ischemic colitis in the early postoperative period following the first debridement.

POSTOPERATIVE CARE

- Optimal nutrition support is critical for expedient recuperation. Oftentimes, this requires some combination or parenteral and enteral nutrition. While recognizing the crucial importance of enteral alimentation, the surgeon should be cognizant of small bowel and gastric ileus that are very common in the setting of NP and postdebridement. Increasing tube feeding volume too rapidly may be detrimental.
- Aggressive physical rehabilitation is also critical. Early planning for discharge to an extended-care treatment facility is prudent; direct communication with health care providers at these facilities is important to maintain the continuity of care.
- Venous thromboembolism is common occurrence in the setting of NP. Patients should be observed carefully and possibly screened with ultrasound on a regular basis. Bright red blood in the surgical drain should be considered visceral arterial pseudoaneurysm until proven otherwise. Often, a small amount of blood is from retroperitoneal venous hemorrhage; however, visceral arterial pseudoaneurysm is a potentially lethal problem that should not be missed. Cross-sectional imaging with computed tomography angiography (CTA) is rapid and widely available; CTA is an excellent first-line test with which to diagnose or exclude pseudoaneurysm.
- Appropriate duration of antibiotic treatment after satisfactory source control is important. However, no clear data exist to inform this treatment decision. Antibiotic treatment of no shorter than 7 days should be employed. We have tried to cut down antibiotic treatment and had recurrent retroperitoneal infected collections. It is noteworthy that retroperitoneal collections infected with resistant bacteria and yeast are extremely hard to clear. Consideration should be given to extended-duration antibiotic treatment in these cases.
- The patient should be observed for the presence of external pancreatic fistula. Measurement of amylase and surgically placed drains will diagnose this condition.
- Enterocutaneous fistulas may occur. These should be managed in a similar fashion to enterocutaneous fistulas developing from other conditions. Duodenal fistula is extremely challenging. Percutaneous transhepatic drainage with diversion of the biliopancreatic secretion will occasionally allow these fistulas to close with nonoperative management.

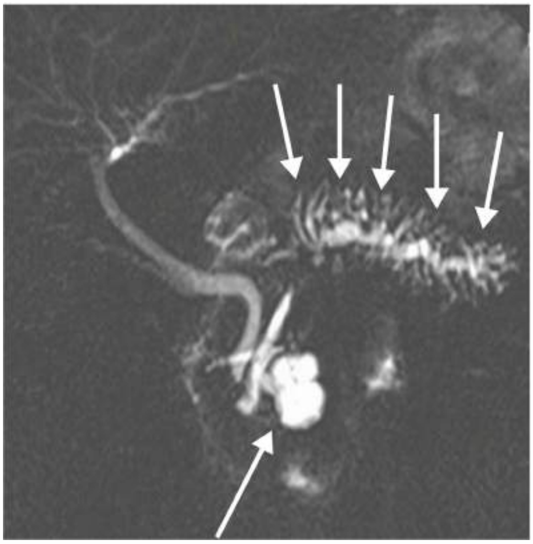

FIG 14 • MRI 2 years after transgastric debridement showing dilated main and side branch pancreatitis ducts *(short arrows)* in the disconnected tail. The etiology of this patient's pancreatitis was the side-branch IPMN *(long arrow)*.

- Patients dismissed from the hospital with controlled external pancreatic fistula and/or supplemental enteral and parenteral nutrition should have early and frequent postoperative follow-up.
- Patients who fail to progress as expected should have early cross-sectional imaging. Additional percutaneous drainage or reoperation may be necessary to regain control of an uncontrolled pancreatic fistula.
- Long-term follow-up is crucial for patients undergoing transgastric debridement, as long-term outcomes from this relatively new approach are unknown. A small number of patients will manifest recurrent pancreatitis (**FIG 14**) or recurrent retroperitoneal fluid collections (pseudocyst) after transgastric debridement.

OUTCOMES

- Mortality after pancreatic debridement in contemporary series ranges from 5% to 10% at specialized centers. Although this mortality is relatively high, this represents substantial improvement from historical mortality figures and is likely most related to improved operative selection. Patients and family members should be educated from the start of this disease process that NP is a long-term problem and that even in the best of circumstances, patients should expect a recuperation period measured in months.
- In general, reports of long-term outcomes for patients with NP and operative debridement are scarce.
- Ideally, patients will have long-term follow-up with primary physician and/or gastroenterologist attentive to exocrine and endocrine functions as well as digestive function.
- A small number of patients with NP will have intraductal papillary mucinous neoplasm (IPMN) or pancreatic adenocarcinoma as the cause. Unfortunately, prognosis in this subgroup of patients is uniformly poor.
- A small subgroup of patients with NP is too well to die but too sick to recuperate with reasonable quality of life. This is an extremely challenging group of patients to care for. However, in a highly select number of these patients, hospice care may be appropriate. These patients, for example, have protracted immobilization, protracted organ failure, and unreconstructable enteric fistulas.
- A highly select number of patients may be candidates for intestinal or multivisceral transplant. Obviously, this is decision making that must be undertaken in conjunction with the organ transplant group.

COMPLICATIONS

- Complications after pancreatic necrosectomy may be related to disease progression or operation. Table 2 highlights these complications.

Table 2: Complications of Necrotizing Pancreatitis

Short-Term	Long-Term
Pancreatic fistula (particularly with disruption of the main pancreatitis duct)	Recurrent retroperitoneal collections/infection
Colonic ischemia	Bile duct or duodenal obstruction from stricture
Venous thromboembolism	Exocrine and endocrine insufficiency
Enteric fistula	Chronic pain
Visceral arterial pseudoaneurysm	Recurrent acute pancreatitis progressing to chronic pancreatitis in the remnant pancreas
	Ventral hernia

Chapter 50

Laparoscopic Pancreatic Debridement

O. Joe Hines Kathleen Hertzer

DEFINITION

- Laparoscopic pancreatic debridement is a minimally invasive technique for pancreatic resection and is indicated in the case of infected pancreatic necrosis as a result of acute pancreatitis. Additional options for pancreatic necrosectomy include laparotomy as well as other minimally invasive methods such as percutaneous catheter drainage and endoscopic drainage. Methods of laparoscopic debridement will be the focus of this chapter.

Differential Diagnosis

- The differential diagnosis of acute pancreatitis includes biliary colic, peptic ulcer disease, cholecystitis, acute mesenteric ischemia, small bowel obstruction, visceral perforation, vascular catastrophes such as ruptured aortic aneurysm, as well as intraabdominal infection.
- In the setting of recent, severe acute pancreatitis, characteristic CT findings and patient history and physical findings are strongly supportive of infected versus sterile pancreatic necrosis, pancreatic abscess, or pancreatic pseudocyst.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Acute pancreatitis has a broad range of clinical symptoms. The majority of cases can be mild and self-limiting; however, about 20% of these patients will develop severe acute pancreatitis and among these patients, approximately 30% to 70% will develop infected necrosis.[1]
- Severe acute pancreatitis is associated with high mortality and morbidity; these patients are at risk for infection, multisystem organ failure, and death.
- Secondary infection of pancreatic necrosis occurs by bacterial or fungal translocation through the GI tract or by seeding through transient bacteremia from invasive monitoring in the intensive care setting.
- Infection of pancreatic necrosis can occur as early as 10 days after the onset of acute pancreatitis. More typically, infection ensues 3 to 6 weeks after the initial onset of symptoms.
- Patient history and physical examination for pancreatitis and pancreatic necrosis include a recent history of acute pancreatitis and continued abdominal pain, chronic low-grade fever, nausea, lethargy, and inability to eat. Those patients with infected pancreatic necrosis will show signs of intraabdominal infection including tachycardia, hypotension, fever, and deteriorating organ function.
- Conservative management is recommended in the case of sterile necrosis. Surgical management can be considered in symptomatic sterile necrosis; not infrequently, occult infection proves to be present. In the setting of clearly infected pancreatic necrosis, debridement or drainage is the preferred method of treatment.
- Methods for debridement include open necrosectomy and multiple minimally invasive modalities, including laparoscopic debridement. Minimally invasive necrosectomy is technically achievable and although there is evidence that a step up minimally invasive technique (percutaneous drainage with or without following retroperitoneal necrosectomy) may reduce morbidity and mortality amongst patients with infected necrotizing pancreatitis, it is unclear if minimally invasive techniques are cost effective.[2,3]

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Plain radiographs are nonspecific. Ultrasound (US) may show a diffusely enlarged, hypoechoic pancreas and can be important in identification of the etiology of pancreatitis (e.g., gallstones).
- Appropriate imaging for acute pancreatitis includes contrast-enhanced computed tomography (CT) scan when complications are clinically suspected. Complications of pancreatitis evolve with time and impending necrosis may not be appreciated on CT imaging obtained within the first 24 to 48 hours of symptoms. CT imaging in the case of mild acute pancreatitis will show pancreatic enlargement, edema, peripancreatic fat stranding as well as effacement of the normal contours of the organ.
- In the setting of pancreatic necrosis, IV contrast can help delineate areas of poor perfusion as well as the extent of necrosis and can be used to predict the severity of disease. Visualization of air bubbles within necrotic tissue is diagnostic of infection (**FIG 1**).

FIG 1 ● Infected pancreatic necrosis. CT scan showing a hypoenhancing pancreas, indicating necrosis, with gas bubbles indicating bacterial infection of the necrotic material. This is likely necrosis mixed with peripancreatic phlegmon.

Table 1: Computed Tomography Grading System of Acute Pancreatitis

Grade	Findings	Score
A	Normal pancreas	0
B	Focal or diffuse enlargement of the pancreas, irregular organ contour	1
C	Peripancreatic inflammation with intrinsic pancreatic abnormalities	2
D	Fluid collections either intrapancreatic or extrapancreatic	3
E	Two or more large collections of gas in the pancreas or retroperitoneum	4

- The grading of severity of pancreatitis can be classified into five categories (Table 1) and a CT severity index can be calculated based on the grading of unenhanced CT findings and the percentage of necrosis demonstrated on contrast-enhanced CT (Table 2). The CT severity index is the sum of the unenhanced CT score and the necrosis score where the maximum is 10 and greater than or equal to 6 indicates severe disease.[4]
- If infected pancreatic necrosis is suspected, the diagnosis is confirmed with culture results from CT-guided fine needle aspiration (FNA) or from specimens collected during necrosectomy.
- FNA and culture should be obtained in patients who show clinical features of sepsis or those with a deteriorating clinical course 1 to 2 weeks after the onset of disease.

Table 2: Necrosis Score

% Necrosis	Score
0	0
<33	2
33–50	4
≥50	6

- Commonly, the Atlanta classification is used to divide acute pancreatitis into mild and severe categories. The criteria for severe acute pancreatitis include the following: a Ranson's score of 3 or greater, an APACHE II score of 8 or greater within the first 48 hours, organ failure, or local complications (necrosis, abscess, or pseudocyst involving the pancreas). Other predictors of disease severity within the first 24 hours of hospitalization include a C-reactive protein of greater than 120 mg/dL, procalcitonin greater than 1.8 ng/mL, and a hematocrit greater than 44.[5]

SURGICAL MANAGEMENT

Preoperative Planning

- Cross-sectional imaging as described earlier is necessary to determine the extent of necrosis, for signs of infection as well as planning of approach.
- The use of prophylactic antibiotics remains controversial. Antibiotics should be restricted to clear cases of CT-proven pancreatic necrosis and tailored to culture results when available. Current recommendations include imipenem or meropenem for 2 weeks for patients with proven necrosis.[6,7] Preoperative antibiotics are recommended prior to incision.
- Access: large-bore IV or central access for fluid resuscitation, rapid blood transfusion, vasopressor infusion; Foley catheter and nasogastric tube placement. Consider central line and arterial line monitoring in the case of hemodynamic instability.
- Timing of the procedure: Better outcomes are achieved if necrosectomy is delayed for at least 21 days.[8–10] This delay allows for clinical stabilization of the patient, resolution of any signs of organ failure, and decreased inflammatory reaction.

Positioning

- Positioning for laparoscopic pancreatic necrosectomy should be supine for a transperitoneal approach and lateral for a retroperitoneal approach. If the patient is supine, prep the entire abdomen from nipple to midthigh.

TECHNIQUES

RETROGASTRIC-RETROCOLIC DEBRIDEMENT (TRANSPERITONEAL)

First Step

- A transperitoneal approach is begun by placing the initial trocar in the periumbilical position (FIG 2).
- A 30-degree angled laparoscope is used to guide the insertion of two right paramedian trocars and an additional assistant's trocar in the left lateral abdomen. Start with exploratory laparoscopy after establishing pneumoperitoneum.

Second Step

- The area of necrosis can be approached through the gastrocolic ligament or the transverse mesocolon (FIG 3).

If a percutaneous drainage catheter is in place, this can be left in position and used as a guide to identify the necrosis. Dissection is accomplished with a harmonic scalpel or bipolar electrocautery device. The left side of the pancreas may be drained by mobilization of the splenic flexure. In addition, if necrosis extends above the pancreas, the lesser sac may also be entered through the gastrohepatic ligament, taking care to safeguard the right and left gastric arteries.

Third Step

- Debridement is accomplished under direct vision with the use of a grasping instrument (FIGS 4 and 5). A 10-mm stone extractor instrument is often most efficient. Necrotic material should be sent for histology and microbiology.

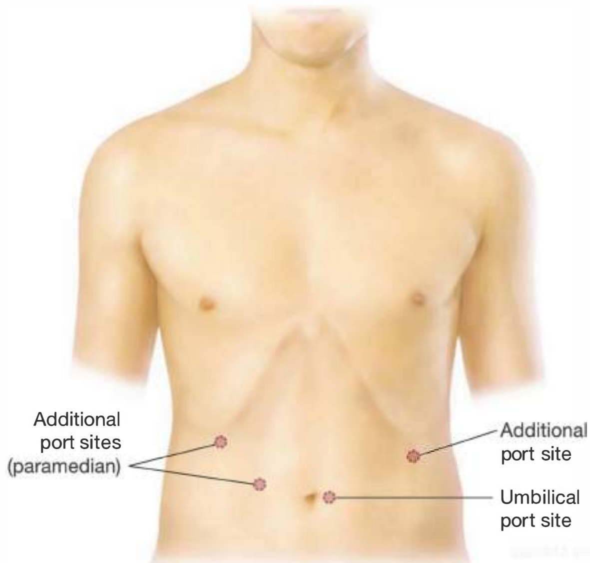

FIG 2 ● Port placement for transperitoneal debridement. Transumbilical port placement and two or more paramedian ports are placed with respect to the location of greatest pancreatic necrosis.

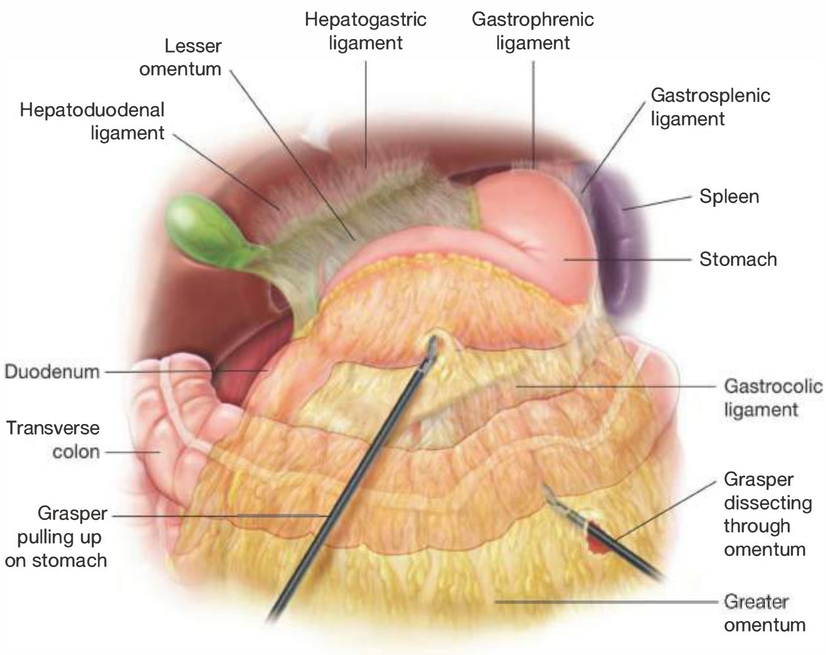

FIG 3 ● Access to the body and distal pancreas can be obtained transperitoneally through the gastrocolic ligament and the left mesocolon.

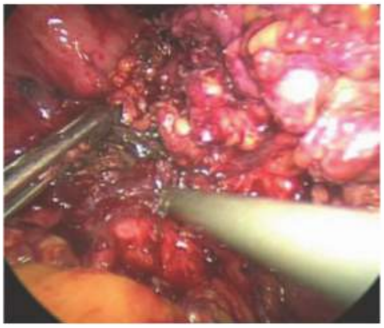

FIG 4 ● Debridement of necrotic pancreas. The pancreas has been accessed laparoscopically through the gastrocolic omentum using a harmonic scalpel. In this case, two drains had been placed preoperatively into fluid collections in the head and tail of the pancreas, respectively. Access was gained to the poorly draining tail collection by following the drain into the lesser sac. After draining purulent fluid, debridement was achieved with the use of blunt forceps.

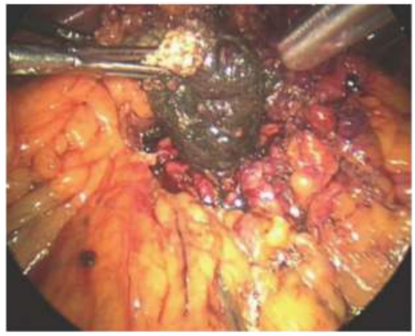

FIG 5 ● Removal of necrotic pancreas. A 6-cm piece of necrotic pancreas was removed through the anterior abdominal wall with the use of an EndoCatch bag.

- Consider intraoperative US for localization of retroperitoneal necrosis and the identification of major vascular anatomy.
- The suction-irrigator can be used to aspirate and break down pancreatic debris. An endobag is a useful tool for further removing debris.
- The cavity can be inspected by introducing the laparoscope into the debridement bed. Referring to the preoperative CT scan helps to ensure all areas of necrosis have been removed. Sump drains are placed through the trocar sites for continuous lavage of the debridement bed in the postoperative period (**FIG 6**).

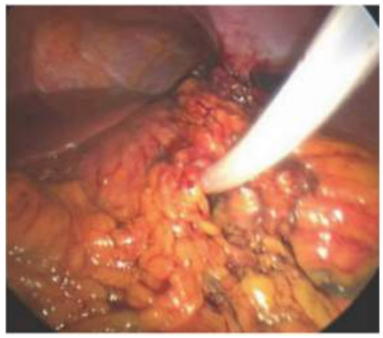

FIG 6 ● Drain placement. After adequate debridement and irrigation, an Axiom drain was placed in the cavity surrounding the body and tail and brought out through the abdominal wall through the midabdominal trocar site and secured in place.

VIDEO-ASSISTED RETROPERITONEAL DEBRIDEMENT

First Step

- Retroperitoneal debridement may be used in early necrotizing pancreatitis, especially if there is minimal fibrotic tissue, inflammation, or edema. This approach allows for examination of the posterior pancreas (**FIG 7**).
- The patient is placed in the lateral decubitus position and the retroperitoneum is entered from the right or left side, depending on the site of most inflammation and damage to the pancreas. This approach can be aided by preoperative access to the retroperitoneal space with catheter placement by interventional radiology into the dominant fluid collection.

Second Step

- A 0-degree laparoscope is inserted in the flank between the iliac crest and the 12th rib posteriorly. Alternatively, a videoscope may be inserted directly over the drain site.
- An angled, rigid, therapeutic thoracoscope facilitates debridement under visualization through a single access point.
- After insufflation, the right and left kidneys can be used as landmarks toward the head or tail of the pancreas.
- Mechanical debridement may be limited by access and visualization and may require multiple interventions; however, peritoneal contamination is limited with this approach.

Third Step

- The remainder of the procedure proceeds as previously described with samples being sent for pathology and microbiology. Drains can be placed through the port sites for continuous lavage.

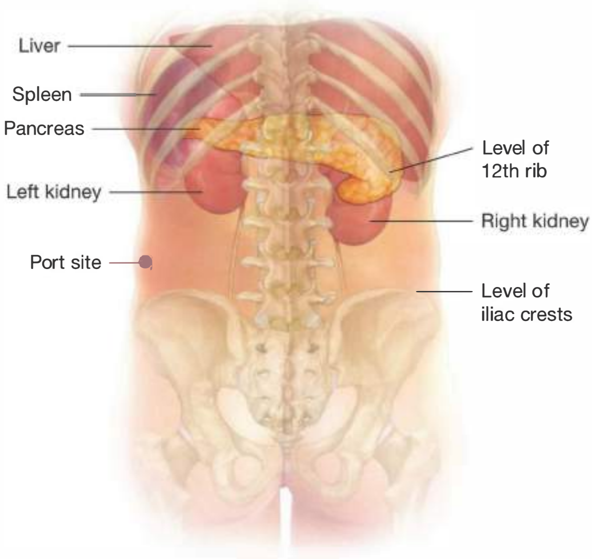

FIG 7 ● Port placement and anatomy of retroperitoneal pancreatic debridement. Patient placement is in the lateral decubitus position and the retroperitoneum can be entered through either the right or left side, depending on the site of greatest damage to the pancreas. A videoscope is placed in the flank between the iliac crest and the 12th rib or over a previously placed percutaneous drain. Other port placement depends on the location of pancreatic debris.

PEARLS AND PITFALLS

Indications	■ Indications for laparoscopic pancreatic debridement include infected pancreatic necrosis and symptomatic sterile necrosis.
Imaging	■ Contrast-enhanced CT imaging is required for determining preoperative planning.
Choice of approach	■ Retroperitoneal approach may limit the ability to adequately debride tissues but is suitable for multiple interventions. ■ Transperitoneal approach may be limited by potential peritoneal contamination and limited reintervention.
Timing	■ The optimal timing of operative intervention is 3–4 weeks following the onset of acute pancreatitis.
Drain placement	■ Preoperative drain placement can aid in initial management as well as guide intraoperative dissection and identification of necrotic material. ■ Place large drains at the time of surgery; consider continuous lavage with isotonic saline.
Indications for reimaging or relook laparoscopy	■ Reimaging and/or reoperation are indicated in cases of clinical deterioration or incomplete debridement.

POSTOPERATIVE CARE

- Immediate postoperative care will depend on the status of the patient perioperatively. However, all patients with necrotizing pancreatitis benefit from close surveillance in an intensive care unit.
- Close attention must be paid to volume status, blood glucose control, maintenance of normothermia, and adequate pain control.[11]
- Because of massive third space fluid losses and fluid shifts postoperatively, some patients will require continued intubation postoperatively in the initial 24 to 36 hours.
- Early aggressive enteral feeding can be started after the first 48 hours of resuscitation postoperatively.

OUTCOMES

- In a meta-analysis of retroperitoneal pancreatic debridement a success rate of 64% was reported with 47% morbidity and 14% mortality.[12] Recent multicenter feasibility studies of the safety and efficacy of video-assisted retroperitoneal debridement (VARD) show a reasonable safety and efficacy profile for retroperitoneal debridement, although the authors were unable to establish that VARD techniques are superior to open necrosectomy.[13]

- There are no controlled trials comparing open necrosectomy to laparoscopic methods.

COMPLICATIONS

- Acute complications include bleeding, sepsis, acute pancreatitis, pancreatic duct leak, need for repeat debridement, exocrine insufficiency, endocrine deficiency, and enteric leak.
- Long-term complications include pancreatic pseudocyst formation, chronic pancreatitis, enterocutaneous fistula, pancreatic fistula, and chronic abdominal/back pain.

Chapter 51

Endoscopic Pancreatic Debridement and Drainage

Udayakumar Navaneethan Andres Gelrud

DEFINITION

- Endoscopic pancreatic debridement is performed in patients with pancreatic necrosis, in particular, walled-off necrosis (WON).
- Pancreatic necrosis is defined by the lack of enhancement of the pancreatic parenchyma on cross-sectional imaging after intravenous contrast administration.
- Pancreatic necrosis is classified as acute necrotic collection and WON depending on the time course (4 weeks) of the diagnosis of pancreatitis and presence or lack of encapsulated wall, by the revised Atlanta classification.[1]
- Acute necrotic collection is defined as a collection containing variable amounts of fluid and necrotic tissue involving the pancreatic parenchyma and/or the peripancreatic tissues occurring within the first 4 weeks of acute pancreatitis (**FIG 1**).[1]
- WON is a mature, encapsulated collection of pancreatic and/or peripancreatic necrosis that has developed a well-defined wall. WON usually occurs more than 4 weeks after onset of necrotizing pancreatitis (**FIG 2**).[1]

DIFFERENTIAL DIAGNOSIS

- It is important to distinguish WON from pseudocyst. Pseudocyst is a fluid collection in the pancreatic or peripancreatic tissue surrounded by a well-defined wall and contains no solid material. Diagnosis can be made usually on these morphologic criteria. Amylase activity is high if the pseudocyst fluid is aspirated. Disruption of the main pancreatic duct or its intrapancreatic branches without necrosis usually leads to pseudocyst formation.[1]
- Cystic neoplasm of the pancreas such as an intraductal papillary mucinous neoplasm or mucinous cystic neoplasm can mimic WON. A previous history of acute pancreatitis helps differentiate both conditions, and in occasion, fine needle aspiration (FNA) needs to be performed to better characterize the collection before endoscopic drainage.

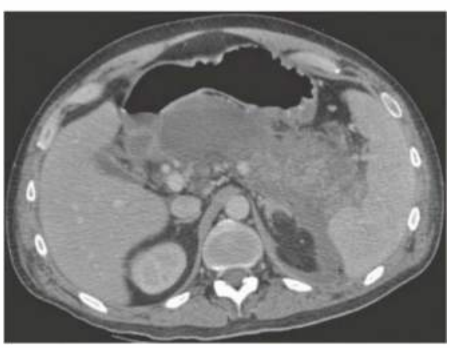

FIG 1 ● Acute necrotizing pancreatitis in a patient admitted 1 week ago now with persistent fevers and leukocytosis. CT reveals lack of contrast enhancement in most of the body and tail of the pancreas without encapsulation.

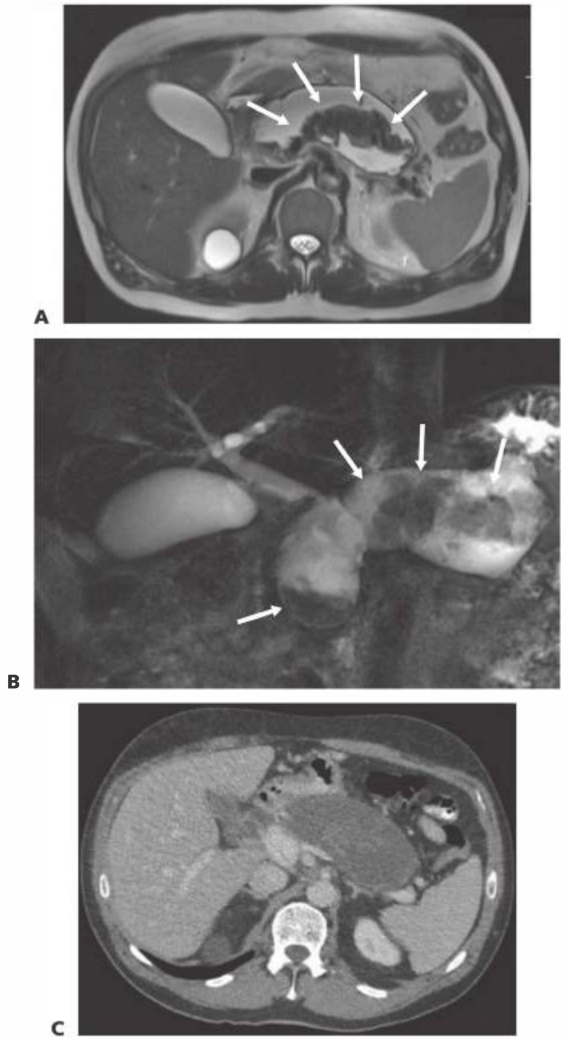

FIG 2 ● **A,B.** MRI revealing WON in a patient presenting with abdominal and back pain 2 months after an episode of necrotizing pancreatitis. In both images, the *arrows* represent necrosis inside the pancreatic and peripancreatic collection. **C.** CT scan image of same patient with WON.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Two-thirds of patients with pancreatic necrosis in the setting of necrotizing pancreatitis have sterile necrosis and can be managed conservatively without any intervention.[2]
- Interventions performed in patients with sterile pancreatic necrosis can increase the risk of introduction of infection into the necrotic tissue, resulting in requirements for additional interventions and its associated morbidity and mortality.[3]

- Sterile pancreatic necrosis requires drainage only in patients with symptoms. External mechanical obstruction of the biliary system (elevated liver enzymes with a dilated bile duct) or gastric outlet with symptoms of nausea, vomiting, early satiety, and inability to resume oral intake. Persistent, narcotic-requiring pain or recurrent acute pancreatitis are indications for drainage.[4]
- However, the main role for endoscopic intervention is the presence, or suspicion, of infected necrosis with concomitant clinical deterioration.
- Debridement should be delayed, if at all possible, until the necrosis is walled off and a well-defined capsule is present, which usually takes around 4 weeks. WON is a prerequisite for successful endoscopic therapy.[4]
- The goal of therapy needs to be well defined and a multimodality approach (clinical pancreatologist, surgery, and interventional radiology) has a higher chance of success and should be considered. Surgical backup during endoscopic drainage is strongly recommended in case of complications at the time of endoscopic debridement.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- The morphologic features of acute pancreatitis and resultant complications are diagnosed by high-resolution multidetector contrast-enhanced computed tomography (CT) and can detect most local complications as reported in the revised Atlanta classification.[1]
- The diagnosis of necrosis is based on imaging features of a heterogeneous collection with liquid and nonliquid density with varying degrees of loculations.
- WON is defined based on the presence of necrosis with a well-formed wall and complete encapsulation.
- CT may not readily distinguish with high sensitivity solid from liquid content to distinguish pseudocyst from necrosis.[1]
- WON may be better diagnosed based on magnetic resonance imaging (MRI) or endoscopic ultrasound (EUS) to detect necrosis within the collection.[1]

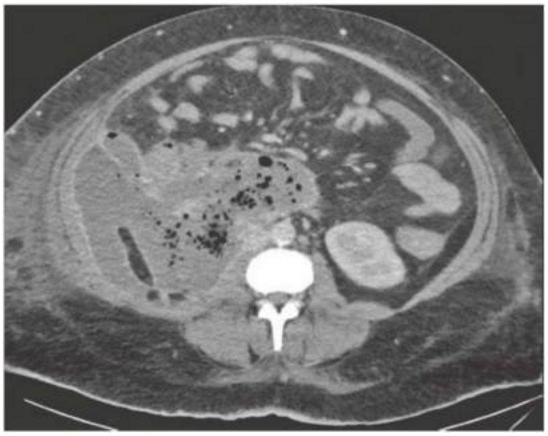

FIG 3 • CT scan image of infected WON with presence of gas within the collection.

- The diagnosis of infection (infected necrosis) of an acute necrotic collection (ANC) or of WON is based on the presence of gas within the collection on CT (**FIG 3**). This extraluminal gas is present in areas of necrosis. The diagnosis must be suspected in a patient with persistent organ failure, fevers, and elevated white blood count after the first week of admission. In situations where the diagnosis of infected necrosis is unclear, FNA for Gram stain and culture may be performed.

SURGICAL MANAGEMENT

Positioning

- The positioning of the patient needs to be selected based on the patient and the nature of the WON. In patients who are unstable, supine position is generally safer.
- In patients with posteriorly located collections, the prone position may allow for better gravitational drainage of WON for better success.

TECHNIQUES

INITIAL ENDOSCOPY

- Initial endoscopy is performed by using a therapeutic, side-viewing video duodenoscope, gastroscope, or echo-endoscope.
- We favor the use of general anesthesia to prevent aspiration.
- Although we use air routinely, carbon dioxide (CO_2) insufflation is always used during these procedures to minimize the theoretical risk of air embolism.
- Antibiotics with good pancreatic penetration should be routinely given prior and after the procedure to patients who are not already on broad-spectrum antibiotics.

ENDOSCOPIC ULTRASOUND

- Endoscopic ultrasound (EUS)-guided access is strongly recommended when gastric varices are present or when no gastric or duodenal compression with bulge formation is present. EUS-guided drainage can avoid local complications related to blind endoscopic drainage.[5]
- Under EUS guidance, the appropriate site of access to drain the WON can be established. This is particularly useful in patients without any bulging visible on endoscopy. The site in the gastric or duodenal lumen needs to be chosen and use of EUS is associated with fewer complications and higher success rates, particularly with those WON in the tail and those patients with varices to permit a safe passage of the needle.[5]
- The most appropriate site of transmural puncture should be through a wall less than 10 mm in thickness. In those

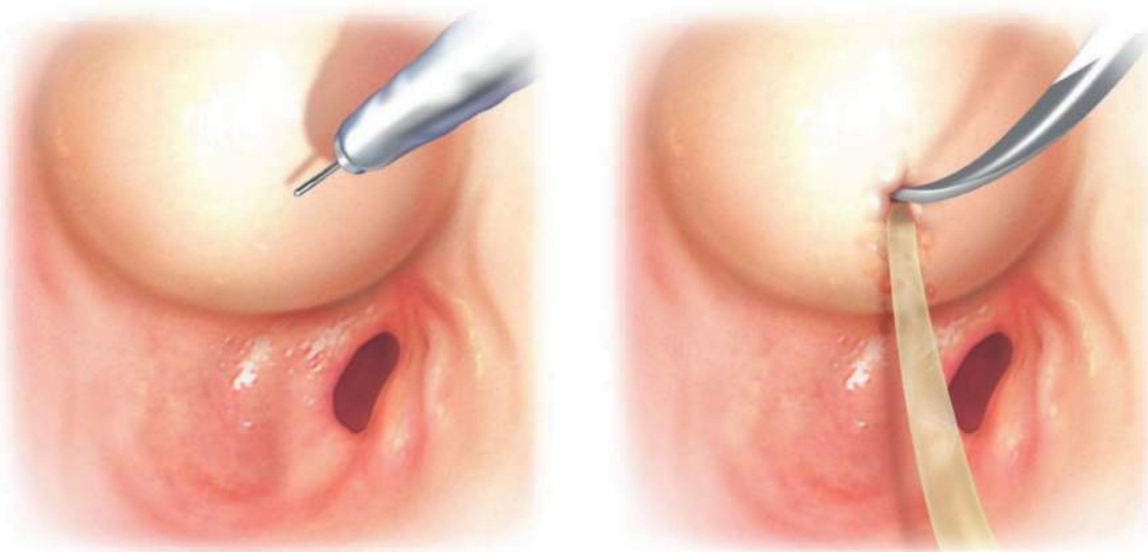
who do not use EUS and in those patients in which no bulging on the gastric or duodenal wall is visible, the most recent cross-sectional imaging may help decide the site of puncture.[6]

- When the appropriate site is identified, the posterior gastric or medial duodenal walls are targeted and punctured.
- In patients undergoing EUS, the use of color-flow Doppler can avoid hitting blood vessels at the time of wall puncture.[5]
- Use a 19-gauge FNA needle for puncture and subsequently the needle sheath for initial dilation of the tract (**FIG 4**).

FIG 4 ● EUS-guided access of pancreatic pseudocyst and necrosis. Loops of guidewire inside the pancreatic fluid collection and inflated balloon dilating the pseudocyst-gastrostomy track for stent placement.

THERAPEUTIC GASTROSCOPE OR DUODENOSCOPE

- A needle knife through a side-viewing duodenoscope can be used to initially enter the necrotic cavity when a bulge is clearly apparent and there are no varices (**FIG 5A–C**).
- Aspiration of the cavity fluid is performed and sent for fluid analysis (amylase, Gram stain, and culture). Contrast injection into the cavity, under fluoroscopic guidance, is also performed to confirm location inside of the cavity.
- Balloon dilation of the tract can be done in diameters ranging from 15 mm or 20 mm in size to allow for forward-viewing gastroscope to enter the cavity for direct endoscopic necrosectomy (**FIG 5C,D**).
- A standard long 460-cm guidewire (0.018 in up to 0.035 in) is advanced into the collection under fluoroscopic guidance, forming at least two loops in order to reduce the risk of inadvertent loss of guidewire access.
- The fistula tract is then created (**FIG 5D,E**).



A **B**

FIG 5 ● Direct endoscopic-guided access of pseudocysts and necrosis. **A.** Bulge present in the posterior wall of the gastric body and needle knife in place. **B.** Puncture site with guidewire in place and fluid drainage. *(continued)*

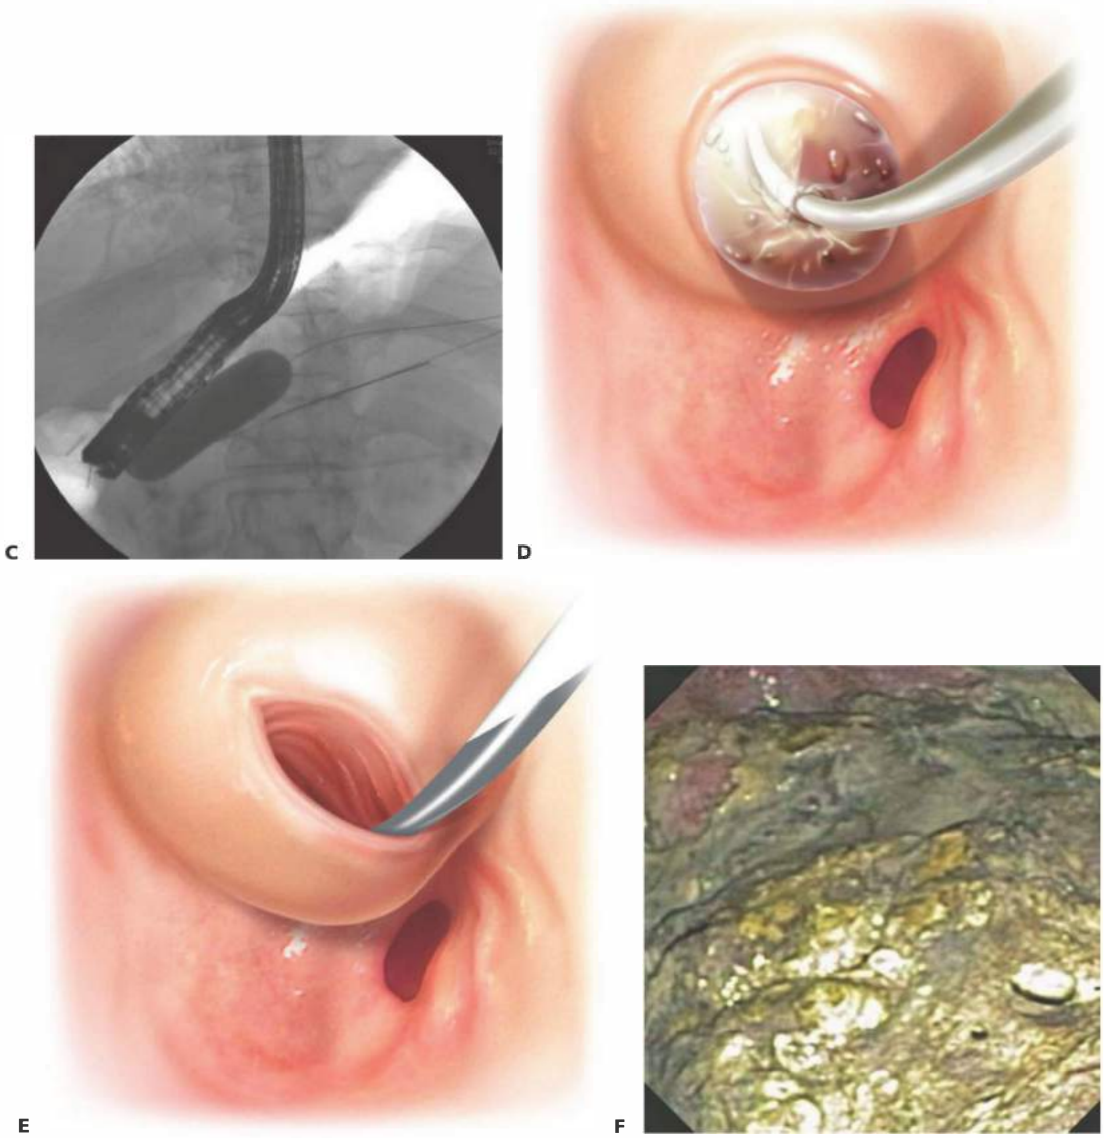


FIG 5 • *(continued)* **C.** Fluoroscopic view of guidewire inside the cavity with inflated balloon. **D.** Endoscopic view of the inflated balloon for fistula tract dilation. **E.** The cyst gastrostomy tract after balloon deflation. **F.** Appearance of the cavity upon entry. Large amount of necrotic debris. *(continued)*

- It is important to emphasize that the tract needs to be dilated enough to facilitate the passage of the endoscope into the cavity.
- Debridement of the intracavitary solid debris is done by using a forward-viewing gastroscope across the gastric or duodenal wall into the necrotic cavity.
- The fluid contents are first aspirated through the endoscope until dry, and devitalized necrotic tissue is then removed (**FIG 5F,G**).
- Several accessories can be used to remove the devitalized pancreatic tissue including snares, grasping forceps, snare with nets, and stone removal baskets.
- The degree of necrosectomy performed at each session is at the discretion of the therapeutic endoscopist; we favor removing as much as possible during the initial intervention to minimize the need for subsequent endoscopic interventions. The goal is to uncover the pink granulation tissue lining the wall.

Stent Placement

- After necrosectomy is performed, stent placement is performed. The stents keep the cyst gastrostomy or cyst duodenostomy site open and help drain the WON during

FIG 5 ● *(continued)* **G.** Large fragments of necrotic debris are removed endoscopically. Most of the necrotic debris are left in the gastric lumen or suctioned with the endoscope. **H.** Multiple soft double-pigtail stents are placed to keep the patency of the cyst gastrostomy site and facilitate further drainage. **I.** Fluoroscopic view of stent placement after cavitary debridement. A nasojejunal feeding tube was also placed to ensure adequate nutrition. **J.** Suctioned fluid during and soon after wall puncture.

liquefaction of the possible retained devitalized tissue inside the cavity.

- Place multiple 10-Fr parallel soft double-pigtail stents (**FIG 5H,I**). Recently, others have used a fully covered metal stent 10 mm in diameter to facilitate subsequent intracavitary intervention.
- Placement of a double-pigtail stent (inside of the metal stent) is frequently performed to prevent metal stent migration and occlusion (**FIG 6**).
- Placement of a single stent is associated with increased risk of occlusion and increases the risk of treatment failure.
- The fistula tract needs to be kept open for any fluid collection and necrotic debris to drain. There is a theoretical benefit of having gastric acid inside the cavity.
- For WON of 20 cm or larger in size, we favor hybrid therapy with placement of percutaneous catheter to be used as a flushing and transmural drainage (**FIG 7A,B**). Other hybrid therapies have been described. More than one endoscopic intervention is frequently required in large WON collections.
- The plastic stents either fall off spontaneously once the WON is resolved or may require removal. Some centers never remove the cyst gastrostomy stents.
- In patients who have a large WON collection or large amount of necrotic content, repeat endoscopic procedure may be required which involves endoscopic removal of stents and repeat necrosectomy.

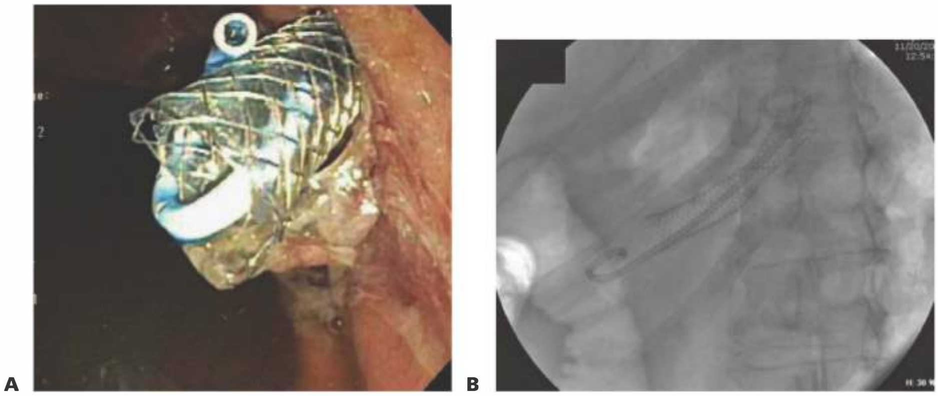

FIG 6 ● **A.** Fully covered metal stent and double-pigtail stent (inside) at cyst gastrostomy site. **B.** Fluoroscopic view of plastic inside metal stent placement at cyst gastrostomy site.

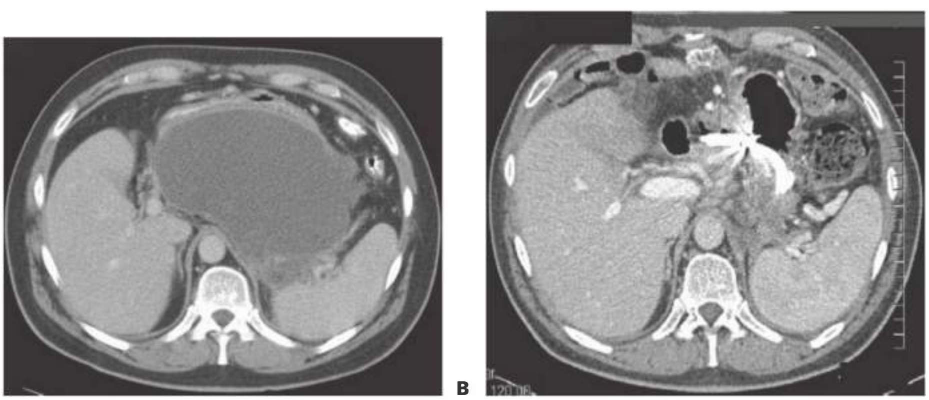
PEARLS AND PITFALLS

Indications	■ A thorough history and physical is required to make a decision whether the WON requires intervention or not. ■ Multidisciplinary team approach ■ Two-thirds of patients with pancreatic necrosis in the setting of necrotizing pancreatitis have sterile necrosis and can be managed conservatively without any intervention. ■ Interventions performed in patients with sterile pancreatic necrosis can increase the risk of introduction of infection into the necrotic tissue. Only patients with symptoms are treated. ■ Cystic neoplasm of the pancreas such as an intraductal papillary mucinous neoplasm and serous or mucinous cystic neoplasm can mimic WON. A previous history of documented pancreatitis must be present. In some patients, EUS with FNA needs to be performed before endoscopic drainage.
Endoscopy preparation	■ Antibiotics should be routinely given prior and after the procedure in patients who are not already on broad-spectrum antibiotics. ■ Antibiotic therapy is continued for 10 to 14 days postprocedure. ■ Use general anesthesia to prevent aspiration. ■ Use CO_2 instead of air for endoscope insufflation.
Site of access	■ The appropriate site of access needs to be established under EUS guidance when varices are present or patients without visible bulge on endoscopy. ■ Endoscopic therapy is only indicated when well-demarcated WON is present and, preferably, the collection should be within 1 cm of the gastrointestinal lumen.
Fistula tract size	■ The fistula tract needs to be dilated to at least 10 mm in size for the forward-viewing gastroscope to enter the cavity; for direct necrosectomy, we favor dilating 15 mm or up to 20 mm.
Stent placement	■ After necrosectomy is performed, multiple (4–6) soft double-pigtail stents are placed. ■ Placement of a single 10 mm in diameter cover metal stent with an inner plastic double-pigtail stent is being used in some centers; no clinical studies available.
Failure of endoscopic procedure	■ If the WON fails to resolve or reaccumulates, disconnected pancreatic duct syndrome should be considered, which will require additional procedures. ■ Large or complex collections may benefit from hybrid, endoscopic, and percutaneous drainage.

POSTPROCEDURE CARE

- The symptoms that lead to the procedure rapidly resolve after successful therapy. If related to extrinsic compression, the patient wakes up with immediate relief; when related to infection symptom, resolution depends on the severity.
- Most patients are able to start a clear liquid diet and rapidly advance to low fat soon after successful debridement.
- Cross-sectional imaging is performed (either MRI or CT scan) 1 month after initial necrosectomy to document resolution (**FIG 8**).
- Additionally, if the collection fails to resolve or reaccumulates, disconnected pancreatic duct syndrome should be considered.
- The treatment of disconnected pancreatic duct syndrome includes endoscopic retrograde cholangiopancreatography (ERCP) with transpapillary stenting across or into the cavity



A B

FIG 8 ● Ambulatory patient that presented 6 weeks after an episode of necrotizing pancreatitis with symptoms of gastric outlet obstruction. **A.** CT scan with well-demarcated WON compressing the gastric lumen. **B.** Five weeks after successful transgastric endoscopic necrosectomy.

and, in occasions, combined with percutaneous drainage. Resection of the distal remnant must also be entertained.

OUTCOMES

- Endoscopic drainage has been shown to be very successful. A large study in the United States, including more than 100 patients from six academic medical centers, reported that the median number of endoscopic procedures required to treat the WON (of median size of 15 cm) was three and the largest size of cyst enterotomy tract dilation performed was 18 mm. WON resolved in 90% of the patients over a period of 4 months.[7]
- Similarly, in a European study of more than 90 patients who underwent necrosectomy, 54% of the WON was infected. Sixty percent of patients had undergone previous percutaneous or transgastric drainage procedures with failure of necrotic pancreatic fluid collection resolution. Patients require a median number of six endoscopic procedures and the tract was dilated to between 15 and 20 mm.[8] Symptom resolution occurred in 80%, whereas greater than 50% of patients demonstrated radiographic resolution.[8]
- In addition to these studies, smaller cohort studies have reported similar rates of resolution of WON from 75% to 95%.[9,10]
- Thus, the overall efficacy of endoscopic necrosectomy is more than 75% in experienced centers.

COMPLICATIONS

- Endoscopic treatment of WON is associated with potential complications. Multidisciplinary approach to determine endoscopic debridement candidacy and surgical backup during the endoscopic procedure are strongly recommended.
- The overall complication rate of transmural drainage or debridement in WON is reported between 15% and 25%.[7,8]
- Pneumoperitoneum perforation is reported in about 5% of patients; only symptomatic patients require further intervention.[7,8]
- It is the author's opinion that death and bleeding leading to blood transfusion, arterial embolization, or surgery may be underreported.
- Only symptomatic patients with mature collections are eligible for endoscopic drainage. WON collection should be within 1 cm of the gastrointestinal lumen.
- Stepwise, balloon dilation of the fistula tract; avoiding overinsufflation of the cavity with CO_2; and performing gentle debridement using baskets, soft snares, and retrieval baskets or nets may decrease the risk of bleeding and perforation.
- Bleeding can occur in up to 18% of patients undergoing debridement of WON.
- Most patients with bleeding can be managed endoscopically, although some may require interventional radiology or surgical intervention.
- Air embolism resulting in death has been reported.
- Other complications include infection particularly if the WON is not appropriately debrided (**FIG 9**), pancreatitis, aspiration, stent migration/occlusion, and complications of sedation.
- Adequate advanced therapeutic training with availability of appropriate surgical backup is necessary to avoid and manage complications.

Chapter 52 Splenectomy (Open and Laparoscopic Techniques)

Vanessa Cranford Janeen R. Jordan Frederick A. Moore

DEFINITION

- Splenectomy is defined as the surgical removal of the spleen.

DIFFERENTIAL DIAGNOSIS/INDICATIONS

- Traumatic rupture
- Autoimmune disorders
- Red blood cell disorders
- Genetic disorders
- Lymphomas/leukemias/myeloproliferative disorders
- Vascular disorders
- Idiopathic/iatrogenic
- Miscellaneous (abscesses, tumors, cysts)

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history should be performed prior to surgery, including a detailed past medical history, all signs and symptoms of disordered bleeding and liver failure, as well as a history of abdominal pain or constitutional symptoms. A list of medications, allergies, and personal and family histories of bleeding, clotting disorders, and cancers should be noted.
- A complete physical exam of the patient should be done and *all* patients should be examined for signs of portal hypertension or liver failure as well as the presence or absence of splenomegaly.
- Patients presenting with splenic trauma have variable clinical presentations determined by the severity of injury, ranging from mild abdominal pain with hemodynamic stability to peritonitis and hemorrhagic shock with complete cardiovascular collapse. This hemodynamic instability can be immediate upon presentation or days later in the case of a delayed rupture.
- Hematologic conditions such as leukemia present with a patient history of purpura, epistaxis, petechiae, gingival bleeding, hematuria, gastrointestinal bleeding, myalgia, or fatigue. Although now a rare indication for splenectomy, patients with lymphomas and myeloproliferative disorders present with diffuse lymphadenopathy, constitutional symptoms, pancytopenia, abdominal pain, splenomegaly, or early satiety.
- Patients with hemoglobinopathies and hereditary disorders present with jaundice, abdominal pain, or splenomegaly. Alternatively, they may be asymptomatic and incidentally identified due to an abnormal laboratory value obtained for a different indication.
- Patients with hereditary spherocytosis (HS) benefit from splenectomy. Sequestration of the defective red blood cells (RBCs) results in splenomegaly in 75% of affected patients.[1] Splenectomy eliminates or improves anemia in patients with moderate HS and eliminates the need for regular transfusions in patients with the severe form of the disease.[2,3] These patients often receive splenectomies in childhood to alleviate symptoms and long-term sequela of the disease including skeletal abnormalities and repeated need for blood transfusion. In mild HS, the purpose of splenectomy is to prevent the production of bilirubin gallstones (a common complication that has an increased prevalence with age). In these cases, splenectomy is combined with a cholecystectomy.
- Splenectomy for hematologic disorders such as idiopathic thrombocytopenia (ITP) is a result of failed medical management to control thrombocytopenia or abdominal pain associated with splenomegaly. Most of these patients will be referred to a treating hematologist. Medical management is the first-line treatment for ITP and most patients initially respond to glucocorticoids. However, in one series, only 39% of prednisone-treated patients achieve complete remission, and only one-half of these patients have sustained remission beyond 6 months of cessation of maintenance therapy.[4] Intravenous immunoglobulin (IVIG) can also be used as first-line treatment and can increase the platelet count in over 75% of patients within 5 days of treatment.[5] However, it is not a long-term cure. It is reserved for those patients with life-threatening bleeding and intracranial hemorrhage and those preparing for splenectomy or other surgical procedures. Otherwise, splenectomy is reserved for patients with symptomatic thrombocytopenia following glucocorticoid administration for at least 8 weeks and having a platelet count persistently less than 30,000/μL. Splenectomy is also indicated in patients who recur after cessation of therapy.
- Splenectomies may be performed via open or laparoscopic technique. The approach is determined by the disease process and clinical stability of the patient. Absolute and relative contraindications for laparoscopic splenectomy are listed in Table 1.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- All patients with a known or suspected hematologic, autoimmune, or myeloproliferative disorder should have a blood smear or bone marrow analysis as needed and a hematologist fully involved in the patient's evaluation and treatment plan.
- Computed tomography (CT) scan is the ideal imaging modality for splenic disorders and is a crucial part of planning

Table 1: Absolute and Relative Contraindication of Laparoscopic Splenectomy

Absolute	Relative
Severe cardiopulmonary disease	Splenomegaly
Cirrhosis with portal hypertension	Short gastric varices with coagulopathy
Pregnancy	Previous abdominal surgery

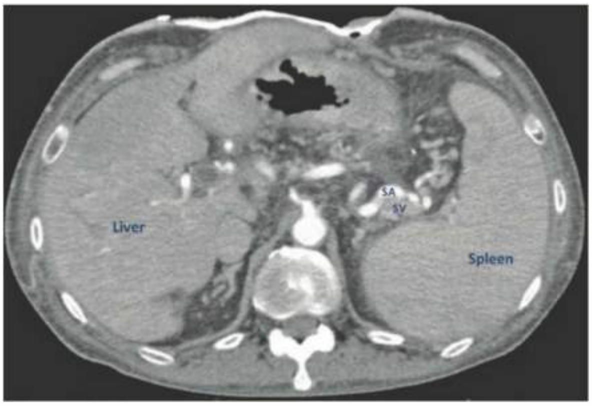

FIG 1 ● CT image demonstrating splenomegaly. The volume of the spleen approaches that of the liver. *SA,* splenic artery; *SV*, splenic vein.

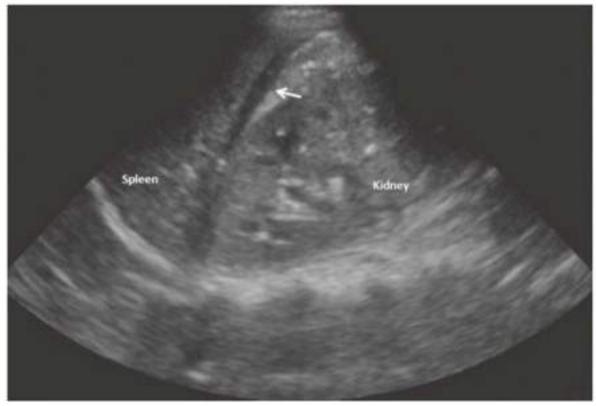

FIG 3 ● Positive FAST showing intraperitoneal fluid. *White arrow* indicates intraabdominal fluid. This would be the appearance of blood in a traumatic injury.

for the operating room (OR). CT has the capability for determining the size of the spleen, the anatomy and size of the splenic vascular supply, the relationship of the spleen to surrounding organs, and potential locations of accessory spleens in the abdomen (**FIG 1**). For stable trauma patients, it can accurately identify the extent of splenic injury (**FIG 2**).

- Ultrasound is a noninvasive modality for the examination of splenomegaly and portal hypertension. In the setting of a trauma, focused abdominal sonography for trauma (FAST) has become an accepted screening tool to diagnose intraperitoneal blood (**FIG 3**).
- Magnetic resonance imaging (MRI) of the spleen is an excellent method for evaluating focal lesions as well as aid in the detection and differential diagnosis of peri- and intrasplenic tumors.[6]

SURGICAL MANAGEMENT

Preoperative Planning

- Certain patients with autoimmune disorders will be treated with prolonged courses of glucocorticoids. It is important to consider administering appropriate stress-dose steroids intraoperatively, with rapid tapering postoperatively.

FIG 2 ● CT of splenic injury. *White arrow* points to one of the lacerations.

- Blood products should be ordered and available intraoperatively. If the need for transfusion arises, it should be given *after* ligation of the splenic artery, provided the splenectomy is performed for hematologic disorders.
- For all elective cases, vaccinations against the encapsulated organisms (*Hemophilus influenza B*, *Streptococcus pneumoniae*, and *Neisseria meningitidis*) should be administered prior to surgery. For emergent cases, vaccinations should also be administered. Timing of vaccination is debated, but 2 to 4 weeks postoperatively is recommended, although for trauma patients, just prior to discharge is acceptable due to a high incidence of patients not returning for postinjury clinic appointments. This is to prevent the incidence of overwhelming postsplenectomy infection (OPSI). It is the most feared complication of splenectomy. OPSI is the development of a fulminant, rapidly fatal bacterial infection following the removal of the spleen. The current incidence of OPSI in the first 2 years postsplenectomy is estimated to be 0.9% for adults and 5% for children.[7] Current guidelines for vaccination to prevent OPSI are listed in Table 2.
- All patients should be given a prophylactic dose of antibiotics to cover skin flora within 60 minutes of making the skin incision in the OR. Nasal or oral gastric tubes should be inserted once the patient is under anesthesia to decompress the stomach and aid in visualization. This will often be left in postoperatively for 24 to 48 hours to prevent gastric distention and subsequent disruption of the ligated short gastric vessels.

Table 2: Guidelines for Overwhelming Postsplenectomy Infection Prophylaxis

Haemophilus influenzae B, pneumococcus, and meningococcus 2 weeks preoperatively (elective cases) or at discharge or 2 weeks postoperatively (nonelective cases)
If patient received immunosuppression therapy, vaccinate 3 months after treatment.
Booster vaccinations for pneumococcus +/− meningococcus every 5 years
H. influenza AB titers can be followed to assess the need for booster dose.
Consider monitoring antibody titers of all three pathogens in immunocompromised patients.

- Laparoscopic splenectomy is the operation of choice for most elective splenectomies. However, other options include hand-assisted or open approaches. Indications for conversion from laparoscopy to an open procedure include intolerability or inability to insufflate the peritoneum, uncontrollable coagulopathy or hemorrhage, massive splenomegaly that is unable to be placed in the extraction bag, or need for another procedure.
- In cases of massive splenomegaly or portal hypertension, preoperative embolization of the splenic artery by interventional radiology will decrease the amount of blood loss and may aid in the technical aspects of the procedure. Embolization of the splenic artery causes decreased perfusion and thereby results in involution of the spleen, making mobilization of the spleen technically easier.

POSITIONING

- Patients undergoing laparoscopic splenectomy can be positioned supine or in the right lateral decubitus position. In the latter position, the beanbag or kidney rest is placed to maximize exposure between the costal margin and iliac crest. The table may also be flexed to assist in widening this space. Ensure that all pressure points are properly padded and the shoulders, extremities, and spine are in comfortable, neutral positions (**FIG 4**).
- For open splenectomies, most patients are placed in a supine position, with both arms extended, and a midline laparotomy incision is made. Indeed, in the case of an exploratory laparotomy in the setting of a trauma, this is the recommended approach as the surgeon will need to evaluate the entire abdomen for other injuries. An additional option in isolated nontraumatic open cases is to make a left subcostal incision.

FIG 4 • Patient positioning in the right lateral decubitus position.

TECHNIQUES

OPEN SPLENECTOMY

Incision

- Prior to incision, ensure adequate monitoring and intravenous access is obtained in preparation for potential bleeding. An arterial line is not mandatory but is recommended. A nasogastric (NG) tube should be placed for optimal gastric decompression, which will be imperative for visualization of the spleen.
- After endotracheal intubation and standard prepping and draping of the patient, a midline laparotomy incision is used to enter the peritoneal cavity (**FIG 5**). If this is an isolated splenectomy with no concern for other injuries, a supraumbilical incision can be made initially with extension inferiorly as needed for exposure. If the operation is done in the setting of an exploratory laparotomy with concern for other intraabdominal injuries, a generous incision from xiphoid to pubis should be made. Quickly evacuate all fluid and particulate matter (if present) and place a retractor to aid in visualization. This step is imperative. Without good exposure from retraction and adequate visualization, the propensity for bleeding will increase, making the operation much more technically difficult.

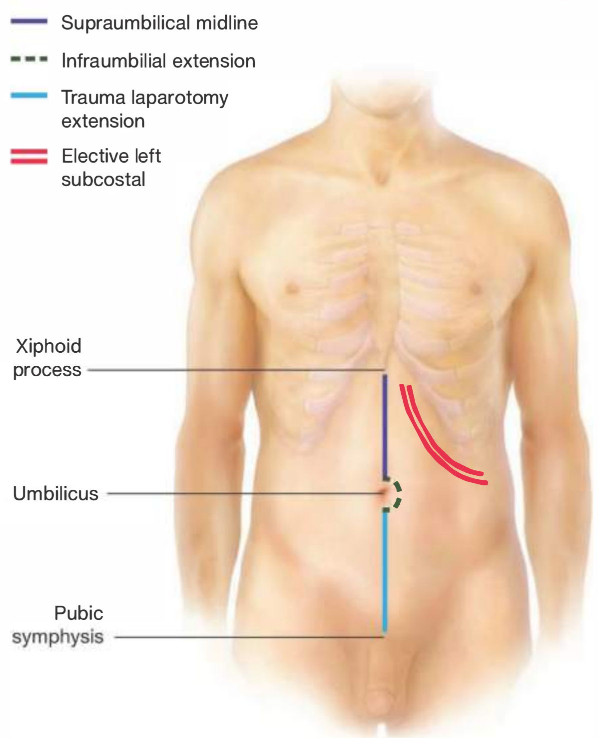

FIG 5 • Various incisions for an open splenectomy.

Mobilization

- The spleen resides high and posterior in the upper left abdomen. In order to remove the spleen, all peritoneal and visceral attachments must be removed. These include the splenorenal attachments to the kidney; the splenophrenic attachments to the diaphragm; the splenocolic

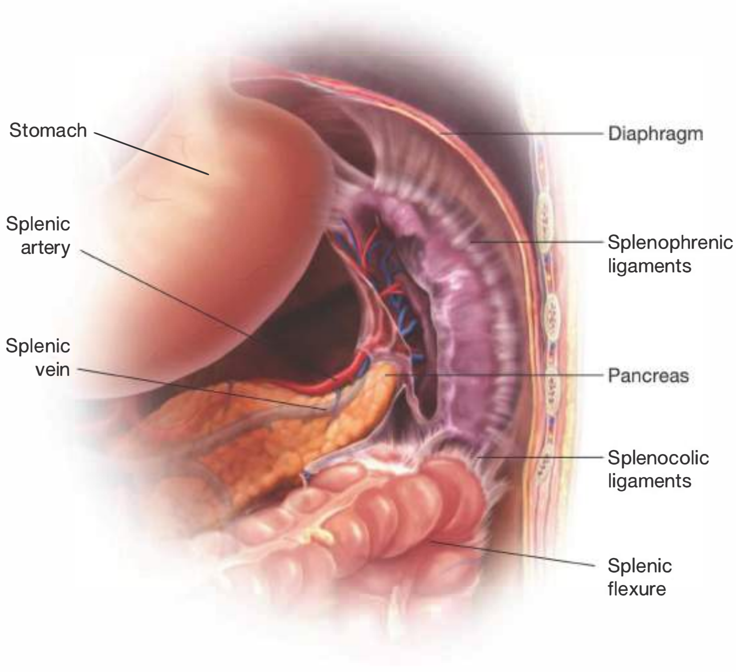

FIG 6 ● Attachments of the spleen in the left upper quadrant.

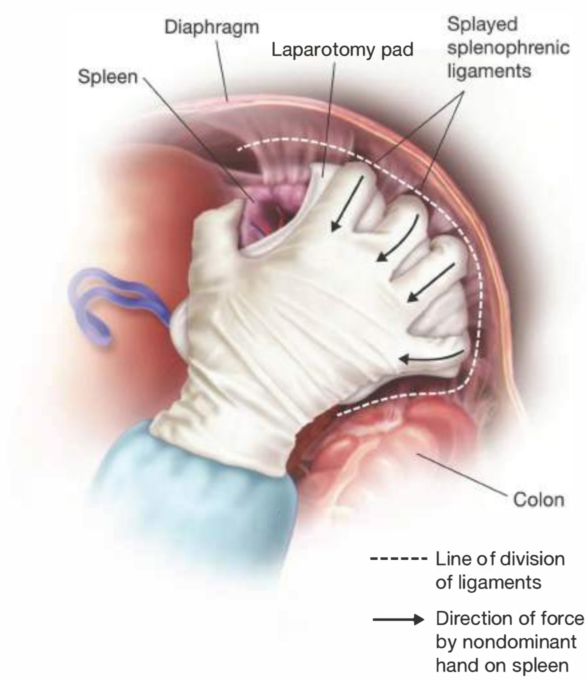

FIG 7 ● Direction of force applied to the spleen and line of division of the splenic attachments.

attachments to the splenic flexure of the colon; and the gastrosplenic ligament, which contains the short gastric vessels (**FIG 6**).

- Splenic mobilization is accomplished using traction and countertraction. The operating surgeon places a splayed, nondominant hand (usually with the aid of a lap sponge for better grip) and applies dorsal and medial traction on the spleen. This will help clearly define the splenorenal and splenophrenic ligaments. Be sure to first mobilize all attachments of the spleen to the anterior abdominal wall or you will find this maneuver cannot be done.
- Downward dorsal and medial traction is important as a tendency for a lifting out of the left upper quadrant often occurs. This can result in capsular tearing, with unnecessary bleeding or hemorrhage.
- Division of the ligaments is initiated with the splenocolic ligament. Mobilization of the splenic flexure displaces the colon away from the spleen (**FIG 7**). This is best done sharply or by using electrocautery. Once this is done, continue laterally toward the splenorenal ligaments, which when divided, separate the spleen from Gerota's fascia of the kidney. Finally, continue superiorly to the splenophrenic ligaments. Again, the importance of traction and countertraction cannot be overemphasized. The first assistant provides countertraction with tissue forceps to divide the ligaments, whereas the surgeon continues to maintain midline traction on the spleen.

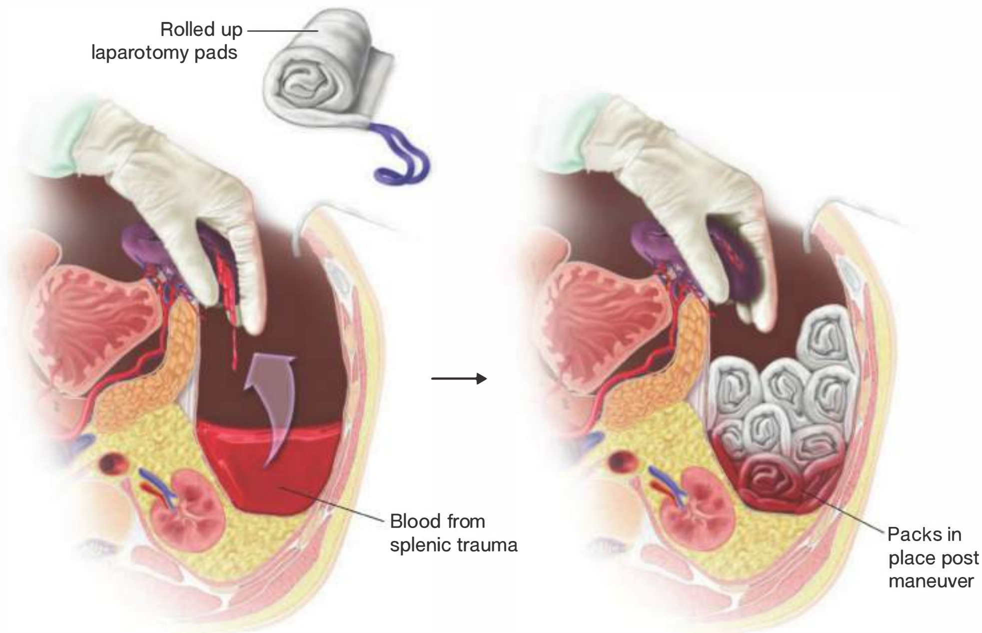

FIG 8 ● Quick blunt mobilization and posterior packing with laparotomy pads in a traumatic injury.

- Even in the setting of trauma and hemorrhage, mobilization of the spleen medially is the key to gaining vascular control. The steps are the same, simply done in a quicker fashion. In many traumatic splenic injuries, the dissection may be done for you by the trauma and resultant hematoma, and much of the remaining dissection can be done bluntly. If facing an exsanguinating spleen in a sea of blood, it may be difficult to see the attachments; however, you will be able to palpate them. Digital traction and blunt mobilization is employed, then laparotomy pads are sequentially placed posteriorly (**FIG 8**). This bluntly dissects the attachments of the spleen for you and aids medial and anterior mobilization. Generally, 5 to 10 laparotomy pads are used for this maneuver.
- Division of the ligaments should be made 1 to 2 cm from the spleen to avoid injury to both the spleen and other organs. As the spleen is mobilized anteriorly, deeper layers of connective tissue are brought into view and can be easily divided either bluntly or sharply.
- Once free from the retroperitoneal attachments, digital control of the hilar vessels can be accomplished and will stop any ongoing hemorrhage and improve visualization.
- As dissection continues lateral to medial, the left adrenal gland will come into view and should remain untouched. The tail of the pancreas and the splenic vein will also come into view. This visualization is crucial and paramount to preservation of the pancreas without disruption (**FIG 9**).

FIG 9 ● Appropriate plane of dissection to mobilize the spleen and pancreas medially.

Ligation of Vessels and Excision

- With the spleen fully mobilized midline, one can turn attention to the vascular supply. Gentle traction can be placed on the gastrosplenic ligament which will allow exposure of the short gastric vessels (**FIG 10**). Traction will also allow visualization of the stomach wall, of which injury should be avoided. The short gastric vessels are then divided using either bipolar electrocautery, ultrasonic shears, or sutures as desired (**FIG 11**).
- The splenic artery is seen on the superior border of the pancreas and is visualized entering the hilum of the spleen. The artery and vein are individually isolated or ligated en bloc, using suture ligature (such as 0-silk), LigaSure (Valleylab, Boulder, Colorado, CA), or vascular load stapler. The spleen is now free and can be passed off for pathologic examination.
- The tail of the pancreas will often extend into the splenic hilum. In 75% of patients, it lies within 1 cm of the hilum, and of these, 30% actually touch it.[8] Care must be taken to ensure a pancreatic injury is avoided when dividing and ligating the splenic vessels (**FIG 12**).
- Once the spleen is removed and hemostasis is obtained, if electrocautery was used for division, the short gastric vessels are oversewn along the greater curvature of the stomach. Careful attention should be made to the apical vessels; this is the most frequent site of missed, surgical bleeding requiring reoperation.
- If the splenectomy was undertaken for hematologic disorders, close inspection for accessory spleens *must* be undertaken or the operation has a high chance for failure to cure. Accessory spleens are identified in up to 30% of patients. Common locations for accessory spleens are the splenic hilum, the splenorenal ligament, the greater omentum, the retroperitoneal area surrounding the tail of the pancreas, the splenocolic ligament, and the small bowel mesentery. These areas must be examined after splenectomy, and if splenic tissue is found, it must be excised as well.

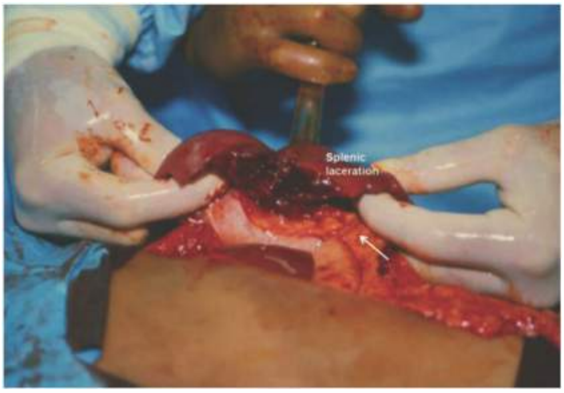

FIG 10 ● Mobilization of the spleen medially and exposure of the gastrosplenic ligament, containing the short gastric vessels *(arrow)*.

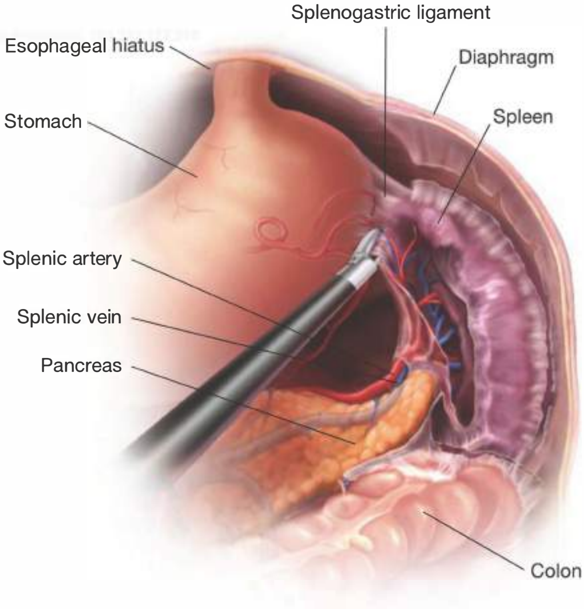

FIG 11 ● Division of the short gastric vessels.

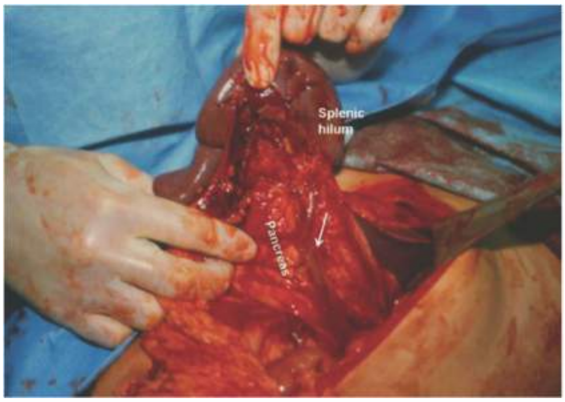

FIG 12 ● The tail of the pancreas abuts the splenic hilum. *White arrow* indicates the splenic vein.

Closure

- Once the spleen is removed, attention must be made to ensuring hemostasis is achieved. All laparotomy pads are removed and careful examination of the splenic bed must be undertaken. Oozing from the splenic bed can usually be controlled with selected cauterization, argon beam, or hemostatic agents.
- Once hemostasis is achieved and assessment for accessory spleens is completed, irrigation of the abdominal cavity may be necessary and the abdomen is closed in the usual fashion. There is no reason to place a closed suction drain

in the splenic bed, unless injury of the tail of the pancreas is known or suspected.

- If the splenectomy occurred in the setting of a damage control laparotomy and multiple injuries are treated, the abdomen is often left open. This allows for a second-look laparotomy and treatment of impending abdominal compartment syndrome. In this situation, it is appropriate to obtain hemostasis as able, then leave laparotomy pads in the left upper quadrant and reevaluate after correction of coagulopathy and sufficient resuscitation.

LAPAROSCOPIC SPLENECTOMY

Incision

- The position of the operating surgeon and placement of the port sites can be seen in **FIG 13**. Once pneumoperitoneum is established, the operation is begun with a thorough exploration of the abdominal cavity, looking for accessory spleens, in locations stated earlier. If found, all accessory spleens need to be excised.

Mobilization

- There are two main approaches for mobilization of the spleen, the supine (anterior) approach and the lateral decubitus approach. As the lateral approach is the one most commonly used when performing laparoscopic splenectomies, it will be the operation described in the following text.
- Following placements of proper monitors, vascular access, antibiotic administration, and endotracheal intubation, the patient is placed in the right lateral decubitus position, with beanbag support and proper padding and positioning of the head, shoulders, neck, and extremities.
- Dissection begins similar to an open procedure, with mobilization of the splenic flexure of the colon from the spleen. This is done using sharp dissection under direct visualization and can be done using hook electrocautery or an ultrasonic dissector. It is important to note that this division of the splenocolic ligament should be done without disturbing the spleen itself, decreasing the risk of a capsular tear (**FIG 14**). As with an open procedure, the technique of traction and countertraction is also employed with the laparoscopic technique.
- Dissection is approached in an inferior to superior counterclockwise direction. The superior splenophrenic attachments are left intact, however, to help facilitate exposure for dissection of the splenic hilum.
- Small accessory vessels can be seen with attachments to the greater omentum. These vessels can be individually divided using electrocautery.
- With the complete release of the splenocolic ligament and posterior dissection up to the splenophrenic ligament, dissection of the hilum itself can now begin.

Ligation of Vessels and Excision

- Similar to the open procedure, the lesser sac is entered and progression moves in a cephalad direction, exposing the anterior surface of the hilum. The posterior aspect of the hilum should already be cleared. This allows the surgeon to have quick access for any unexpected bleeding should it arise before isolating the vessels themselves.

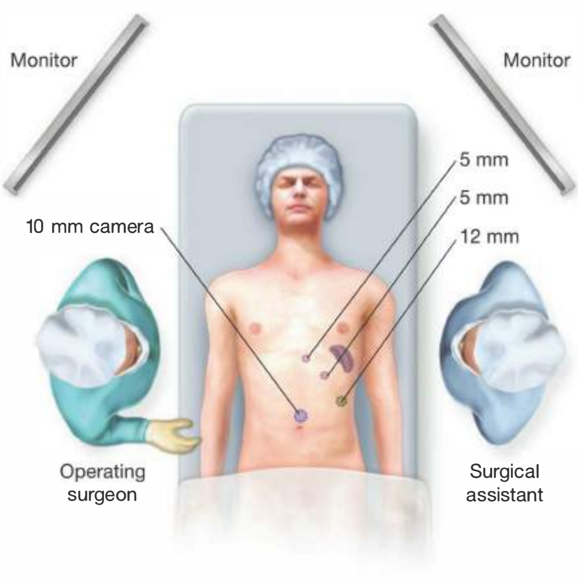

FIG 13 ● Arrangement and port site placement for a laparoscopic splenectomy. Note that patient is drawn supine to clearly show port site placement.

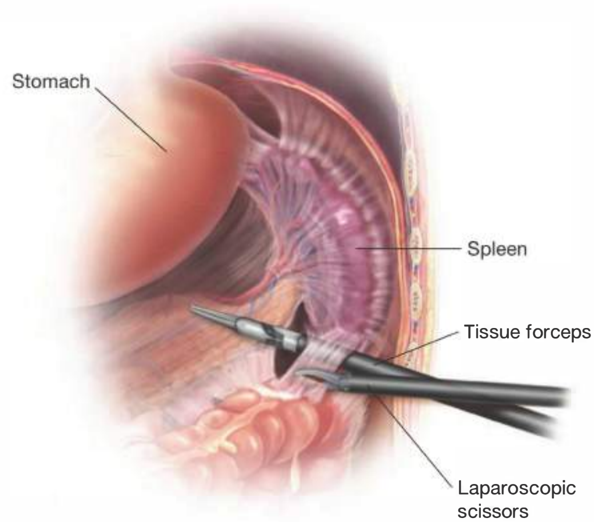

FIG 14 ● Laparoscopic division of the splenocolic ligament.

- The short gastric vessels and main vascular pedicle are visualized. The short gastric vessels are divided using an ultrasonic or bipolar electrocautery dissector along the greater curvature of the stomach. With this released, the hilum of the spleen is easily accessible.
- Once the splenic artery and vein are dissected free using a combination of blunt dissection and hook electrocautery, the vessels are ligated in a similar fashion to the open approach, using suture ligature or (more commonly) an endoscopic vascular stapler (**FIG 15**). Ligating and dividing the artery and vein individually to prevent a future arteriovenous fistula was once standard practice; however, resection of the vessels en masse with an endoscopic vascular stapler is acceptable.
- As with the open procedure, close attention must be given to the tail of the pancreas when dividing the hilar vessels to avoid injury.
- With the spleen completely devascularized, it is now suspended by the small cuff of splenophrenic attachments. These attachments can be transected at this time, or, if necessary, used to assist placing the spleen in the extraction bag. Introduction of an extraction bag is done using one of the port sites (usually the left lateral port). Once the bag is deployed in the peritoneal cavity, the spleen is placed inside. The remaining attachments are then divided (if not done previously), the drawstring of the bag closed, and the open end of the bag brought out through a large trocar site (usually the hand port or the umbilical or epigastric sites). The extraction site occasionally will need to be lengthened to facilitate removal of the spleen.
- The spleen often requires finger fraction or morcellation with ring forceps and removed piecemeal (**FIG 16**). As the spleen is rarely excised in the setting of malignancy, this is an accepted practice. Although a rare occurrence, there have been case reports of splenic implants in the surgical wound and contamination should be avoided.
- The abdomen is then examined for hemostasis, pneumoperitoneum is stopped, and the port sites are closed by usual means. We recommend fascial closure for all incisions measuring greater than 1 cm to avoid future hernias.
- Drainage of the splenic bed is performed selectively, as stated earlier.

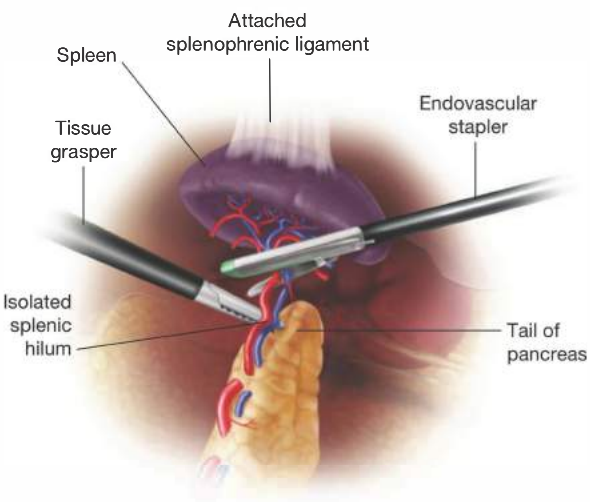

FIG 15 ● Laparoscopic ligation of the splenic artery and vein.

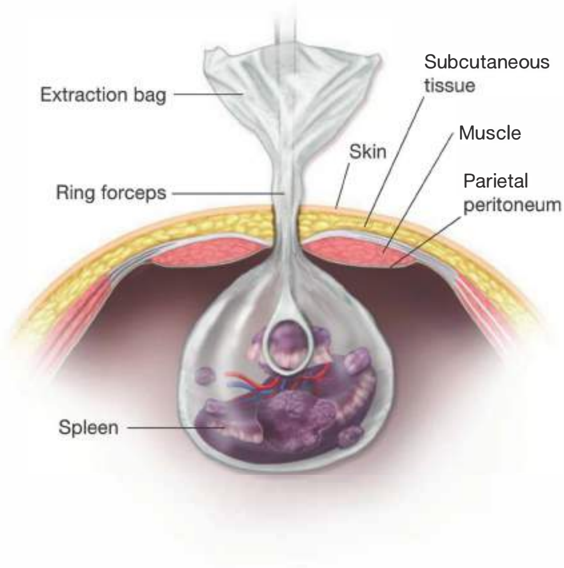

FIG 16 ● Extraction and morcellation of the spleen.

PEARLS AND PITFALLS

Imaging and other diagnostic modalities	■ Involvement of a hematologist is essential for proper diagnosis and preoperative medical management. ■ For elective splenectomies, CT of the abdomen is pivotal in the preoperative planning.
Preoperative planning	■ All elective splenectomy patients need vaccinations 2 weeks preoperatively. ■ Consider prophylactic embolization for splenomegaly or portal hypertension. ■ Have blood products with a current type and screen, type and crossmatch readily available intraoperatively.
Technique—open splenectomy	■ Quick mobilization to the midline is a key maneuver in a hemorrhaging spleen. ■ Keep dorsal and medial traction when mobilizing to avoid capsular tears. ■ Work lateral to medial. ■ Leave a 1- to 2-cm cuff of peritoneum to prevent damage to surrounding organs or further injury to the spleen. ■ Ligate the splenic artery and vein, with close attention not to injure the pancreatic tail.
Technique—laparoscopic splenectomy	■ Positioning the patient with maximal exposure between the iliac crest and costal margin is key. ■ Examine the entire abdomen for accessory spleens. ■ Let gravity help you in the dissection.
Technique—closure	■ No need for a drain unless there is a known or suspected pancreatic injury, infection, or bleeding.

POSTOPERATIVE CARE

- Most patients who undergo laparoscopic splenectomy have a swift recovery and short hospital stay. In one review, hospital stay ranged from 1.5 to 6.4 days.[9] Most patients are able to return to work in a week.
- Patients who undergo open splenectomy have a longer hospital stay, longer return to a full diet, and increased need for narcotics.[10,11] This is not a surprising finding, however, given that most patients undergoing open splenectomies either have a contraindication for laparoscopic procedures or have surgery under emergent conditions (i.e., in the setting of a trauma).

OUTCOMES

- The hematologic and long-term cure rates are the most important factors when patients undergo elective laparoscopic splenectomies. For some disorders (i.e., the hemoglobinopathies), cure is not possible, and the goal of splenectomy is to alleviate the symptoms of the disease. For other diseases, splenectomy offers the relief of pain and early satiety that can accompany splenomegaly.
- Patients undergoing splenectomy for ITP generally have excellent outcomes. It has the highest rate of complete and durable remission; in fact, two-thirds of patients treated with splenectomy for ITP achieve a complete remission (defined as a normal platelet count with no further glucocorticoid requirements). An additional 20% will have a partial response, with a platelet count greater than 50,000 μL, with or without continuation of steroids. Younger patients have a more favorable response.[12] Also, favorable response to splenectomy is also found in patients with a postoperative platelet count greater than 150,000 by postoperative day 3.
- Patients undergoing splenectomy for HS have reasonable outcomes. Coupling the splenectomy with a cholecystectomy obviates the need for a cholecystectomy later in life if pigmented stones are present. For severe HS, splenectomy eliminates the need for regular blood transfusions; however, an anemia will still persist. Growth failure or skeletal changes from the high degree of erythropoiesis needed to compensate for the hemolytic anemia is reversed for children after the spleen is removed.[13]

COMPLICATIONS

- Bleeding 4% to 16% (most common)
- Thromboembolic events/thrombosis 2% to 4%
- Pancreatic injury
- Seroma
- Hematoma
- Incisional hernia
- Wound dehiscence
- OPSI

Chapter **53** Splenorrhaphy

Shawn D. Larson Saleem Islam

DEFINITION

- Splenorrhaphy literally translates to "suturing of the spleen." Broadly applied, splenorrhaphy encompasses numerous operative strategies aimed at preserving splenic tissue and maintaining normal physiologic function in the setting of injury. Other terms for splenorrhaphy include splenic salvage, splenic preservation, and partial splenectomy. Partial splenectomy may be preferred to control disease or repair injury in selected cases. Understanding various operative techniques for splenorrhaphy is a required component of the armamentarium of all general surgeons.

DIFFERENTIAL DIAGNOSIS

- Splenic trauma: grades I to IV (Table 1).[1]
  - Grade V splenic injuries are *not* amenable to splenorrhaphy (see Part 3, Chapter 52).
- Iatrogenic injuries—commonly during retraction of the transverse colon/stomach or during left upper quadrant laparoscopic operations
- Hemoglobinopathies
  - Hereditary spherocytosis (HS)
  - Thalassemia/sickle cell disease
- Splenic cysts (e.g., epithelial or epidermoid cysts)
- Splenic hamartomas

PATIENT HISTORY AND PHYSICAL FINDINGS

- Prior to elective surgery, a thorough history should be obtained, including an account of abdominal pain or constitutional symptoms, detailed past medical/surgical history, and all current medications and allergies. Particular attention should be directed to eliciting any symptoms of liver disease, clotting or bleeding disorders, and a blood product transfusion history.
- Patients presenting with splenic trauma require rapid assessment making use of the principles outlined in the American College of Surgeons Advanced Trauma Life Support (ATLS®) protocol. Hemodynamic instability is a general contraindication to splenorrhaphy. A thorough history should be obtained as outlined earlier. Particular attention must be paid to associated injuries as these will influence decisions regarding nonoperative management (NOM), splenorrhaphy, or splenectomy (**FIG 1**). In *pediatric patients*, NOM is the preferred treatment choice and early consultation with a pediatric surgeon is highly recommended. Adult trauma patients with low-grade splenic injuries may be managed with NOM (Table 2).
- Patients presenting with hemoglobinopathies have abnormal laboratory profiles and often present with abdominal pain/discomfort, a history of jaundice, or splenomegaly. Rarely, patients will be completely asymptomatic. Patients with HS often present with sequestration of abnormal red blood cells (RBCs) and may have splenomegaly.[2,3] Historically, these patients benefited from splenectomy. Recently, clinical evidence demonstrates that patients with HS are amenable to partial splenectomy (PS), eliminating the need for repeat transfusions and significantly reducing the risk of overwhelming postsplenectomy infection (OPSI). Additionally, patients with sickle cell anemia have shown improvement following PS.[2–4]
- A complete and thorough physical examination should be performed on *all* patients. The presence or absence of splenomegaly should be noted. All signs of portal hypertension or liver failure should be elicited. Presence or location of surgical scars must be considered prior to determining operative approach.
- Splenorrhaphy is best performed via an open technique, which allows full visualization of the injury. An open approach allows easy conversion to a splenectomy should the clinical situation warrant this. Elective PS may be performed via an open or laparoscopic technique. Laparoscopic PS requires substantial experience in minimally invasive surgery and therefore, we prefer an open or a laparoscopic-assisted technique.

Table 1: American Association for the Surgery of Trauma Organ Injury Scaling: Spleen

Grade	Injury	Description
I	Hematoma	Subcapsular, <10% surface area
	Laceration	Capsular tear, <1 cm parenchymal depth
II	Hematoma	Subcapsular, 10%–50% surface area; intraparenchymal, <5 cm in diameter
	Laceration	Capsular tear, 1–3 cm parenchymal depth not involving trabecular vessel
III	Hematoma	Subcapsular, >50% surface area or expanding; ruptured subcapsular or parenchymal hematoma; intraparenchymal hematoma >5 cm or expanding
	Laceration	>3 cm parenchymal depth or involving trabecular vessels
IV	Laceration	Laceration involving segmental or hilar vessels producing major devascularization (>25% of spleen)
V	Laceration	Completely shattered spleen
	Vascular	Hilar injury with devascularized spleen

Adapted from Moore EE, Cogbill TH, Jurkovich GJ, et al. Organ injury scaling: spleen and liver (1994 revision). J Trauma. *1995;38(3):323–324.*

IMAGING AND OTHER DIAGNOSTIC STUDIES

- All patients with a suspected or known hemoglobinopathy require input from a hematologist. Patients should have a blood smear and/or bone marrow analysis, a complete blood count (CBC), and specialized blood studies as indicated by the disease process.
- Computed tomography (CT) scanning should be performed for all hemodynamically stable patients with suspected splenic trauma. CT is an excellent modality for preoperative

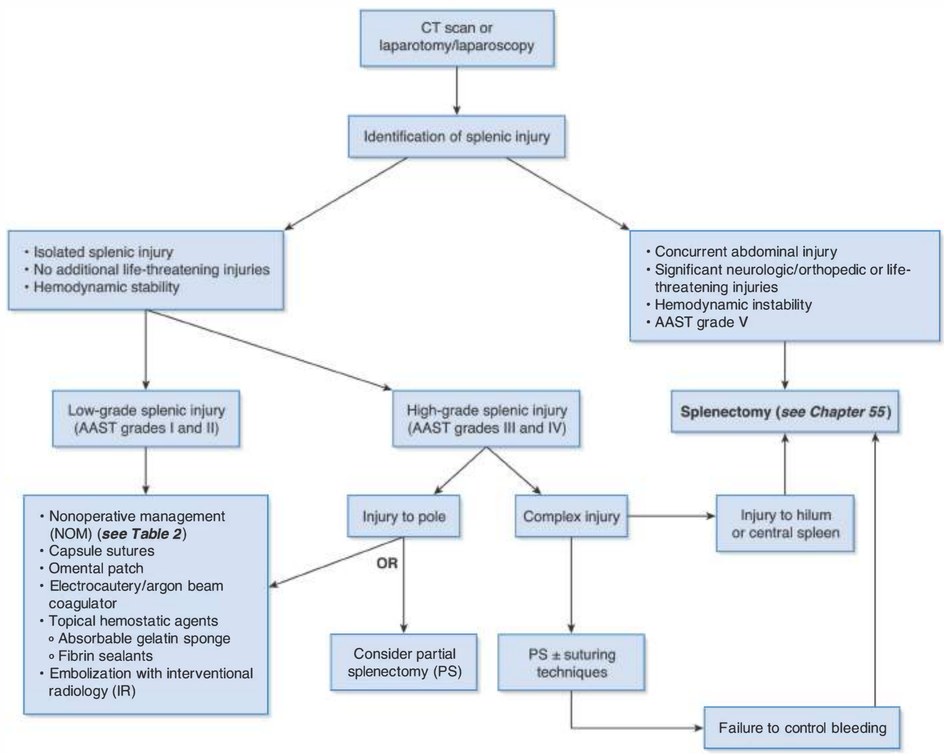

FIG 1 ● Treatment algorithm for splenic injury outlining various options based on grade of injury. AAST, American Association for the Surgery of Trauma.

planning to evaluate injury extent and to delineate vascular anatomy. CT is recommended for elective PS to determine the relationship of the spleen to adjacent organs, splenic size, and potential locations of accessory spleens (**FIG 2**).

- Ultrasound (US) is a noninvasive imaging modality to assess for splenomegaly, presence of splenic cysts/masses, and determination of portal hypertension in selected patients. US is particularly useful in assessing the spleen in children with the added advantage of minimizing ionizing radiation exposure. In the evaluation of trauma patients, focused abdominal sonography for trauma (FAST) is an accepted screening tool to diagnose intraperitoneal fluid or blood. Preoperative US should be performed for all patients with symptomatic biliary colic and patients with hemoglobinopathies to evaluate for cholelithiasis. Patients with cholelithiasis should be considered for concurrent cholecystectomy.
- Magnetic resonance imaging (MRI) is a recognized method for evaluating splenic lesions without the use of ionizing radiation. MRI is not recommended in the setting of splenic injury.

Table 2: Criteria and Contraindications to Nonoperative Management for Splenic Injury

Criteria for Nonoperative management (NOM)

- Hemodynamic stability
- No additional comorbid injuries (e.g., head injury, significant orthopedic trauma)
- Limitation of splenic-related blood transfusion (≤2 units)
- CT scan documenting splenic injury and grade
- Absence of active intrasplenic bleeding on CT
- Absence of other intraabdominal injuries on CT requiring operative intervention

Contraindications for NOM

- Hemodynamic instability ± peritonitis
- Associated intraabdominal/retroperitoneal organ injury
- Inability to perform reliable serial abdominal exams
- Need for anticoagulation
- Inability to correct coagulopathy
- Ongoing blood transfusion requirement
- AAST grade V splenic injury

CT, computed tomography; AAST, American Association for the Surgery of Trauma.

SURGICAL MANAGEMENT

Preoperative Planning

- Patients undergoing PS for elective indications should receive vaccinations for encapsulated organisms (*Haemophilus influenzae B*, *Streptococcus pneumoniae*, and *Neisseria meningitidis*) 2 to 4 weeks prior to surgery. Although PS should theoretically eliminate the risk of OPSI, vaccinations should be administered in the event that a total splenectomy is performed. Patients undergoing PS in the setting of splenic injury should receive vaccinations 2 to 4 weeks postoperatively. Current guidelines for OPSI prevention are outlined in Part 3, Chapter 52, Table 2.
- Blood products should be ordered and available intraoperatively including packed red blood cells (PRBCs), platelets, and fresh frozen plasma (FFP).

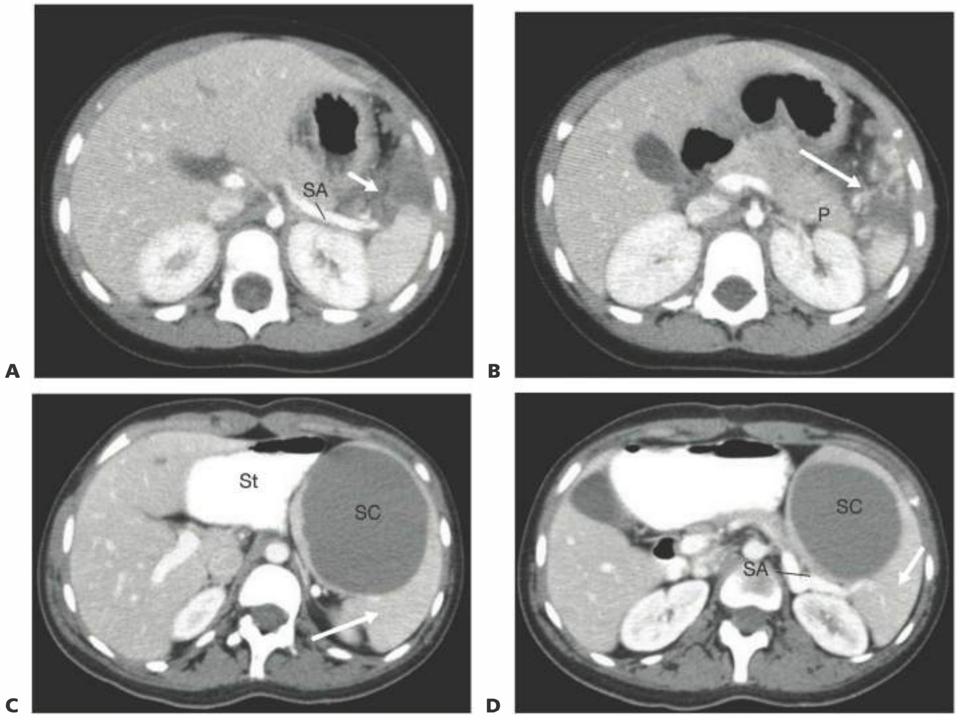

FIG 2 ● CT scan of splenic laceration **(A,B)** and splenic cyst **(C,D)**. **A.** CT demonstrating isolated injury to the spleen *(white arrow)* from blunt abdominal trauma with hemoperitoneum. Note the proximity to the splenic artery (SA). **B.** CT from same patient demonstrating extent of splenic injury *(white arrow)* extending to inferior pole. Note the proximity of the spleen to the tail of the pancreas (P). **C.** CT demonstrating a large splenic cyst (SC) compressing normal splenic parenchyma *(white arrow)*. The cyst is compressing the stomach (St). **D.** CT image from same patient demonstrating the relationship of the SC to the SA. This patient underwent successful laparoscopic PS with preservation of normal splenic parenchyma. *Large white arrow*, splenic laceration; *narrow white arrow*, normal spleen.

- All patients should receive prophylactic antibiotics to cover skin flora within 60 minutes prior to the skin incision.
- Appropriate antithrombotic precautions should be instituted, including sequential compression devices (SCDs) for all patients age 12 years and older. Appropriate anticoagulation medications (e.g., low-molecular-weight heparin) should be administered preoperatively per hospital protocol.
- A nasogastric tube (NGT) should be inserted following induction of anesthesia to decompress the stomach and aid in visualization. Consideration should be given to leaving the NGT in situ for 24 to 48 hours postoperatively to prevent gastric distension.
- An open approach is recommended for patients undergoing splenorrhaphy for splenic injury. The human hand as a retractor to provide compressive hemostasis is invaluable in the successful performance of PS. This approach also provides good exposure and allows for possible splenectomy should attempts at splenorrhaphy prove unsuccessful.
- PS may be performed by a laparoscopic approach in the elective setting. Laparoscopic PS requires advanced laparoscopic skills and should only be undertaken by a surgeon familiar with the procedure.
- In adult splenic trauma patients, consideration should be given to preoperative splenic artery embolization (SAE) by interventional radiology. SAE has been demonstrated to improve the use of NOM, with improvement in splenic salvage, length of hospital stay, and mortality.[5] Pediatric patients with splenic trauma rarely require embolization and consultation with a pediatric surgeon is highly recommended before treatment with SAE is commenced.[6]

Positioning

- For open splenorrhaphy, patients are placed in a supine position with both arms extended. For patients with isolated splenic trauma, an upper midline incision from the xiphoid process to the umbilicus allows adequate exposure. This incision can be extended inferiorly if additional exposure is required or other intraabdominal injuries are identified. For pediatric patients, a left subcostal incision or a transverse incision starting at the left 12th rib tip can be used (see Part 3, Chapter 52, FIG 5).
- Patients undergoing laparoscopic PS can be positioned supine with both arms tucked at the side. A beanbag or kidney rest is placed under the left flank to increase exposure between the 12th rib and iliac crest. The table may be rotated to allow near-supine positioning for port placement and then rotated during the operation to achieve a right lateral decubitus position. As with all operations, all pressure points should be appropriately padded (see Part 3, Chapter 52, FIG 4).

SPLENORRHAPHY

Incision

- A variety of incisions can be used to perform splenorrhaphy depending on the clinical situation.
  - Trauma patients. A midline incision extending from the xiphoid process to the pubis is used to enter the peritoneal cavity. This incision allows maximal exposure. A quick thorough inspection of each quadrant and the pelvis should be performed. Active bleeding should be immediately addressed. Retractors should be placed to maximize visualization and determine if additional sources of bleeding are present. All fluid and particulate matter should be quickly evaluated. Additional abdominal/retroperitoneal injuries discovered at the time of laparotomy should be prioritized and dealt with as outlined in corresponding chapters.
  - Isolated splenic injury. A midline incision extending from the xiphoid process to the level of the umbilicus can be used. Should additional exposure be required, the incision can be extended inferiorly. Retractors are placed to allow maximal exposure of the left upper quadrant. If a splenic injury occurs while performing an upper abdominal laparoscopic procedure, consideration should be made to convert to an open procedure depending on the extent of the injury. For higher grade injuries (American Association for the Surgery of Trauma [AAST] grades III and IV), a left subcostal incision can be made approximately 3 cm inferior to the costal margin (see Part 3, Chapter 52, FIG 5).
  - Pediatric patients. A midline incision can be used similar to adult patients in the setting of trauma. For isolated splenic injuries, either a left subcostal incision or a transverse incision can be used. For a transverse incision, the tip of the 12th rib is identified and the incision is extended medially to allow for exposure of the spleen.

Mobilization

- Anatomically, the spleen resides superiorly and posteriorly in the left upper abdomen. For adequate assessment of a splenic injury and successful splenorrhaphy, the spleen must be completely mobilized by removing all peritoneal and visceral attachments. This includes the splenophrenic attachments to the diaphragm, the splenocolic ligament to the splenic flexure of the colon, the splenorenal ligaments, and the gastrosplenic ligament (see Part 3, Chapter 52, FIG 6). The splenophrenic and splenorenal ligaments are avascular and can be divided sharply. Conversely, the gastrosplenic ligament (containing short gastric vessels) and the splenocolic ligament require careful attention to ensure excellent hemostasis. Vessels in these ligaments should be ligated with ties or an energy-based sealant device.
- Division of the ligaments begins first with the splenocolic ligament, allowing the splenic flexure of the colon to be mobilized away from the spleen. Splenic mobilization is further achieved by the operating surgeon placing their left hand posteriorly on the spleen (a laparotomy pad may improve the grip) and rotating it anteromedially. This maneuver will better expose the splenophrenic and splenorenal ligaments. Once the spleen is free of these attachments, it can be carefully mobilized into the wound. The gastrosplenic ligament is then carefully divided. Laparotomy pads can be carefully placed posteriorly to further aid in mobilization.
- Division of the ligaments should be made 2 to 3 cm from the spleen to avoid injury to both the spleen and adjacent organs (i.e., pancreas).
- The tail of the pancreas extends to the splenic hilum in most patients. Care must be taken during mobilization of the spleen to avoid iatrogenic injury. The tail of the pancreas should be fully visualized, particularly as the spleen is rotated into the operative field. The splenic artery and vein are located on the superior border of the pancreas and must be carefully isolated to avoid injury.
- Once the spleen is mobilized from the retroperitoneal attachments, control of the hilar vessels can be quickly achieved if necessary to control bleeding. Active bleeding can be controlled by direct compression of the hilar vessels between the surgeon's thumb and forefinger. This maneuver allows for thorough assessment of the extent of splenic injury.
- Note: Full splenic mobilization may be unnecessary for small isolated injuries (e.g., capsular tear) that occur intraoperatively and can be completely visualized. In all other situations, complete splenic mobilization should be performed.

Repair of Low-Grade Splenic Injuries (AAST Grades I and II)

- After mobilizing the spleen, a thorough inspection can occur to allow complete assessment of the injury (see Table 1 and **FIG 1**). If necessary, vascular control can be obtained by compression of the hilar vessels as discussed earlier.
- Grades I and II injuries can generally be controlled by simple techniques including the following:
  - Direct compression (for minor capsular tears <1 cm)
  - Application of topical hemostatic agents
    - Absorbable gelatin sponge
    - Absorbable oxidized regenerated cellulose
    - Fibrin sealants
  - Electrocautery or argon beam coagulator (ABC) (**FIGS 3** and **7**)
  - Absorbable sutures placed in the capsule (interrupted or running) (**FIGS 3** and **8**). For most low-grade injuries, suture pledgets are not required.
- Following repair, the injury should be observed for 5 to 10 minutes to ensure that bleeding is controlled. Ongoing bleeding may require a combination of techniques listed earlier to repair the injury. Once the injury is controlled, the spleen is carefully returned to the left upper abdomen.

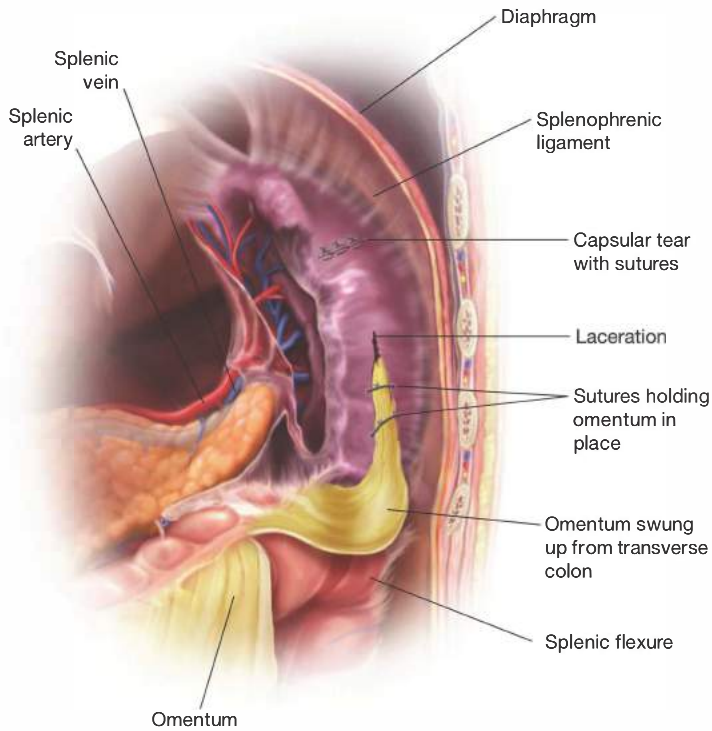

FIG 3 ● Splenorrhaphy technique demonstrating (1) use of interrupted sutures for linear capsular tear and (2) patch with omentum mobilized and rotated upward. Sutures are placed into splenic capsule and around omentum to buttress injury.

Repair of Moderate to High-Grade Splenic Injuries (AAST Grades III and IV)

- After complete mobilization of the spleen, a thorough inspection is performed. The vascular supply of the spleen is carefully inspected and if an injury is present, PS may be possible if 20% or more of the spleen can be salvaged (**FIG 1**). If significant injury to the splenic artery or vein is present, then consideration for a splenectomy should be strongly considered (see Part 3, Chapter 52). Vascular control is achieved by compression of hilar vessels as discussed earlier.
- Devitalized tissue should be debrided either sharply or with electrocautery to healthy splenic tissue (**FIG 4**).
  - Penetrating vessels to a devitalized segment should be ligated. If a line of demarcation is present, the splenic capsule can be incised with electrocautery. A linear stapling device can be used to transect a devitalized pole.
  - Clips can be applied to trabecular vessels. Gentle compression of the cut of the edge of the spleen will help control bleeding.
  - An ABC can be used to achieve hemostasis. Alternatively, mattress sutures can be placed along the cut edge. Pledgets are recommended to prevent further capsular damage (see **FIGS 7** and **8**).
  - Topical hemostatic agents can be applied and pressure held with a laparotomy pad for 10 minutes. Continued bleeding will require additional hemostatic agent and compression.
  - Alternatively, omentum from the transverse colon can be swung up and placed in the splenic laceration. Mattress sutures can then be placed to compress the edges and secure the omentum in place (**FIG 3**). Hemostatic mesh can be used in place of omentum.
- PS can be considered for segmental injury and will be discussed in the following text.

AAST Grade V Splenic Injuries

- Splenorrhaphy is *not* indicated for AAST grade V injuries. Patients with these injuries require expeditious splenectomy (see Part 3, Chapter 52).

Closure

- Once splenorrhaphy has been successful, the spleen is carefully inspected to ensure hemostasis. The spleen is then carefully returned to the upper left abdomen.
- Careful inspection of the abdomen should be undertaken by the surgeon and assistant surgeon independently to ensure all laparotomy pads have been removed. A preliminary count should be simultaneously performed. The abdomen is then irrigated to remove all blood clots.
- The abdomen is then closed in the usual fashion. Drains in the left upper abdomen are unnecessary unless there is a suspected or known injury to the tail of the pancreas. In the setting of abdominal trauma, a decision may be made to leave the abdomen open, allowing for a "second look" operation in 24 to 48 hours.

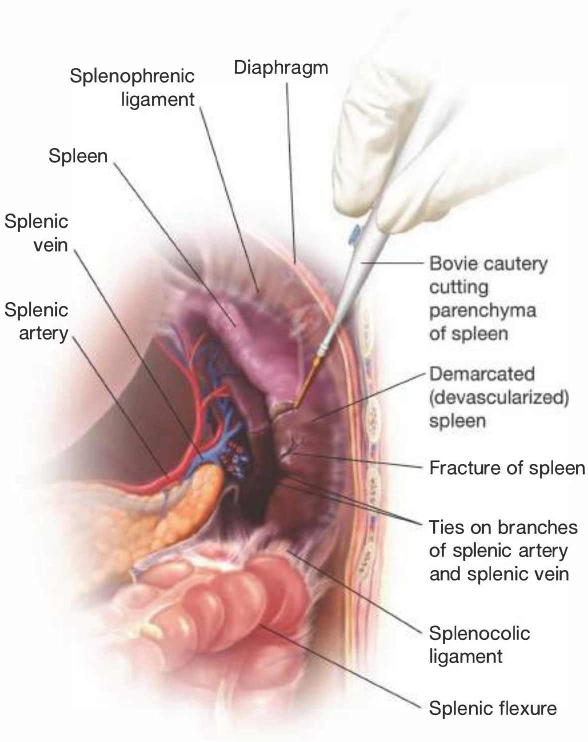

FIG 4 ● Division of spleen using electrocautery. A splenic fracture of the lower pole is present. Branches of the splenic artery and vein have been ligated and divided with subsequent demarcation of the avascular lower pole. The splenic capsule is now divided along the line of demarcation. The splenic artery and vein can be compressed between the thumb and finger of the operative surgeon to control blood loss while the parenchyma is divided.

PARTIAL SPLENECTOMY

Incision

- For open PS, the incision will be dependent on the age of the patient and indications for surgery.
  - Adult patients. An upper midline incision extending from the xiphoid process to the umbilicus should allow adequate exposure. This incision can be extended inferiorly should additional exposure be required. Alternatively, a left subcostal incision can be used for isolated splenic lesions. Caution should be exercised in using this incision if splenomegaly is present.
  - Pediatric patients. A left upper abdominal transverse incision can safely be used, starting from the 12th rib tip and extending medially. Alternatively, a left subcostal incision can be used.
- For laparoscopic-assisted PS, ports are placed in a similar fashion to a laparoscopic splenectomy (see Part 3, Chapter 52). After mobilization of the spleen, a left transverse or left subcostal incision can be used to perform the PS.

Mobilization

- The spleen should be completely mobilized by dividing the splenophrenic, splenorenal, splenocolic, and gastrosplenic ligaments (see earlier discussion).
  - For open PS, mobilization begins in a similar fashion to open splenectomy (see Part 3, Chapter 52) and as discussed under the "Splenorrhaphy" section. The spleen needs to be completely mobilized.
  - For laparoscopic-assisted PS, mobilization begins in a similar fashion as discussed in preceding chapters (see Part 3, Chapter 52). Once the spleen is completely mobilized laparoscopically, an open incision can be made as described in the preceding section. The spleen needs to be mobilized to allow it to be brought completely into the incision.

Division of Spleen

- Once the spleen is completely mobilized into the incision, the splenic vessels can be identified. Depending on the location of the lesion, branches of the splenic artery and splenic vein can be ligated (**FIG 3**). The main splenic artery and vein branches at the hilum should be preserved. Once the penetrating vessels are ligated, the spleen will demarcate (**FIGS 3–5**).
- For PS to be effective, approximately 10% to 20% of the spleen should remain vascularized after ligation of penetrating vessels to preserve physiologic function of the splenic remnant.[4] Care must be taken to ensure that the remaining blood supply is from a splenic artery branch. Relying solely on short gastric arteries will not be adequate to maintain adequate blood flow to the splenic remnant.
- Once the spleen demarcates, the splenic capsule can be incised using electrocautery (**FIG 4**). Potential blood loss can occur; anesthesia team should be notified and blood

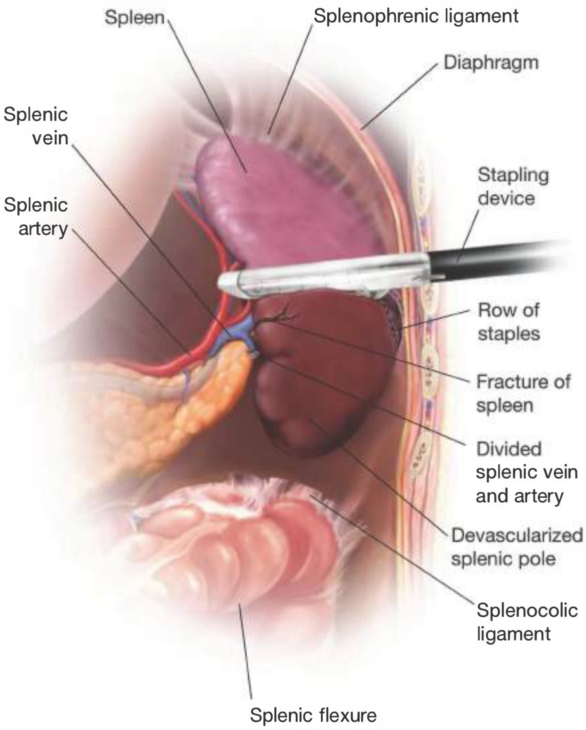

FIG 5 ● Division of the spleen with a linear stapling device. Following ligation and division of branches of the splenic artery and vein to the lower pole, the demarcated spleen is then divided using multiple fires of a linear stapling device. Staple size is dictated by the size of the spleen. Vascular control can be achieved by compression of the main branch of the splenic artery and vein between the surgeon's thumb and index finger until the spleen is divided.

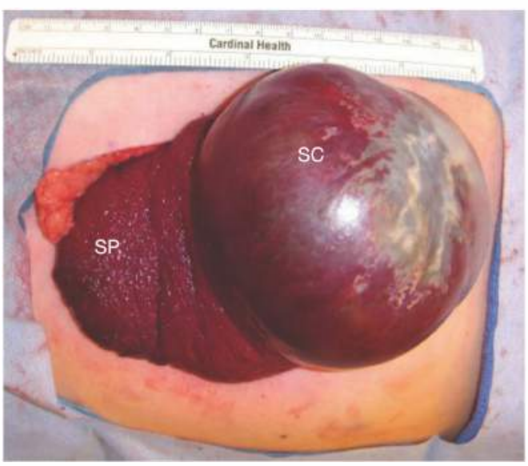
should be available in the operating room (OR) preoperatively. Vascular control can be achieved by compression of the main splenic artery and vein (between the thumb and forefinger as discussed earlier).

- The splenic parenchyma can be divided using electrocautery or a linear stapling device (**FIGS 4** and **5**). Gentle compression can be applied to vascularized splenic edge to assist in controlling bleeding.
- Once the splenic parenchyma is completely divided and the specimen passed off the table, an ABC is used to control bleeding from the cut edge. The ABC is used until bleeding is minimized and the cut edge is thoroughly cauterized (**FIG 7**). Note that the source of argon gas is not pressure regulated. During laparoscopy, intraabdominal pressure must be closely monitored and the abdomen vented as indicated to prevent intraabdominal hypertension.
- An absorbable topical hemostatic agent is then applied to the cut edge and pressure is held with a laparotomy pad (**FIG 6**). Pressure is held for 5 minutes and the laparotomy pad is then carefully removed and ongoing bleeding is assessed. Additional use of ABC may be necessary to control points of bleeding.
- Bleeding from the cut edge of the spleen can be further controlled by placement of absorbable mattress sutures as discussed in the "Splenorrhaphy" section (**FIG 8**).
- Once hemostasis is meticulously achieved, the remainder of the spleen is observed for adequate blood flow. Again, 10% to 20% of the total splenic tissue should remain viable to preserve splenic physiologic function. The splenic remnant is then carefully returned to the left upper abdomen.
  - To prevent torsion of the splenic remnant, consideration can be given to performing splenopexy. Sutures are carefully placed in the splenic capsule and then attached to the lateral abdominal wall or retroperitoneum for fixation. At least two points of fixation should be used. Once placed, these sutures should have minimal tension to avoid tearing the capsule.
  - Depending on the site of PS, omentum can be placed against the cut surface of the spleen. Sutures can be placed to hold the omentum in place as discussed in the preceding section.
- In the case of PS for hemoglobinopathies (e.g., HS), a thorough search for accessory splenic tissue should be performed. The incidence of accessory spleens is 10% to 30%. The most common location for an accessory spleen is at the splenic hilum (approximately 75%), followed by the tail of the pancreas (approximately 20%). The



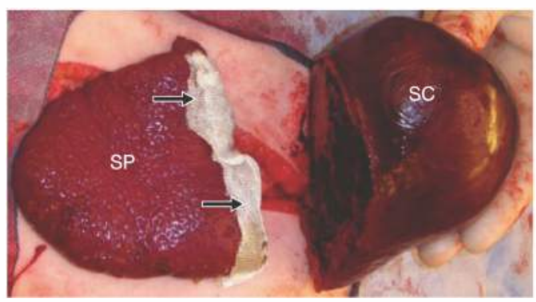


FIG 6 ● **A.** Large epidermoid cyst *(SC)* of the lower pole of the spleen. **B.** Following division of the splenic parenchyma, the superior pole *(SP)* remains perfused. Absorbable hemostatic agent is applied to the cut edge following coagulation with an ABC *(arrows)*. SC, splenic cyst; SP, superior pole of spleen; arrows, absorbable hemostatic agent.

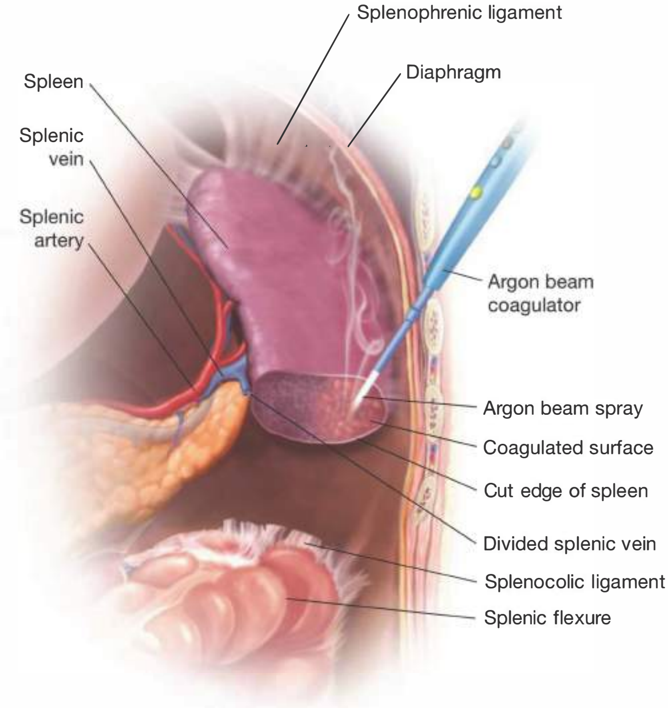

FIG 7 ● Use of ABC to coagulate cut surface of spleen. Branches of the splenic artery and vein to the lower pole have been ligated. The splenocolic ligament has been divided for splenic mobilization.

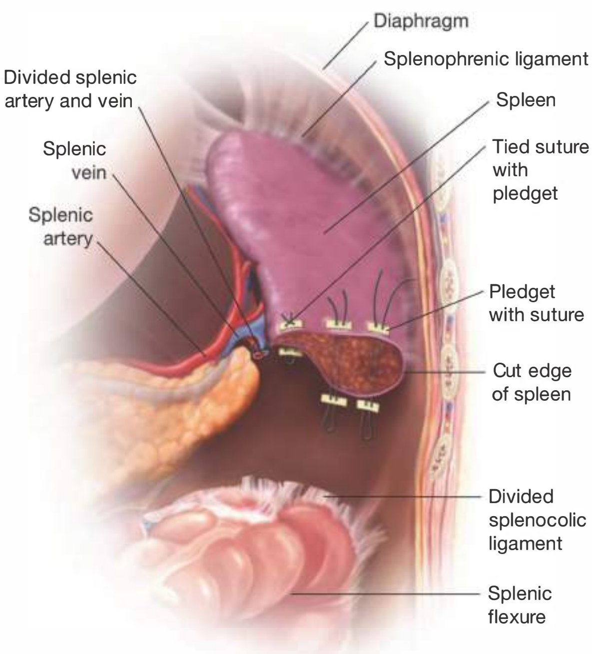

FIG 8 ● Use of interrupted horizontal mattress sutures with pledgets for hemostasis following PS. The splenic artery and vein branches have been divided to the lower pole and the lower pole removed. Sutures are placed in close proximity to reapproximate the capsule. The use of pledgets is recommended to prevent sutures from tearing the splenic capsule.

remainder is located along the splenic artery, in the mesentery, or in the omentum.[7] If accessory splenic tissue is located, it should be completely removed with careful attention to hemostasis.

- Consideration should be given to a concurrent cholecystectomy for patients with symptomatic biliary colic or preoperative US evidence of cholelithiasis.

Closure

- After returning the spleen to the left upper abdomen, a thorough inspection of the peritoneal cavity is performed to ensure there are no retained laparotomy pads. A preliminary count should be performed prior to closing.
- The abdomen is thoroughly irrigated with warmed normal saline. All blood should be removed from the abdomen. The spleen should be inspected to ensure exquisite hemostasis.
- The abdominal incision is then closed in the standard fashion. Drains are not necessary. If the procedure was performed with laparoscopic assistance, ports are removed and port sites are closed in the standard fashion.

PEARLS AND PITFALLS

Indications	■ Splenorrhaphy is used to repair an injured spleen (AAST grades I–IV). ■ Splenorrhaphy is *contraindicated* in AAST grade V injuries. ■ PS can be used as a splenorrhaphy technique or to treat various hemoglobinopathies (e.g., HS), splenic cysts, or splenomegaly.
Imaging and other diagnostics	■ CT scanning is recommended for hemodynamically stable patients with suspected intraabdominal trauma. ■ Patients with hemoglobinopathies should have preoperative imaging to plan operative approach (i.e., vessel location, splenic size) ■ Patients undergoing PS for hemoglobinopathies are recommended to have preoperative US evaluating for cholelithiasis. ■ Involvement of a hematologist is essential for patients with hemoglobinopathies for proper diagnosis and preoperative medical management.
Preoperative planning	■ Vaccinations need to be administered 2 weeks prior to elective PS. ■ Crossmatched blood and blood products should be readily available intraoperatively. ■ Consideration of stress-dose steroids for patients with hemoglobinopathies (review past medication history) ■ CT imaging (see earlier discussion) available in the OR for intraoperative guidance ■ Placement of an NGT for gastric decompression
Technique—splenorrhaphy	■ Hemodynamically *unstable* patients are not candidates for splenorrhaphy. ■ Complete mobilization of the spleen is key to assessing injury and performing splenorrhaphy. ■ Work lateral to medial for mobilization. ■ Leave a 1- to 2-cm cuff of peritoneum to prevent damage to surrounding organs. ■ Lower grade injuries can often be repaired with sutures. ■ Moderate to high-grade injuries may require a combination of techniques including PS. ■ Be prepared to proceed to total splenectomy should splenorrhaphy techniques fail.
Technique—PS	■ May be performed via open or laparoscopic approach ■ Laparoscopic PS requires advanced minimally invasive skills and an elective setting. ■ Identify the splenic artery and vein. A viable splenic remnant requires blood supply from the artery. ■ Do not rely on short gastric blood supply for remnant. ■ After division of blood supply, allow spleen to demarcate prior to dividing spleen. ■ Approximately 30% of the spleen should remain viable for splenic function postoperatively. ■ A thorough search for accessory spleens should be undertaken (and removed if found). ■ Consider performing splenopexy to prevent torsion of remnant. ■ Consideration for concurrent cholecystectomy for patients with symptomatic biliary colic or preoperative US evidence of cholelithiasis.
Technique—closure	■ Drains should not be used unless there is a known or suspected pancreatic injury.

POSTOPERATIVE CARE

- Patients undergoing splenorrhaphy will require ongoing hemodynamic monitoring in the immediate postoperative period. Hemodynamic instability should prompt further investigation for bleeding from the splenic repair.
- The NGT can be removed when evidence of bowel function is present. A diet can be initiated and advanced as tolerated.
- Careful attention to pulmonary toilet should be made, including the use of incentive spirometer, early mobilization, and pain control.
- Most patients undergoing splenorrhaphy will have concurrent injuries that will require continued attention.

OUTCOMES

Splenorrhaphy

- NOM should be considered the standard of care for low- to moderate-grade splenic injuries. NOM has demonstrated splenic preservation rates ranging from 81% to 91% for AAST grades I to III injuries.[8]
- Splenectomy has been demonstrated to be an independent risk factor for infectious complication following blunt splenic trauma. The authors recommend broader consideration for the use of splenic-preserving techniques.[9]
- Splenorrhaphy has been shown to be successful in 86% of patients with intraoperative splenic injury.[10] However, some caution is warranted in interpreting these findings as most reports of this nature are based on small sample sizes.
- The use of ABC dramatically improved rates of successful splenorrhaphy. ABC can be used for many splenic injury types/grades. The ABC can also be used successful with laparoscopic procedures.

Partial Splenectomy

- PS for HS leads to clinically significant improvements in hematologic profiles and symptoms in the pediatric population. Hemoglobin levels significantly increased, whereas reticulocyte count and bilirubin levels decreased.[2]
- PS for other congenital hemolytic anemias (i.e., sickle cell disease) has been demonstrated to control symptoms of hypersplenism and splenic sequestration. Splenic immune function also appears to be preserved in patients following PS who were followed for 4 years from surgery.[3,4]
- PS can be safely performed with few conversions to total splenectomy. Consideration should be given at the time of operation for cholecystectomy for children with symptoms of biliary colic and/or preoperative US demonstrating cholelithiasis.

COMPLICATIONS

Splenorrhaphy

- Bleeding (most common)
- Pancreatic injury/fistula
- Atelectasis/pneumonia/left pleural effusion
- Intraabdominal abscess (3% to 13%; higher rates with use of drains)
- Wound complications (higher rates with open procedures)
  - Seroma
  - Infection
  - Wound dehiscence

Note: Complication rates will be higher in multisystem trauma patients.

Partial Splenectomy

- Bleeding
- Splenic regrowth
- Disease recurrence (may occur when too large of a splenic remnant remains)
- Need for total splenectomy
- Splenic remnant torsion
- Pancreatic injury/fistula
- Wound complications (higher rates with open procedures)

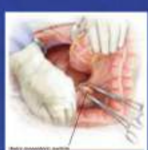
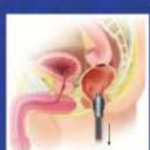
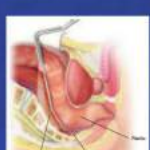
Part 4 Operative Techniques in Colon and Rectal Surgery







Chapter 1

Laparoscopic Small Bowel Resection

Oliver Varban

DEFINITION

- Laparoscopic small bowel resection involves laparoscopic segmental resection of a portion of the duodenum, jejunum, or ileum as well as its associated mesentery. A small bowel resection may be performed in the setting of obstruction, bleeding, or malignancy.

DIFFERENTIAL DIAGNOSIS

- The following conditions represent pathology that may require a small bowel resection:
  - Inflammatory bowel disease (Crohn's disease)
  - Polyp
  - Tumor. Tumors of the small intestine are rare and represent only 1% to 3% of all gastrointestinal neoplasms. (Table 1)
  - Ulcer
  - Diverticula
  - Stricture
  - Intussusception

PATIENT HISTORY AND PHYSICAL FINDINGS

- Obstruction results in nausea, vomiting, obstipation, abdominal pain, and distension with absent bowel sounds. Peritoneal signs and fever may indicate ischemia, necrosis, or perforation.
- Bleeding may result in hematemesis, hematochezia, or heme-positive stools. Additionally, a brisk bleed may result in hemodynamic instability with hypotension and tachycardia. Abdominal pain is typically absent, unless bleeding is associated with ulcer disease or obstruction.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Computed tomography (CT) with oral and intravenous (IV) contrast can assist with the location and etiology of obstruction. A transition point is noted when the proximal small bowel is dilated and the distal small bowel is decompressed.
- Magnetic resonance imaging (MRI) and magnetic resonance enteroclysis (MRE) along with CT may assist with the diagnosis of small bowel tumors.[1]
- Tagged red blood cell (RBC) scan and CT angiogram may localize intraluminal bleeding in cases where bleeding rates are at least 0.1 to 1.0 mL per minute.
- A technetium-99m pertechnetate, or Meckel scan, can detect gastric mucosa associated with a Meckel's diverticulum.
- Small bowel enteroscopy and capsule endoscopy may also be used to identify the location of a tumor or site of bleeding in a stable patient. If small bowel enteroscopy is performed, the location of the tumor can be tattooed for easy intraoperative identification.
- Diagnostic laparoscopy can assist with localization of disease and can help avoid unnecessary laparotomy.
- An elevated white blood cell (WBC) count and lactate level is concerning for ongoing ischemia or necrosis.
- A decrease in hemoglobin or hematocrit is indicative of bleeding.

Table 1: Tumors of the Small Bowel

Benign	GIST (benign or leiomyoma) Adenoma Lipoma Hemangioma
Malignant	Adenocarcinoma Carcinoid Lymphoma GIST (malignant)

GIST, gastrointestinal stromal tumor.

SURGICAL MANAGEMENT

Preoperative Planning

- The patient requires adequate IV access for resuscitation and, if necessary, blood transfusion if bleeding.
- A nasogastric tube assists in gastric and proximal small bowel decompression. This decreases the risk of aspiration during intubation as well as injury to the stomach or small bowel during port placement.
- A Foley catheter is placed for accurate intraoperative assessment of urine output and also to decompress the bladder for safe port placement.
- Preoperative antibiotics should cover enteric organisms in the event of spillage.

Positioning

- The patient is placed in the supine position. Arms may be out at 90 degrees or tucked at the side of the patient. Tucking the arms may assist with the ergonomics of the operation as both surgeon and assistant may stand on the side of the patient comfortably.
- For operations that take place on the proximal small bowel, it is optimal for the surgeon to stand on the patient's right (**FIG 1**). Meanwhile, for operations that take place in the distal small bowel, it is optimal for the surgeon to stand on the patient's left.
- Operations that take place solely on the duodenum may be performed in split-leg position.

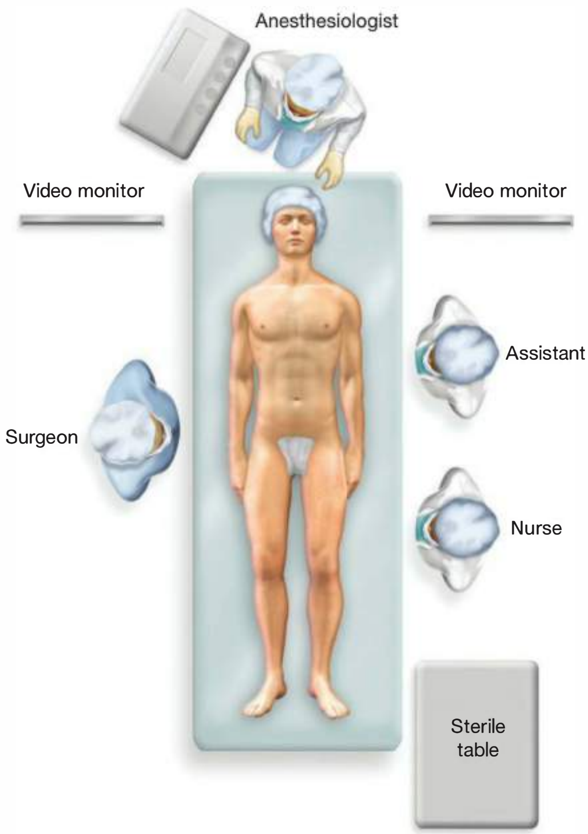


FIG 1 ● Room setup for laparoscopic small bowel resection.

ACCESS TO THE ABDOMINAL CAVITY

- Accessing the abdominal cavity can be performed in a variety of ways based on surgeon's comfort (i.e., open cut-down technique vs. Veress needle insufflation). An open cut-down technique may be advantageous in the setting of obstruction because the chance of blindly injuring dilated bowel is lower.
- Typical insufflation settings for laparoscopy include an intraabdominal pressure of 15 mmHg and a flow of 20 L per minute.
  - Veress needle entry
    - With a nasogastric tube in place and the stomach decompressed, a stab incision with a no. 11 blade is made through the dermis in the left upper quadrant of the abdomen, below the costal margin in the midclavicular line (**FIG 2**).
    - A Veress needle is placed through this incision and advanced until two distinct clicks are heard, signaling that the blunt-tip portion of the Veress needle has sprung forward. The second click is heard as the needle enters the peritoneal cavity.
    - A "drop test" can be performed by placing 10 mL of saline through the needle using

FIG 2 ● Veress needle entry in the left upper quadrant.

FIG 3 ● Drop test performed with saline using a syringe without a plunger. Saline is expected to enter the abdominal cavity freely by gravity alone.

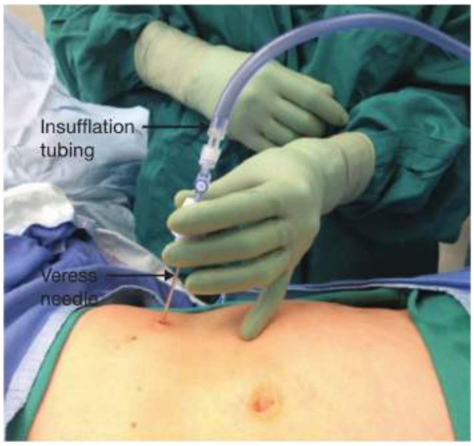

FIG 4 ● Veress needle connected to insufflator tubing for creation of pneumoperitoneum.

a syringe without a plunger (**FIG 3**). If the saline drops into the abdominal cavity with gravity alone, then the needle may be connected to the insufflator (**FIG 4**).
    - Once the abdomen is fully insufflated to an intraabdominal pressure of 15 mmHg, the Veress needle is removed and a 5-mm port is placed through the same incision. The port is then connected to the insufflator.
- Open cut-down technique
    - A 2-cm curvilinear incision is made with a no. 11 blade just below the umbilicus and tissue is dissected down to the level of the fascia.
    - S-shaped or L-shaped retractors are placed to assist with exposure.
    - The umbilical stalk is then grasped with a Kocher and elevated, thus pulling the fascia away from the underlying bowel.
    - A 2-cm longitudinal incision is made in the fascia with a no. 15 blade, and the edges are grasped and retracted using Kocher clamps. The peritoneum is identified below, grasped with DeBakey forceps in two separate locations, and then incised under direct vision.
    - A Hasson port is placed into the abdominal cavity and then connected to the insufflator.

PORT PLACEMENT

- After the first port is placed, a laparoscope is introduced into the abdominal cavity. A 5-mm or 10-mm, 30-degree angled laparoscope is used to perform the operation.
- After placement of the first port, the laparoscope is used to examine the bowel and organs just below the site of port entry to ensure no inadvertent injury occurred during insufflation/entry of the abdominal cavity.
- The remaining ports are placed under laparoscopic visualization, which assists in avoiding injury to intraabdominal organs and the inferior epigastric vessels.
- The 5-mm ports accommodate most laparoscopic grasping and dissecting instruments (**FIG 5**).
- The 12-mm ports accommodate laparoscopic stapling devices and autosuturing devices.
- Port placement for optimal exposure and manipulation of the proximal small bowel is demonstrated in **FIG 6**.
- Port placement for optimal exposure and manipulation of the distal small bowel is demonstrated in **FIG 7**.

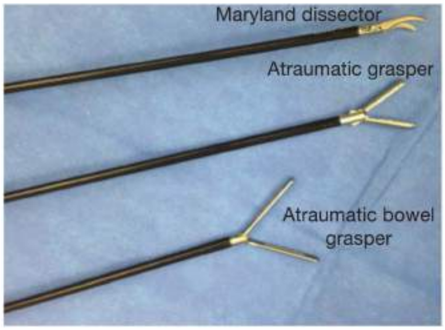

FIG 5 ● Laparoscopic atraumatic graspers and dissectors that can be used through a 5-mm port.

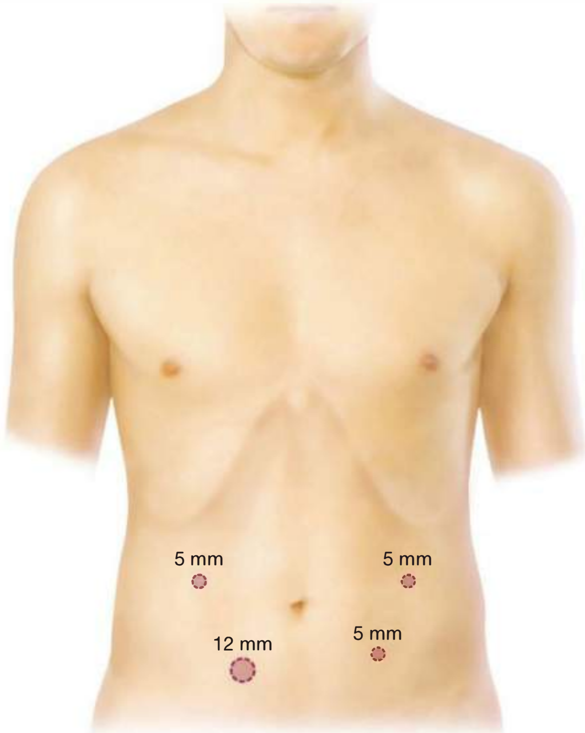

FIG 6 ● Optimal port placement for exposure of the proximal small bowel.

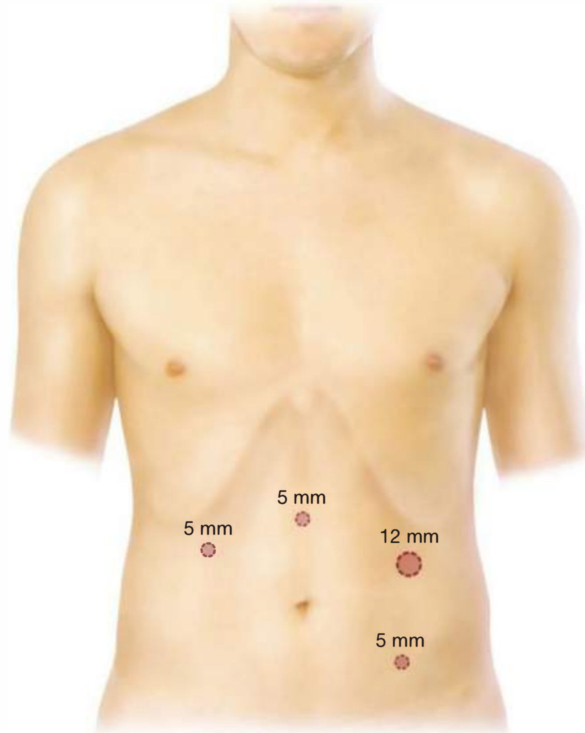

FIG 7 ● Optimal port placement for exposure of the distal small bowel.

IDENTIFICATION OF DISEASE

- The small bowel is run from the ligament of Treitz to the terminal ileum using atraumatic nonlocking graspers.
- To identify the ligament of Treitz, the assistant grasps the epiploicae of the transverse colon and retracts it cephalad, gaining exposure to the base of the colon mesentery. The surgeon then grasps the small bowel and follows it back hand over hand toward the base of the mesentery until they feel resistance and see the proximal jejunum emanate from the retroperitoneum (**FIG 8**).
- With the proximal small bowel identified, the small bowel can be run, hand over hand to the terminal ileum until the diseased portion can be identified.

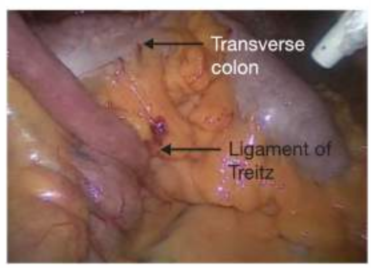

FIG 8 ● Identification of the ligament of Treitz requires elevation of the transverse colon and exposure of the transverse mesocolon. The small bowel is grasped and followed hand over hand proximally until it can be seen emanating from the retroperitoneum.

SMALL BOWEL RESECTION

- The surgeon grasps the proximal small bowel, and the assistant grasps the distal small bowel.
- Creation of a mesenteric window is performed using a Maryland dissector (**FIG 9**) at a location both proximal and distal to the diseased portion of small bowel.
- A laparoscopic dividing stapler (gastrointestinal anastomosis [GIA] type) is then placed through this window and the bowel is divided at proximal and distal points of resection. A stapler loaded with 2.5-mm staples is typically used (**FIG 10**).

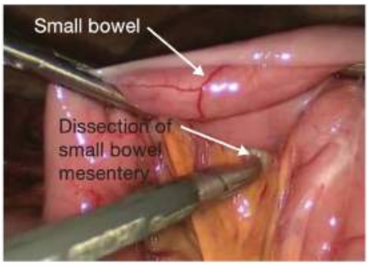

FIG 9 ● Creation of mesenteric window, allowing for placement of the laparoscopic dividing stapler.

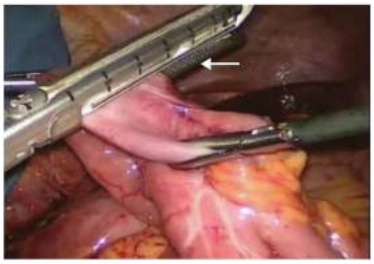

FIG 10 ● Placement of the laparoscopic dividing stapler through the mesenteric window. Arrow represents: Laparoscopic stapler.

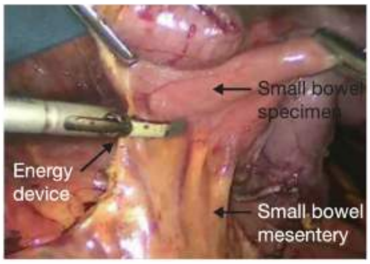

FIG 11 ● Mesenteric division using an energy device (i.e., ultrasonic scalpel).

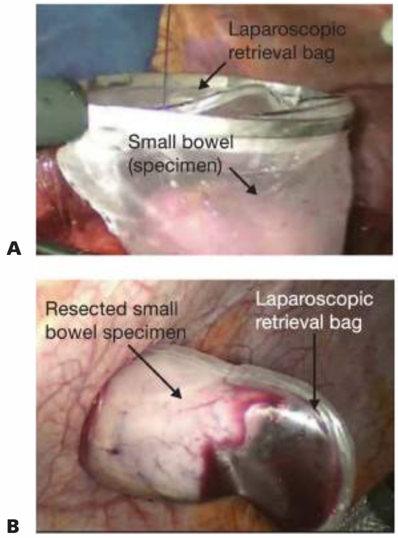

FIG 12 ● Placement of specimen in a laparoscopic retrieval bag **(A)** and removal from 12-mm port site **(B)**.

- The mesentery is divided using an energy device, such as an ultrasonic scalpel or laparoscopic bipolar device (**FIG 11**).
- The segment of resected bowel is then placed into a laparoscopic specimen retrieval bag (**FIG 12A**) and removed through the 12-mm port site (**FIG 12B**). This can be performed either before or after the anastomosis.

SMALL BOWEL ANASTOMOSIS

- The two divided ends of small bowel are placed side-to-side and a seromuscular traction suture is placed using 2-0 absorbable suture, approximately 8 to 10 cm from the ends along the antimesenteric surface of the bowel. A freehand suture may be performed or may be placed using an autosuture device. The tails of the suture are cut approximately 5 cm long so that they may be grasped and used for retraction.
- With the assistant holding the traction suture, the surgeon creates an enterotomy in each segment of bowel, approximately 1 cm from the stapled ends. Enterotomies may be created with an L-hook cautery or with an ultrasonic scalpel. The enteric contents are suctioned in order to contain spillage.
- Each limb of a laparoscopic linear stapler (2.5-mm staples, 60 mm in length) is placed separately into each enterotomy and aligned along the antimesenteric border (**FIG 13**). The stapler is closed and fired to create the anastomosis. Once the stapler is removed, the inside of the staple line is examined for hemostasis.
- The common enterotomy can be closed using a running suture or in a stapled fashion.
- When closing the common enterotomy with a stapler, three traction sutures are placed (one at each end and one in the middle) to approximate the enterotomy and elevate the edges. The tails of each suture are left long (approximately 5 cm) to allow for easy manipulation. A laparoscopic stapler (2.5-mm staples, 60 mm in length) is positioned beneath the cut edges and fired. Care is used to avoid including excessive amount of tissue in the stapler as it can narrow the anastomosis (**FIG 14A**).
- When closing the common enterotomy with suture, a running 2-0 absorbable suture may be placed for the inner layer and interrupted 2-0 permanent sutures may be placed in the seromuscular layer for the outer layer. Sutures may be placed freehand or with an autosuture device (**FIG 14B**).
- The mesenteric defect (**FIG 15A**) is closed with either a running or an interrupted series of 2-0 permanent sutures to prevent an internal hernia. Sutures are placed superficially in order to avoid injuring the blood supply (**FIG 15B**).

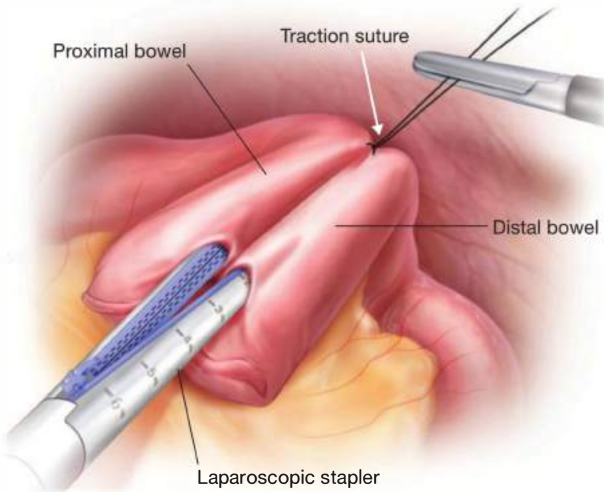

FIG 13 ● Placement of a laparoscopic linear stapler in separate enterotomies made on each limb of bowel for creation of anastomosis. A traction suture placed 8 to 10 cm from the ends is held by the assistant.

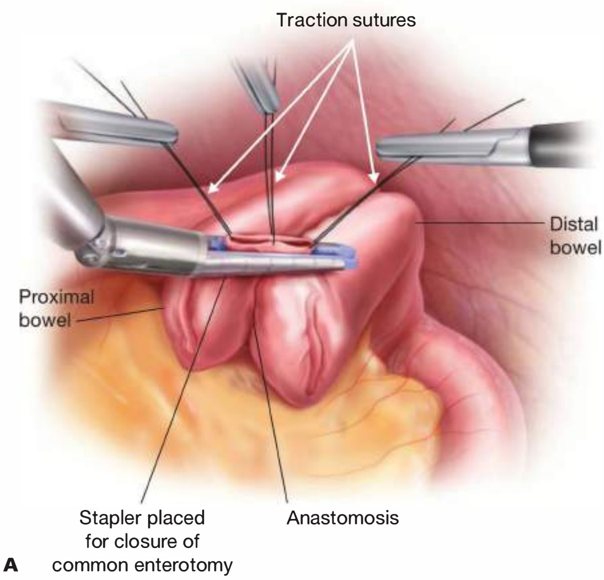

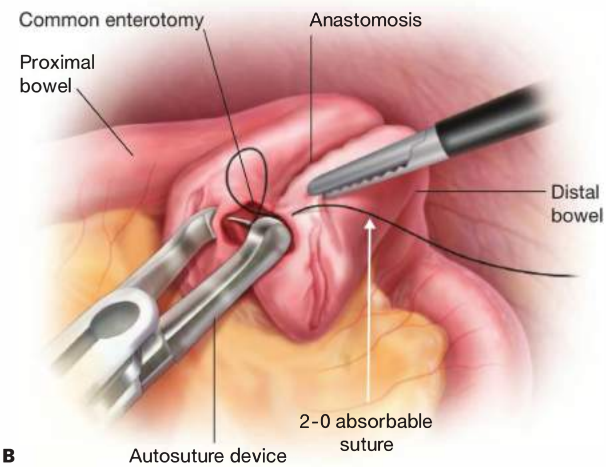

FIG 14 ● **A.** Stapled closure of the common enterotomy is performed by placing traction sutures at either end of the enterotomy and one in the middle. The tails of the sutures are left long so they may be grasped and assist with placement of the stapler. The enterotomy is closed transversely so as to avoid narrowing the anastomosis. **B.** Suture closure of the common enterotomy is performed using an autosuture device. It may be performed with freehand suturing as well. The first row is performed with a 2-0 absorbable suture in a running fashion, closing the enterotomy transversely. The second layer consists of interrupted seromuscular imbricating sutures using a 2-0 nonabsorbable suture.

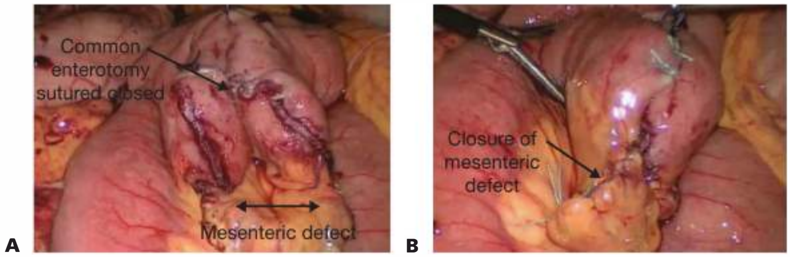

FIG 15 ● The mesenteric defect **(A)** is approximated with a running permanent suture **(B)**.

REMOVAL OF SPECIMEN

- Once the specimen is placed in a laparoscopic retrieval bag, it may be removed by expanding the size of one of the port sites. Alternatively, the specimen may be removed from a separate incision and with the use of a wound protection device.

CLOSURE

- It is recommended to close the fascia for all port sites greater than 10 mm. This may be performed using a single absorbable or permanent 0-suture and a Carter-Thomason suture-passer device (**FIG 16A–C**).
- The site of specimen extraction may be closed in a similar fashion; however, larger defects do not maintain pneumoperitoneum and are more difficult to close laparoscopically. As such, these may be closed by placing interrupted sutures in an open fashion using a suture on a UR-6 needle.
- The skin is closed with interrupted absorbable subcuticular sutures.
- Drains are not required.

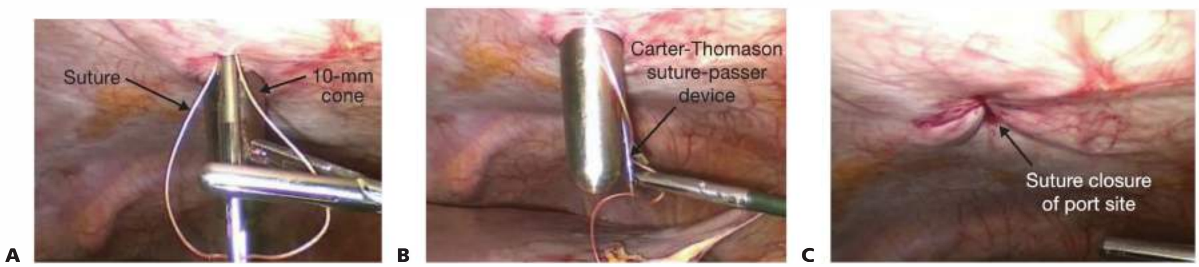

FIG 16 ● **A.** A Carter-Thomason suture-passer device is used to pass a free suture through the port site defect using a cone to direct the passage of the suture through one side of fascial defect. **B.** The Carter-Thomason is then passed without the suture on the opposite site of the defect in order to grasp the suture. **C.** The end of the suture is then pulled up through the fascia and tied.

PEARLS AND PITFALLS

Port placement	■ Optimal port placement enhances operative exposure and use of laparoscopic instruments in an ergonomic fashion. ■ Ports should be placed at least 10 cm apart and allow for triangulation of camera and instruments. ■ An open cut-down technique may reduce the risk of inadvertent injury in the case of obstructive disease and dilated bowel.
Identification of disease	■ Localization of intraluminal tumors can be facilitated with MRE or preoperative double-balloon enteroscopy and tattooing. ■ If unsure, areas of suspected disease can be marked with a suture laparoscopically and then a hand-port or minilaparotomy incision can be used for a tactile evaluation.

Small bowel resection	■ Creation of a mesenteric window allows for easy placement of a laparoscopic GIA stapler. ■ Edematous or thicker bowel may require 3.5-mm stapler cartridge.
Small bowel anastomosis	■ Traction sutures placed along the common enterotomy assist in accurate placement of a laparoscopic GIA stapler during closure of the common enterotomy. If the anastomosis appears narrowed with placement of the stapler, a sutured closure is preferred. ■ Ensure that the bowel undergoing anastomosis is well vascularized and not under tension. Edematous bowel is best approximated by a hand-sewn anastomosis. This may also be performed as an extracorporeal anastomosis through a small incision.
Removal of specimen	■ Use of a laparoscopic catch bag or wound protector can reduce the risk of wound infection.
Closure	■ Remove ports under laparoscopic visualization and inspect for bleeding prior to closure.

POSTOPERATIVE CARE

- After a laparoscopic small bowel resection, patients are admitted to the hospital for observation. If an extensive adhesiolysis is performed, a nasogastric tube may be placed at the end of the operation. Return of bowel function is signaled by production of flatus or formed bowel movements.
- A clear liquid diet may be started on postoperative day 1 after an uncomplicated laparoscopic small bowel resection. A solid diet may be started after return of bowel function.
- The patient may ambulate immediately after laparoscopic surgery and does not require prolonged bladder catheterization.
- Patients are usually seen in follow-up within 2 weeks of surgery.

OUTCOMES

- Laparoscopic small bowel resection is safe and effective resulting in lower lengths of hospital stay, less wound complications, and better cosmesis when compared to an open approach.[2,3] Laparoscopy also minimizes pain and severity of ileus as well as adhesive disease.[4]
- Small bowel obstruction makes laparoscopic surgery challenging and increases the likelihood for conversion to an open procedure.[5,6]
- Surgeons must acquire suturing skills to assure safe performance of advanced laparoscopic surgery.[7]
- Complete recovery is expected after small bowel resection. However, results depend on the condition prior to the procedure, the patient's overall health, and the length of bowel removed.

COMPLICATIONS

- Postoperative ileus
- Wound infection
- Anastomotic leak
- Anastomotic stricture
- Small bowel obstruction
- Port site incisional hernia

Chapter 2

Strictureplasty and Small Bowel Bypass in Inflammatory Bowel Disease

Douglas W. Jones   Kelly A. Garrett

DEFINITION

- Strictureplasty and small bowel bypass are methods used to avoid bowel resection in patients with Crohn's disease.
- The technique of strictureplasty was initially described in the treatment of tuberculous strictures as an alternative to resection. This procedure is mainly used in patients with jejunoileal Crohn's disease but may also be used in select patients with duodenal disease. There are different techniques, but all involve division of the strictured area either transversely or longitudinally with a distinctive closure that serves to widen the lumen.
- Small bowel bypass involves bypass of an affected segment of small intestine that is deemed unsuitable for resection or strictureplasty. Resection of the diseased segment is usually preferred. Bypass may be used in gastroduodenal Crohn's disease, complex small bowel disease, or ileocolic disease when a patient's comorbidities preclude resection.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history and physical examination should be performed. History should include duration and distribution of disease as well as current or prior medical therapy.
- Crohn's disease may manifest in one of three disease patterns: fibrostenotic, inflammatory, or perforating. Fibrostenosing disease is the most common and typically presents with a progressive course in which stricturing of the small bowel leads to obstructive symptoms.[1]
- Pattern of disease distribution should be determined prior to operative intervention. Anatomic location of disease can be classified as terminal ileal, colonic, ileocolonic, and upper gastrointestinal (GI). Over time, 15% of patients experience a change in anatomic location and 46% of patients demonstrate an alteration in disease behavior.[2]
- Past surgical history is of particular importance because many Crohn's disease patients have had prior abdominal surgery and this may affect operative planning. A detailed surgical history also allows for an estimation of the length of remaining small bowel.
- A detailed description of the patient's medical management should be obtained. The disease can be managed with antiinflammatory medications such as derivatives of 5-aminosalicylic acid; with immunosuppressors such as corticosteroids, azathioprine, 6-mercaptopurine, and methotrexate; and/or with immunomodulators such as antibodies targeting tumor necrosis factor-α. These medications can influence perioperative morbidity.
- A detailed history should also be obtained in order to distinguish Crohn's disease from ulcerative colitis. The two inflammatory bowel diseases can have similar patterns of presentation, although they have different principles of surgical management.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- The distribution of active disease needs to be mapped out preoperatively. Thought should be given to the risk of exposure to ionizing radiation as many patients with Crohn's disease can have flares over the course of many decades and hence require repeat imaging studies.
- Conventional radiologic techniques for imaging the small bowel include small bowel enteroclysis (SBE) and small bowel follow-through (SBFT). Strictures may appear as narrowed areas with delayed passage of contrast. Dynamic images may reveal impaired peristalsis in strictured areas. Computed tomography (CT) and magnetic resonance (MR) enterography have almost completely replaced the use of these studies at most academic centers.
- CT performed with intravenous and oral contrast is helpful in identifying abscesses and other inflammatory processes outside the bowel lumen. Recent developments have also improved the ability of CT to identify strictures, fistulas, and areas of active inflammation. CT enterography uses low-density oral contrast in place of barium or iodine-based oral contrast used in standard scans. This in combination with intravenous iodinated contrast allows for better definition of the mucosa and thickness of the bowel wall.
- MR enterography is being increasingly used to evaluate extent of active disease.[3] MR enterography can also be performed using low-density oral contrast and offers the additional benefit of sparing patients' exposure to radiation.
- Ultrasound, although not as widely used, may be able to identify areas of bowel wall thickening, strictures, and decreased peristalsis. It is also useful for identifying abscesses and fistulas. Although ultrasound spares patients' exposure to ionizing radiation, it is operator dependent and may not be able to distinguish inflammatory versus fibrotic strictures.
- All of the previously described imaging studies may help determine whether an area of stricture has an active inflammatory component that may respond to medical therapy, aid in determining the extent of disease prior to surgery, and facilitate operative planning.

SURGICAL MANAGEMENT

Preoperative Planning

- Indications for surgery in patients with Crohn's disease include the following: failure of medical therapy, perforation, obstruction, worsening inflammation, hemorrhage, neoplasia, growth retardation, and/or extraintestinal manifestations.[3]
- When preoperative imaging reveals stricturing small bowel disease with minimal area of inflammation in patients with obstructive symptoms, additional medical therapy is unlikely to resolve the symptoms and the patient should be considered for surgery. Patients with suspected active inflammation who have failed medical therapy should also be considered for surgery.

- Strictureplasty should not be performed in every patient with stricturing Crohn's disease. In most patients, simple resection and reanastomosis is sufficient. Indications for strictureplasty are the following:[4]
  - Diffuse jejunoileitis causing obstructive symptoms unresponsive to medical therapy
  - Recurrent stricturing disease in patients with multiple prior intestinal resections (high risk for short bowel syndrome)
  - Recurrence of strictures within 12 months of prior resection
  - Isolated ileocolonic anastomotic strictures
  - Selected duodenal strictures such as proximal lesions near the pylorus[5]
- Contraindications to strictureplasty are the following:[4]
  - Diffuse peritonitis
  - Free intraabdominal perforation of the affected bowel segment
  - Phlegmon or abscess of affected bowel segment
  - Fistulous disease with significant inflammation of affected bowel segment
  - Multiple areas of stricture, within a short distance of each other, more amenable to single resection
  - Suspicion for neoplasia
  - Hypoalbuminemia
- In some cases, bypass of affected segments of the GI tract are indicated. These include the following:
  - Gastroduodenal Crohn's disease—The duodenum is involved in 0.5% to 4% of patients with Crohn's disease and can cause obstruction or hemorrhage.[6] In this scenario, resection is excessively morbid, so strictureplasty and bypass play a larger role.
    - With obstruction of the first or second portions of the duodenum, a gastrojejunostomy should be performed. Although traditionally performed to prevent marginal ulceration, current use of effective acid-suppressing medications have rendered vagotomy unnecessary.[6,7] Furthermore, vagotomy may increase morbidity in patients already predisposed to diarrhea from extensive or poorly controlled Crohn's disease or short-gut syndrome.
    - In patients with obstruction of the third or fourth portions of the duodenum, a duodenojejunal bypass should be performed.
  - Active inflammation of the duodenum and small bowel can lead to duodenoenteric fistula formation, commonly involving recurrence at a previous ileocolic anastomosis. Resection of diseased areas may require partial resection of involved duodenum as well. In these cases, bypass with a gastrojejunostomy may be required.
  - In complex small bowel or ileocolonic Crohn's disease.[8] Bypass should be considered when resection would be unsafe as in the presence of an ileocecal phlegmon that is adherent to the retroperitoneum or iliac vessels.
- Bypass of small bowel disease should be avoided if resection is possible. An excluded segment should eventually be resected in order to avoid development of perforation, recurrent disease, carcinoma, or blind loop syndrome.[8]

Preparation

- A mechanical bowel preparation is not necessary for patients who are undergoing small bowel or ileocolic resection and should be avoided in patients with stricturing disease.
- If there is a chance that a stoma will be created, the patient should be evaluated by an enterostomal nurse to help avoid the development of pouching problems postoperatively.
- Appropriate antibiotic and venous thromboembolism prophylaxis are administered prior to incision.

Positioning

- Supine position is useful for patients who have uncomplicated ileocolic disease or gastroduodenal disease.
- Modified lithotomy position is preferred if patients have distal disease that may require intervention. This allows for intraoperative colonoscopy to be performed for diagnostic purposes or to interrogate an anastomosis or repair if necessary. This position is also advantageous if the procedure will be done laparoscopically as it allows the surgeon to stand between the patient's legs, which can assist with running the small bowel or with mobilization of the flexures if needed.

APPROACH

Placement of Incision

- The procedure can be performed via a laparoscopic or open approach.
- Laparoscopy for ileocolic Crohn's disease has been shown to result in earlier return of bowel function, shorter length of stay, and decreased postoperative pain.[9] This approach may not be feasible for all patients, however, as many will have had extensive previous abdominal surgery.
- For open surgery, a standard midline laparotomy incision is usually performed. This can be limited to the upper midline if minimally active disease is suspected.
- In patients with multiple abdominal operations, entering the abdomen in an area that has not previously been opened is recommended to avoid inadvertent bowel injury.

Evaluation of the Bowel

- Adhesiolysis may be necessary to allow for complete evaluation of the small bowel. Strictured areas are often identified by fibrotic, narrowed bowel with proximal dilation. Other external indications of stricture are fat wrapping, thickened mesentery and serosal corkscrew vessels.[4] Areas of suspected stricture are marked with a stitch on the antimesenteric bowel surface.
- In patients with multiple previous abdominal operations and obliterative scar tissue, the use of injectable saline can be useful to help delineate bowel loops.
- After the most obvious area of stricture is identified, the lumen is opened longitudinally along the antimesenteric border in preparation for strictureplasty or resection. A Foley catheter is placed into the bowel lumen and

filled with varying amounts of water. The catheter is then advanced or withdrawn through bowel in both directions to identify area of stricture that may not be externally evident.

- Patients may have multiple areas of disease that require a combination of resection and strictureplasty. Resections should be performed first.
- Once the decision is made to perform a strictureplasty, the length of affected small bowel must be determined as this dictates the type of strictureplasty performed.
  - Less than 8 to 10 cm: Heineke-Mikulicz strictureplasty
  - 10 to 25 cm: Finney strictureplasty
  - Extensive, long-segment disease: side-to-side isoperistaltic strictureplasty

HEINEKE-MIKULICZ STRICTUREPLASTY

- The stricture is isolated proximally and distally using umbilical tape or bowel clamps. The stricture is opened longitudinally on the antimesenteric border, beginning in normal bowel approximately 2 to 3 cm from the stricture. A clamp is placed into the bowel lumen and the incision is carried across the stricture using electrocautery and ending 2 to 3 cm into normal bowel.
- Two 3-0 polyglactin sutures are placed on opposite sides of the incision in the center of the stricture. These are used to create tension perpendicular to the incision, thereby opening the incised area of bowel and allowing the bowel to be closed transversely.
- Interrupted seromuscular 3-0 polyglactin sutures are then placed to close the incision transversely.[10] (**FIG 1**)

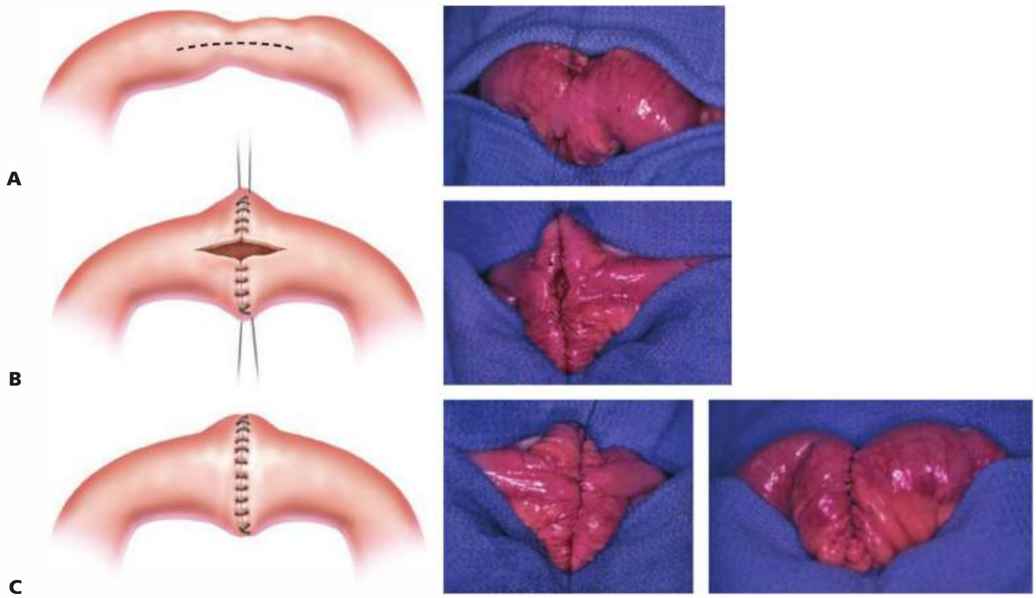

FIG 1 ● Heineke-Mikulicz strictureplasty. The bowel is opened longitudinally across the stricture **(A)** and then closed transversely **(B)** to increase the bowel lumen **(C)**.

FINNEY STRICTUREPLASTY

- For strictures 10 to 25 cm in length, a Heineke-Mikulicz strictureplasty creates excessive tension, so the Finney strictureplasty is preferred. A Finney strictureplasty should not be performed in a strictured segment that is longer than 25 cm, however, because this may risk a blind loop syndrome.
- The strictured area of bowel is isolated as previously described and the bowel is placed in a U shape with the midpoint of the stricture as the apex in order to simulate the finished strictureplasty and guide the bowel incision.
- The bowel is incised on the antimesenteric border beginning in normal bowel 2 to 3 cm from the stricture. This incision is then carried through the stricture using electrocautery. As the incision reaches the apex of the U shape, it should take a gradual course toward the mesenteric border as this allows for better tissue apposition. The incision finishes in 2 to 3 cm of normal bowel after having been brought back to the antimesenteric border.
- Interrupted, full-thickness 3-0 polyglactin sutures are used as marking sutures to approximate normal bowel edges at the base of the strictureplasty and are also used to fix the diseased bowel at the apex. Continuous 3-0 polyglactin suture is then used to close the posterior wall followed by the anterior wall of the strictureplasty. Interrupted sutures may also be used to reinforce the continuous suture at various points and maintain tissue apposition[4] (**FIG 2**).

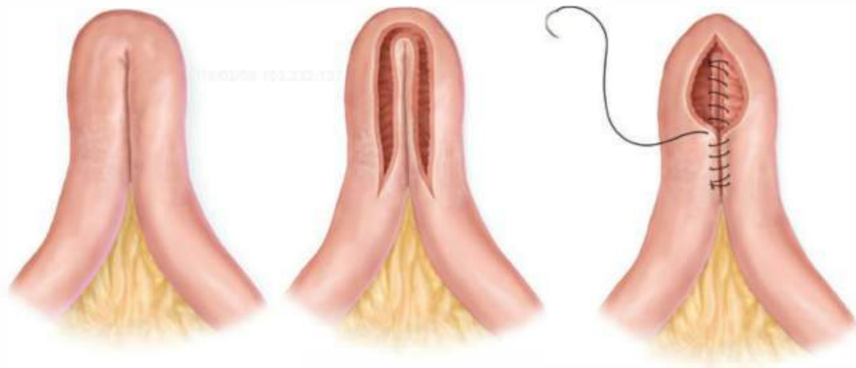

FIG 2 ● Finney strictureplasty. The bowel opening is made longitudinally across the stricture along "an omega loop" and is then closed side-to-side (posterior and anterior rows).

SIDE-TO-SIDE ISOPERISTALTIC STRICTUREPLASTY

- For extensive stricturing Crohn's disease not amenable to strictureplasty of isolated segments, the side-to-side isoperistaltic strictureplasty can be performed.
- The affected bowel is first transected at the midpoint. The proximal bowel is then brought to overlie the distal segment in an isoperistaltic fashion (**FIG 3**). An enterotomy is performed on the antimesenteric border and extended 2 to 3 cm into normal mucosa (**FIG 4**).
- The transected ends of bowel are spatulated in order to avoid creation of blind stumps.
- Similar to the Finney strictureplasty, tissues are brought together at both ends of the treated segment with interrupted 3-0 polyglactin sutures. The posterior layer is closed with a running 3-0 polyglactin suture followed by closure of the anterior layer (**FIG 5**).

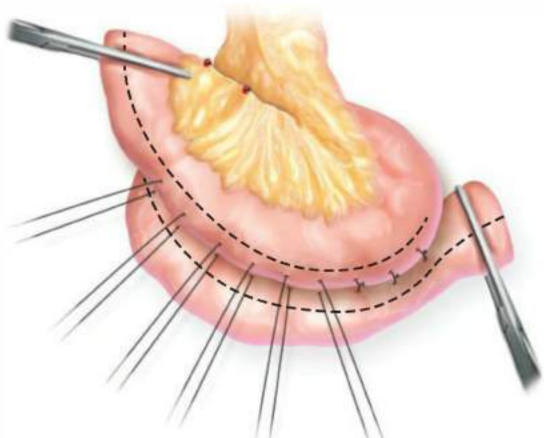

FIG 3 ● Side-to-side isoperistaltic strictureplasty. The affected bowel is first transected at the midpoint. The proximal bowel is then brought to overlie the distal segment in an isoperistaltic fashion.

FIG 4 ● Side-to-side isoperistaltic strictureplasty. An enterotomy is performed on the antimesenteric border and extended 2 to 3 cm into normal mucosa.

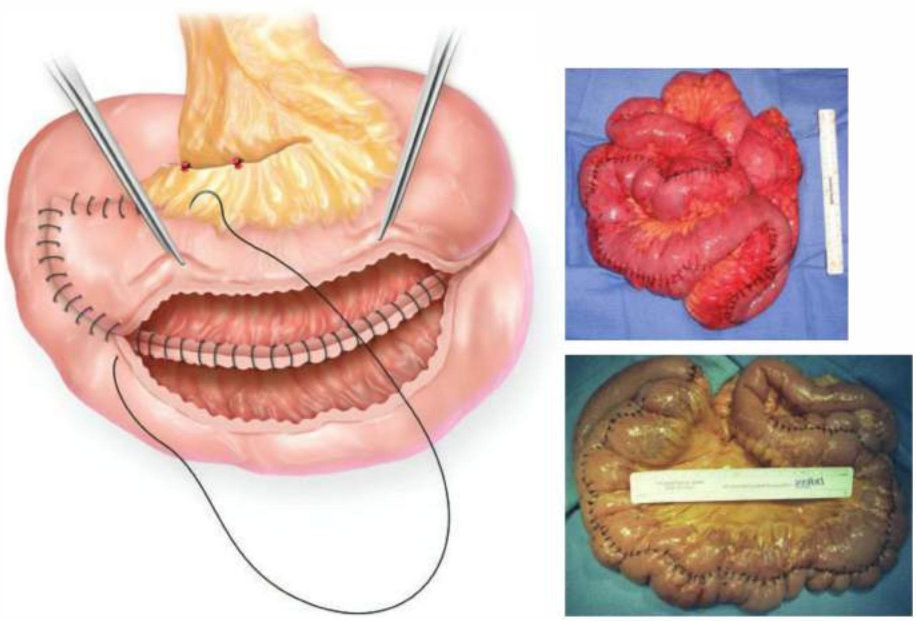

FIG 5 ● Side-to-side isoperistaltic strictureplasty. Similar to the Finney strictureplasty, tissues are brought together at both ends of the treated segment with 3-0 polyglactin sutures.

SMALL BOWEL BYPASS

Gastrojejunal Bypass

- Gastrojejunostomy is performed by bringing the most proximal loop of jejunum that easily reaches the greater curvature of the stomach. The anastomosis can be done using either a hand-sewn (**FIG 6**) or stapled technique (**FIG 7**). It can also be done antecolic or retrocolic. The antecolic approach avoids dissection through the transverse colon mesentery and also keeps the anastomosis away from the retroperitoneum.

Duodenojejunal Bypass

- A longitudinal enterotomy in the proximal jejunum is made in an area that is free of disease. A Foley catheter is inserted and passed proximally through the duodenal sweep and filled with varying amounts of water to assess for duodenal stricture. If there is a stricture isolated to

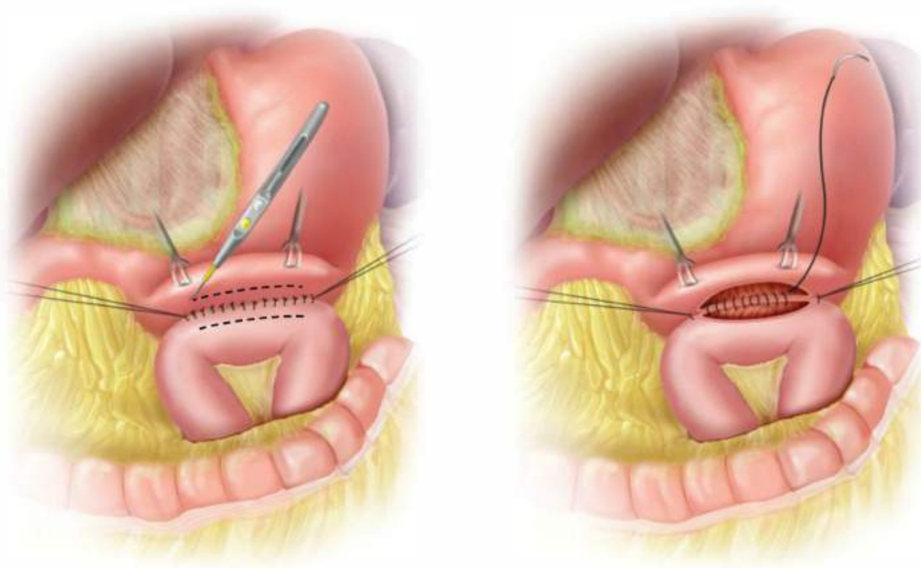

FIG 6 ● Gastrojejunal bypass: hand-sewn technique.

the third and fourth portions of the duodenum and it is determined that there is healthy, patent bowel in the first and second portion, then a bypass may be performed. A longitudinal duodenotomy is performed in the healthy portion of the duodenum. 3-0 polyglactin sutures are placed to approximate the jejunal enterotomy to the duodenotomy.

- A posterior layer of interrupted 3-0 silk sutures is placed to approximate the duodenal and jejunal segments (**FIG 8**). This is followed by a continuous inner suture layer of 3-0 polyglactin suture. A layer of interrupted 3-0 silk is then placed on the anterior surface to complete the anastomosis (**FIG 9**). The use of a stapler is not recommended.[8]

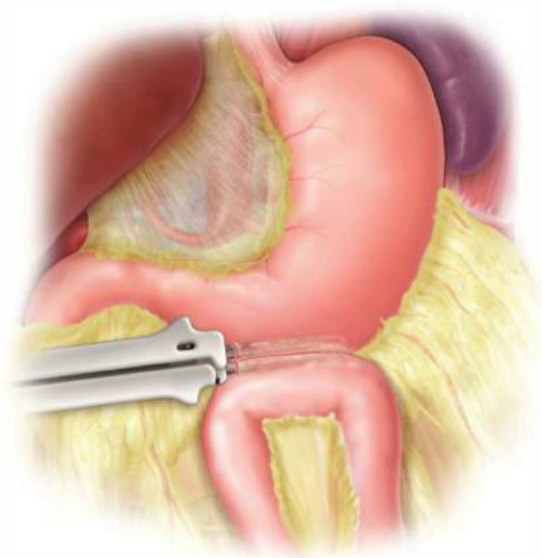

FIG 7 ● Gastrojejunal bypass: stapled technique.

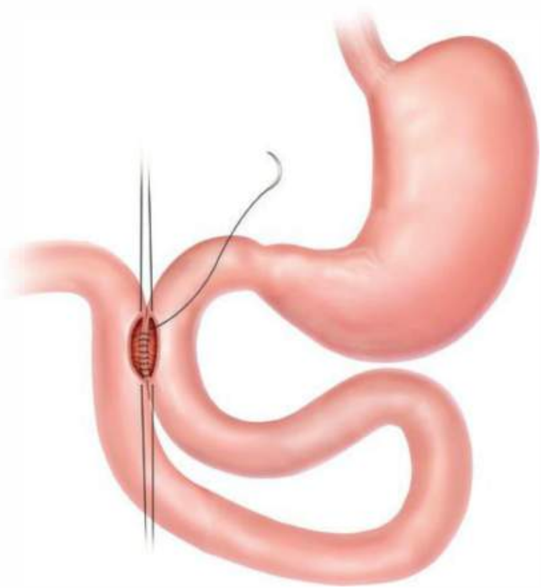

FIG 8 ● Duodenojejunal bypass: A posterior layer of interrupted 3-0 silk sutures is placed to approximate the duodenal and jejunal segments.

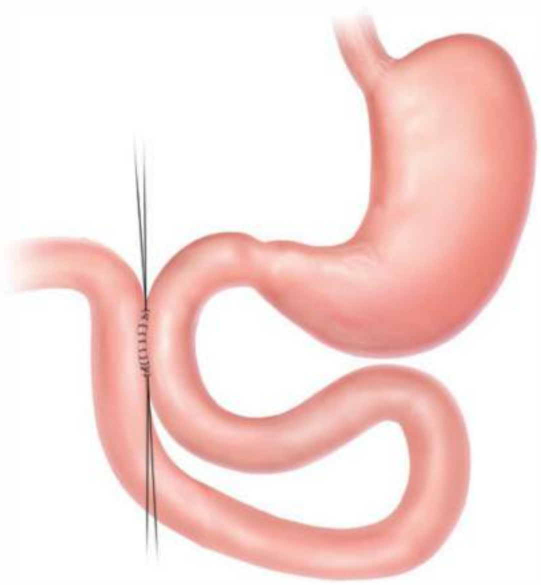

FIG 9 ● Duodenojejunal bypass: A continuous inner suture layer of 3-0 polyglactin suture and a layer of interrupted 3-0 silk are then placed on the anterior surface to complete the anastomosis.

ILEOTRANSVERSE BYPASS

- When ileocolic disease is severe and resection is deemed unsafe, an ileotransverse bypass may be performed.
- The small bowel is transected proximal to the involved ileum.
- A hand-sewn anastomosis is performed in an end-to-side fashion with the end of the transected ileum anastomosed to the side of a segment of transverse colon (**FIG 10**). This is done in a similar fashion as described for the duodenojejunal bypass. Alternatively, the anastomosis can be performed in a side-to-side fashion using a gastrointestinal anastomosis (GIA) stapler[8] (**FIG 11**).

FIG 10 ● Ileotransverse bypass: hand-sewn technique.

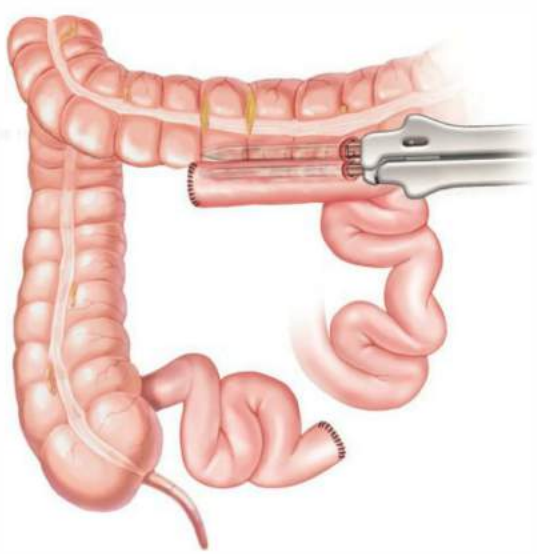

FIG 11 ● Ileotransverse bypass: stapled technique.

OTHER CONSIDERATIONS

- Duodenal strictures
  - Patients with nonperforated, nonphlegmonous strictures of the duodenum can undergo Heineke-Mikulicz strictureplasty.
  - Patients with refractory obstruction, pain, or extensive duodenal stricturing may require bypass with gastrojejunostomy or duodenojejunostomy. The role of vagotomy in this setting has been debated; however, as stated previously can most often be omitted.
  - Duodenal resection is not indicated for Crohn's disease due to its excessive morbidity.
- Colonic strictures that cannot be evaluated by colonoscopy biopsy or cytology should be resected as approximately 7% of these may contain occult malignancy.[11] Biopsy of the strictured bowel wall should be considered to evaluate for possible occult malignancy.[12]

PEARLS AND PITFALLS

Imaging	■ Preoperative imaging studies should be used to determine the extent of disease and to facilitate surgical planning. ■ Extent of active inflammation should be estimated preoperatively as this is potentially responsive to medical therapy.
Choice of procedure	■ Resection with simple reanastomosis should be performed for most patients with small bowel and ileocolic disease. ■ Strictureplasty should be performed in patients with previous resections who are at risk for short bowel syndrome or patients with diffuse or recurrent stricturing disease. ■ Bypass of affected segments is most useful for gastroduodenal Crohn's disease and should only be employed in small bowel or ileocolonic Crohn's disease if resection is deemed too unsafe. ■ When a strictured area is identified, a longitudinal incision is made and the proximal and distal bowel is evaluated with a Foley catheter to determine extent of disease. ■ Metallic clips should be placed on the mesentery at the strictureplasty sites for future identification during imaging or surgery. ■ The length of remaining small bowel should be measured and recorded, especially in patients who are having reoperations. This will help in planning during possible future operations.

POSTOPERATIVE CARE

- Patients undergoing resection, strictureplasty, or bypass for Crohn's disease often have proximally dilated small bowel. Chronically dilated intestine should be expected to have dysfunctional peristalsis, and as such, recovery of full bowel function may take up to 1 week or more. For severe obstruction, nasogastric tube decompression may be indicated. Total parenteral nutrition may also be useful in the postoperative period to allow adequate healing at anastomosis or strictureplasty sites.

OUTCOMES

- Resection: Recurrence of stricturing disease requiring surgery occurs in 25% and 50% of patients at 5 and 10 years, respectively.[1] Recurrence is unaffected by the presence of active microscopic inflammation at the resection margin and as such, only macroscopically involved segments of bowel should be resected.[10]
- Strictureplasty: Recurrence following strictureplasty occurs in 28% and 34% of patients at 3.5 and 7.5 years, respectively. Younger patients are at higher risk for recurrence following stricturoplasty.[1] Overall recurrence rates are comparable to those following resection.
- Duodenal Crohn's disease: Bypass or strictureplasty of the duodenum are relatively uncommon procedures but have been performed with good results. Major morbidity of these procedures may be as high as 27%. It is thought that use of laparoscopy to perform gastrojejunostomy may decrease complication rates.[6] Recurrence and reoperation rates are variable.

COMPLICATIONS

- Surgical site infection
- Intraabdominal infection
- Anastomotic leak
- Anastomotic hemorrhage
- Ileus
- Small bowel obstruction
- Short bowel syndrome

Chapter 3

Surgical Management of Enterocutaneous Fistula

William Sanchez

DEFINITION

- A fistula is an abnormal communication between two epithelialized surfaces. An enterocutaneous fistula (ECF) is an abnormal communication between the bowel lumen and the skin. An enteroatmospheric fistula (EAF) is the communication between the bowel and the environment, with absence of skin continuity (open abdomen fistula).
- Anastomotic leaks occurring during the first postoperative week are considered anastomotic line failures and not fistulas (no epithelialized tract has formed during that short period of time). They are usually detected because of drainage of intestinal material in the peritoneal cavity leading to the formation of an abscess or diffuse peritonitis. These patients are taken to surgery urgently either to repair the leak or to perform proximal diversion ostomies to ensure patient recovery.

CLASSIFICATION AND PROGNOSTIC FACTORS

Classification

- Anatomic: on the basis of the affected segment
  - Gastrocutaneous, duodenocutaneous, enterocutaneous, and colocutaneous
- Etiology: Multiple causes are described, including the following[1,2]:
  - Infectious and inflammatory (Crohn's disease, ulcerative colitis, tuberculosis, mycosis, diverticulitis, salmonellosis, amoebic abscess)
  - Iatrogenic (postoperative, open abdomen, postradiation)
  - Traumatic
  - Cancer
  - Foreign bodies
- Fistula output:
  - High output: more than 500 mL per day. These fistulas are associated with a severe electrolyte and nutritional abnormalities.
  - Intermediate output: 200 to 500 mL per day
  - Low output: less than 200 mL per day

FIG 1 ● Patient with open abdomen and multiple EAFs.

Prognostic Factors

- Deep EAFs drain the intestinal content into the abdominal cavity, giving rise to peritonitis. Mortality associated with this condition is higher than that of the superficial fistula that drains its content to the outside, creating an abdominal granulation wound with no diffuse contamination of the abdominal cavity.[3]
- In surgical patients with secondary fistula, we characterize the most important adverse prognostic factors associated with the course of treatment, which are analyzed following the initial resuscitation and stabilization stage (48 to 72 hours). These factors include the following:
  - Open abdomen
  - Diameter larger than 5 mm; output greater than 500 mL per day
  - Presence of abscess and/or diffuse peritonitis, generalized sepsis
  - Need for mechanical ventilation
  - Inability to provide enteral feeding
  - Presence of multiple fistulas (**FIG 1**)
  - Severe comorbidities (cancer, immunosuppression, radiation therapy, etc.)
- The probability of a spontaneous fistula closure is related to different factors summarized in Table 1. Three risk groups are then established in order to arrive at an objective determination of the degree of complexity of the fistula, the goals of the proposed treatment, and the predicted clinical course (Table 2).
  - Risk group I: good prognosis. This group includes patients with no debilitating disease who are in good general condition and no systemic inflammatory response syndrome (SIRS), with fistulas that have a good probability of closing spontaneously (diameter <5 mm, output <200 mL per day, single). Treatment is limited to support, and surgical closure is not considered initially.

Table 1: Probability of Fistula Closure

Spontaneous Closure	No Spontaneous Closure
Esophageal, duodenal stump, jejunal	Gastric, Ligament of Treitz, Ileal
Enteric wall defects <1 cm	Enteric wall defects >1 cm
Fistula tracts >2 cm	Fistula tracts <2 cm
No abdominal wall defect	Open abdomen
Albumin level >25 g/L	Albumin level <25 g/L
No FRIEND factors[a]	FRIEND factors
Output <200 ml/d	Output >500 ml/d
Conservative treatment	Surgical treatment

[a]*Nonhealing ECFs are associated with FRIEND factors: **F**oreign body, **R**adiation, **I**nflammation, **I**nfection, **I**nflammatory bowel disease, **E**pithelization of the fistula tract, **N**eoplasms, and **D**istal obstructions.*

Table 2: Fistula Treatment Outcomes, Prognostic Risk Groups

Prognostic Group	I	II	III
Degree of complexity of the fistula	Low	Intermediate	High
Goals of the proposed treatment	Spontaneous closure	Early surgical closure	Late surgical closure
Predicted clinical course (mortality)	Exceptional mortality	Mortality 10%–25%	Mortality >25%

FIG 2 ● CT scan showing aortoenteric fistula with gas around the aorta.

- Risk group II: intermediate prognosis. This group includes patients in acceptable general condition with no SIRS but with fistulas that have small probability of closing spontaneously (diameter >5 mm, output >500 mL per day, multiple fistulas). The treatment strategy is to initially stabilize the patient and subsequently perform early surgical closure.
- Risk group III: poor prognosis. This group includes patients in poor condition who are malnourished, with debilitating diseases, who exhibit SIRS, and who have fistulas with small probability of closing spontaneously. The initial goal of treatment is to reduce fistula output, to achieve granulation and ostomization of the fistula, as well as to care for the open abdomen. The surgical closure is performed at a later stage (6 to 12 months), once the patient has recovered and both objective and subjective signs of recovery are satisfactory.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- The role of imaging is to define the anatomy, evaluate associated processes, and provide therapeutic alternatives for treatment.
- Fistulograms are the most direct method of linking a cutaneous opening with the gastrointestinal (GI) tract. In the absence of sepsis, fistulograms may be the only imaging study needed. Two classes of contrast media are commonly used to evaluate the fistula tract, each with particular risks and benefits. Barium is a non–water-soluble media with high radiographic density, isotonic osmolarity, and an inert nature. Barium provides high-quality mucosal images, demonstrating areas of inflammation and the presence of fistula tracts with good accuracy. Unfortunately, if extravasated, barium causes significant peritoneal inflammation, including foreign body granulomas and peritoneal adhesions. Aqueous contrast agents, such as Gastrografin, are hyperosmolar and water-soluble. Water-soluble agents provide less mucosal detail; areas of inflammation, mucosal projections, and fistula tracts themselves may be missed. Gastrografin is rapidly absorbed within the peritoneal cavity if extravasated with minimal inflammation. To minimize risk and maximize benefits, water-soluble contrast material is often injected initially, followed by barium if no extravasation is seen and additional information is required.[1,3,4]
- Small bowel follow-through (SBFT) studies provide a more global view of the intestinal tract. Multiple views are typically taken to optimize visualization. Ideally, barium is used for contrast as Gastrografin can be diluted as it moves distally through the GI tract. Fistulas with narrow lumen and distal fistulas may not be detected in SBFT studies. Previously opacified loops of bowel may complicate visualization of the fistula.
- Ultrasound. Limitations of ultrasound include operator dependency, obesity, and difficulty of evaluating certain portions of the small bowel including duodenum and jejunum. Injection of hydrogen peroxide through the fistula orifice has been reported to increase the diagnostic accuracy of ultrasound from 29% to 88% in ECF complicating Crohn's disease.[5]
- Computed tomography (CT) allows for the identification of extraluminal pathology, downstream disease, and inflammation (**FIG 2**).
- Computed tomography enterography (CTE) uses "negative" contrast, which appears dark, allowing for distention of the bowel. With the concomitant administration of intravenous (IV) contrast that will delineate mucosa, negative contrast provides additional information concerning the mucosa surrounding a fistula tract.[4]
- Magnetic resonance imaging (MRI) is a promising adjunct to primary imaging modalities. Its use in ECF evaluation is beginning to be understood.

SURGICAL MANAGEMENT

Preoperative Planning

- The fundamental pillars for fistula management, initially described by Chapman,[6] can be summarized by the **SOWATS** acronym: management of the **S**eptic condition, **O**ptimization of the nutritional status, surgical **W**ound care, fistula **A**natomy, right **T**iming for surgery, and **S**urgical strategy.[1] By adopting this strategy, they reduced ECF mortality from 40% down to 15%.
  - **Sepsis:** Associated infection is the primary cause of death in fistula patients. The initial management of a patient with an ECF, with or without associated infection, is fluid resuscitation to address dehydration and prevent renal

failure. Blood transfusion has to be considered if required. There are two stages associated with the management of infection:

- Early stage. When a fistula is suspected or diagnosed, the goal is to prevent or control generalized contamination of the abdominal cavity and subsequent peritonitis. Treatment at this stage is surgical or percutaneous invasive therapy together with the use of antibiotics.
- Late stage. After the fistula tract has been established, the goal is to prevent or treat any secondary focus of infection, usually nosocomial (catheter-related sepsis, pneumonia, residual abscesses, etc.). Treatment at this stage is systemic or preventive.

- **Optimization of the nutritional status:** Effective nutritional support is a priority. Although parenteral nutrition may be needed in some cases, recent publications favor enteral nutrition as a protective factor against associated infections. The enteral route must be considered when it is suspected that the fistula will not close spontaneously, when it is a low-output fistula, or when it is localized in the terminal ileum or the colon. The use of somatostatin and octreotide, which lower endocrine and exocrine secretion, reduces fistula output. The use of antiperistaltic agents such as loperamide and codeine is also helpful. The basic nutritional requirements consist of carbohydrates and fats 20 kcal/kg/day and proteins 0.8 g/kg/day. Caloric and protein requirements may increase to 30 kcal/kg/day and 1.5 to 2.5 g/kg/day, respectively, in patients with high-output fistulas.[1,3]
- **Surgical wound care:** The goal of treatment is to avoid maceration and excoriation of the skin surrounding the ECF, one of the main causes of chronic pain in these patients. Multidisciplinary treatment is recommended preferably in a specialized wound clinic.
- **Fistula anatomy:** It is crucial to identify the origin and tract of the fistula in order to plan treatment. Diagnostic imaging studies with water-soluble contrast through the fistula tract or through the GI route provide accurate information about the problem. CT scans are useful to assess the entire abdominal cavity and to identify other associated problems requiring treatment (abscesses, free fluid collections, obstructions, etc.). In some cases, endoscopic evaluation is useful, given the possibility of performing therapeutic maneuvers to obliterate the fistulous tract (stent, clips, glue sealant).[7]
- **Right timing for surgery:** The decision on the right timing for the surgical closure of an ECF must be made after analyzing all prognostic variables for each individual patient. A period of 6 weeks is considered the minimum time between the development of the fistula and the surgical repair procedure because it is the time required for the patient to recover from the inflammatory response and to achieve a good nutritional status that will help avoid a new, possibly fatal, complication. Preoperative albumin level of less than 2.5 g/L is a strong adverse prognostic factor associated with mortality ($p < .001$); this result has been replicated in other series.[2] In open abdomens, the time required for regression of the inflammatory state, the nutritional recovery, and the best course of potential abdominal adhesions is between 6 and 12 months. Patients are eligible for surgery when septic foci have been treated adequately and the subjective criteria for a good clinical and nutritional condition are satisfactory. These criteria include a patient who can walk, feels well, interacts actively, and is impatiently waiting for the restorative surgery. The absence of signs of sepsis is determined by the increase in albumin and hemoglobin levels, together with lower leukocyte, reactive protein C, and thrombocytosis values.[1,3]
- **Surgical strategy:** There are multiple surgical techniques and strategies for the treatment of ECFs. There is no single technique, and the combination of several different strategies is usually required. Generally, the surgical goals include the following:
  - Fistula resection
  - Restore continuity of bowel transit.
  - Address the factors that promote fistula formation (obstruction, foreign body, tumors, diverticular disease, inflammations).
  - Abdominal wall closure
  - Perform as few anastomoses as possible, all of which need to be covered by healthy tissue and separated from other anastomosis lines.
  - Avoid the use of nonabsorbable mesh for closure of the abdominal wall.
  - Avoid leaving skin defects that might promote the formation of a new fistula.
  - Ensure adequate nutrition.

Surgical Tips

- In established fistulas with a defect larger than 5 mm in diameter and an output greater than 500 mL per day, attempting a primary closure with sutures is often ineffective and may increase the size of the damage to the intestinal wall. In order to attempt the primary closure of the fistula, all granulation tissue at the edges must be removed, the closure must be done under no tension, and the defect must be covered.
- No balloon catheters (Foley) must be introduced or inflated inside the fistula tract or the gut lumen because this will increase the size of the fistula. When the fistula is close to the ligament of Treitz, a feeding tube may be introduced distally for enteral nutrition.
- In fistulas with an open abdomen, the use of the Bogota bag is not very effective because it does not allow for control of ongoing contamination of the abdominal cavity and there is persistence of skin erosion. These problems are solved with the use of the wound vacuum-assisted closure (VAC®) system (the right foam must be selected in accordance with the clinical situation). In some cases, VAC® therapy together with other strategies results in primary closure of the fistula. If primary closure is not achieved, VAC® therapy promotes granulation and wound healing, maturation of the fistula into a controlled stoma, and patient recovery so that surgical closure and abdominal wall reconstruction may follow (**FIGS 3–5**).[8,9]
- Patients with ECF difficult to reach and/or control (i.e., ECF in frozen open abdomen, duodenal fistulas, aortoenteric fistula, etc.) can develop ongoing peritonitis leading to persistent sepsis. Attempting extensive surgery (pancreatoduodenectomy, diverticulization, etc.) or multiple diversions in this setting usually results in a poor outcome and

FIG 3 ● Soldier wounded in combat with multiple intraabdominal injuries and complex ECF.

FIG 4 ● Wound VAC® therapy is very effective to allow control of fistula fluids or of contamination of the abdominal cavity.

FIG 5 ● Wound VAC® therapy promotes granulation, wound healing, and control of the fistula. This allows the patient to recover in preparation for surgical closure and abdominal wall reconstruction.

extremely high mortality rates. In these critical situations, we pass a self-expandable coated stent or an impermeable corrugated prosthetic tube through the fistula defect and into the intestinal lumen in an attempt to seal off the fistula, to restore intestinal transit, and to prevent ongoing soilage of the peritoneal cavity. The use of the wound VAC® therapy in this setting collects any spillage of bowel fluid leaks that may occur and promotes granulation and healing of the abdominal cavity. Surgery must be performed at an early stage, before the patient goes into multiple organ failure and is beyond rescue. After the patient recovers (weeks or months later), and if the fistula has closed, an attempt is made to recover the prosthesis through enteroscopy or surgery. If the fistula has not closed, the relevant repair surgery is planned. The introduction of this concept is controversial, but its use may be acceptable in extreme situations, based on the wide clinical experience with the use of stents or shunts in other GI, vascular, and colonic diseases (**FIG 6**).[10]

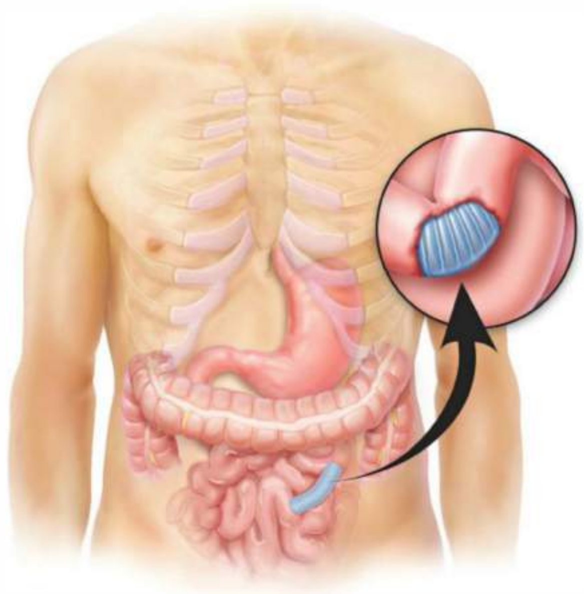

FIG 6 ● Use of a stent or corrugated prosthetic tube with intestinal bypass in a patient with a complex fistula in the fourth portion of duodenum.

SURGICAL CLOSURE OF COMPLEX ENTEROATMOSPHERIC FISTULA

Step 1. Peritoneal Contamination Control

- Remove the Bogota bag (**FIG 7**), wash and clean the abdominal cavity, and then place a tube for enteral feeding, covering the open abdomen partially with a wound VAC® system (**FIG 8**).

FIG 7 ● Temporary abdominal closure with a Bogota bag.

Step 2. Granulation of the Abdominal Wound and Conversion of the Fistula into a Stoma

- Continue with wound VAC® therapy until the peritoneal contamination is under control, promoting granulation of the abdominal wound (**FIG 9**). The end point of this step is to achieve conversion of the fistula into a functional stoma (**FIG 10**).

Step 3. En Bloc Resection of the Fistula and Abdominal Wound

- En bloc dissection is performed of the entire abdominal scar component and the fistula, working inward from the surface (**FIG 11A,B**).

FIG 8 ● Placement of feeding tube and a wound VAC® system.

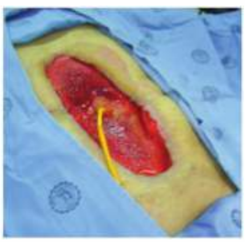

FIG 9 ● This strategy allowed for excellent granulation tissue to form around the ECF in the open abdominal wound.

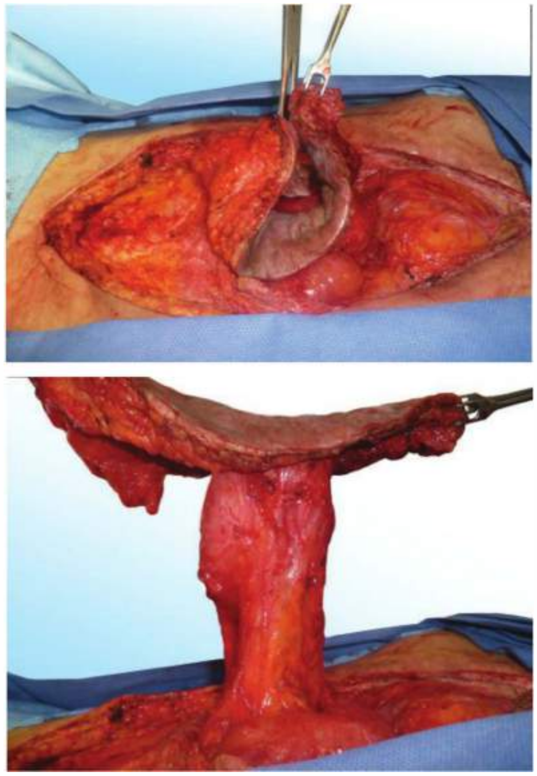
FIG 10 ● The end point of therapy prior to surgical excision of the ECF is when the fistula has been transformed into a stable stoma.



A

B

FIG 11 ● **A,B.** En bloc dissection of ECF and granulation tissue bed.

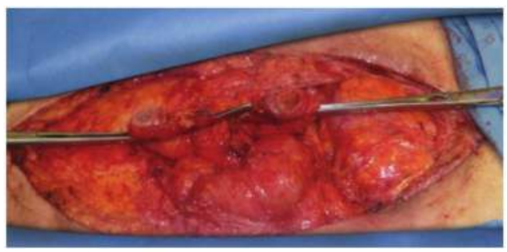


FIG 12 ● Resection of the ECF.

Step 4. Reconstruction of the Intestinal Transit and the Abdominal Wall

- The ECF is then resected (**FIG 12**), and the intestinal tract is reconstructed with a hand-sewn (**FIG 13**) or stapled technique (**FIG 14**). The abdominal wall is reconstructed using partially absorbable mesh with carboxymethyl cellulose coating or, preferably, with a biologic coating (**FIG 15**).

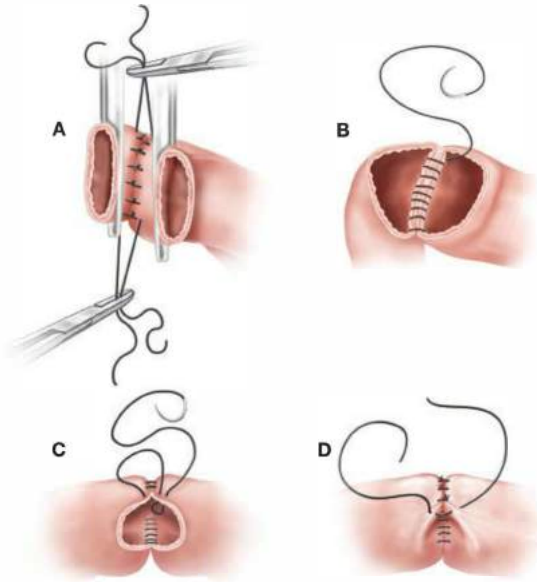

FIG 13 ● Reestablishment of intestinal continuity. End-to-end hand-sewn anastomosis technique.

FIG 14 ● Reestablishment of intestinal continuity. Side-to-side stapled anastomosis technique.

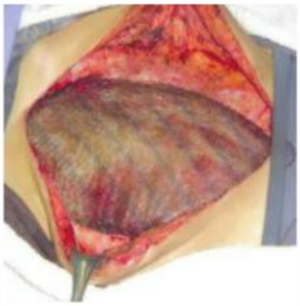

FIG 15 ● The abdominal wall is reconstructed using partially absorbable mesh with carboxymethyl cellulose coating.

NONSURGICAL CLOSURE OF A COMPLEX ENTEROATMOSPHERIC FISTULA

- A newborn, 31 weeks of gestation with necrotizing enterocolitis, develops EAF after right hemicolectomy (**FIG 16**). In patients such as this one, with otherwise no significant comorbidities, a nonsurgical approach to ECF closure may be attempted.

Step 1: Peritoneal Contamination Control

- Start with general resuscitation measures and use of the SOWATS protocol. Control contamination and intestinal fluid leaks using wound VAC® therapy (**FIG 17**).

Step 2: Granulation of the Abdominal Wound and Fistula Control

- Continue the wound VAC® therapy until the peritoneal contamination is under control, promoting granulation of the abdominal wound, and channel the fistula to reduce output gradually (**FIG 18**).

Step 3. Closure of the Fistulous Tract Using Fibrin Glue

- Once the fistula output is down to a minimum, fibrin glue is applied through the fistula tract (**FIG 19**). Continue with general measures and wound VAC® therapy until healing of the fistula and closure of the abdominal wall are achieved (**FIG 20**).

FIG 16 ● Newborn with ECF secondary to necrotizing enterocolitis.

FIG 17 ● A wound VAC® has been placed to control the fistula, protect the skin, and promote granulation tissue formation.

FIG 18 ● Excellent granulation tissue has been achieved.

FIG 19 ● Fibrin glue application into the fistula tract to accelerate ECF closure.

FIG 20 ● Full healing of ECF after nonoperative management of ECF fistula.

PEARLS AND PITFALLS

Burn injury	■ An ECF may occur from a bowel lesion created inadvertently by diathermia during open or laparoscopic surgery (**FIG 21**).
Suture line protection	■ Anastomotic lines should not be in contact with other suture lines or prostheses. An omental pedicle flap is a good option to protect the anastomosis. Although the use of fibrin glue sealants has also been advocated for this purpose, there is no conclusive evidence in the literature about their benefit.
Use of nonabsorbable mesh in direct contact with the bowels should be avoided.	■ A good option is to use biologic mesh or synthetic mesh coated with carboxymethyl cellulose (nonadherent).
Fistulas secondary to adhesions	■ The prophylactic use of antiadhesive substances, such as carboxymethyl cellulose and hyaluronic acid, has been shown to reduce the presence and degree of complexity of the adhesions and, consequently, lower the possibility of fistula formation secondary to surgical injuries.[11]
Open abdomen–related fistulas (25% incidence)	■ The fistula forms as a result of direct injury, desiccation, or erosion due to foreign bodies that become incorporated into the gut wall (Packing, Wittmann Patch). Partial coverage of the abdominal cavity using the VAC® system is a good option for lowering the probability of fistula formation.[8,9]

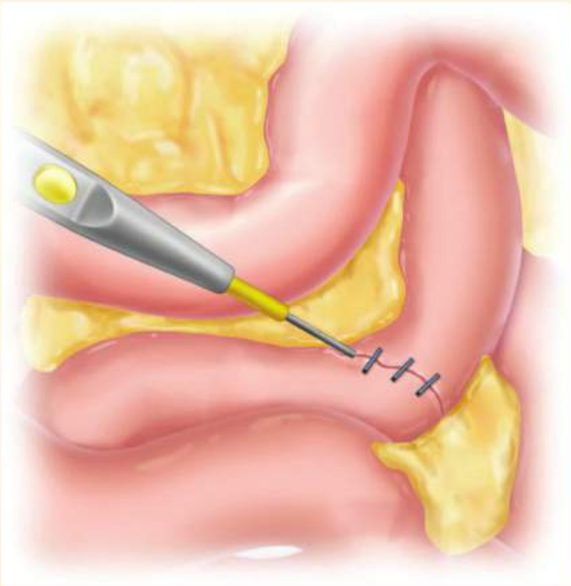

FIG 21 ● A fistula may originate from a bowel lesion created inadvertently by diathermia.

COMPLICATIONS

- **Local:** abscess, diffuse peritonitis, other fistulas, bleeding from erosion of adjacent structures, skin damage
- **Systemic:** fluid and electrolyte imbalances, malnutrition, abscess of distant solid viscera (liver, lung, brain), sepsis, SIRS

CONCLUSION

- Currently, the main causes of ECFs are those associated to the complications of surgery. Review and practice of prophylactic surgical tips can reduce its incidence.
- The treatment of fistulas must be multidisciplinary. Adherence to a driving guide, such as SOWATS, allows for a sequential and ordered therapeutic strategy with an increased chance of better clinical outcomes.
- Patients with intestinal fistulas should be categorized into risk groups in order to predict its prognosis and to define the management strategy necessary. There is no one single standard treatment; the selection of the treatment depends on the individual condition of each patient and the characteristics of the fistula itself.

Chapter 4

End and Diverting Loop Ileostomies: Creation and Reversal

Kathrin Mayer Troppmann

END AND DIVERTING LOOP ILEOSTOMIES: CREATION

DEFINITION

- An ileostomy is an artificially created opening of the distal ileum that is externalized on the abdominal wall. It can be temporary or permanent.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough review of the patient's history and a physical examination, including a review of all past operative notes and diagnostic studies, are necessary to carefully select patients who are appropriate candidates for an ileostomy and to determine the most appropriate type of ileostomy to be created.
- The history and the physical examination should be obtained with the functional and anatomic implications, treatment plan, and prognosis of the underlying disease in mind.
- Additionally, the patient's comorbidities, ability to perform activities of daily living and self-care, mobility limitations, and body contour must be thoroughly assessed.

PREOPERATIVE IMAGING AND OTHER DIAGNOSTIC STUDIES

- Appropriate imaging studies must be obtained according to the patient's underlying disease and diagnosis. Any abnormal findings should be thoroughly worked up to ensure that the correct operation and diversion techniques are chosen. These tests may include the following:
  - Colonoscopy with biopsy if malignancy or inflammatory bowel disease is suspected
  - Computed tomography (CT) scan, upper gastrointestinal contrast study, and fistulogram to rule out intestinal obstruction or leak and to assess underlying disease severity
  - Anal manometry and endorectal ultrasound to evaluate the anal sphincter
  - Colonic motility study (e.g., SITZMARKS® test) to identify the region of intestinal dysmotility and to tailor the procedure and type of stoma to the patient's needs
  - Prior to ileostomy formation, the nutritional status must be assessed (including albumin and prealbumin levels) and the patient's comorbidities must be addressed (e.g., coronary artery disease, diabetes [HbA_{1c}]) in order to minimize perioperative risk.

SURGICAL MANAGEMENT

General Considerations

- If possible, a stoma should be avoided, as the morbidity of creation and reversal can be significant.
- An ileostomy can be constructed as an end ileostomy (Brooke ileostomy) or as a diverting loop ileostomy. Alternatives to the more commonly used end and loop ileostomy techniques include the divided (or separated) loop ileostomy for maximizing fecal diversion and the end-loop (or loop-end) ileostomy for patients with a short, contracted mesentery and vascular pedicle.
- An end ileostomy is the preferred configuration for a permanent ileostomy because it allows for a symmetric and protruding spout that is more easily constructed and managed.
- Permanent end ileostomies are usually created when the distal intestine is not suitable for restoration of intestinal continuity due to underlying disease or poor intestinal function. Typical scenarios include:
  - Following total proctocolectomy for inflammatory bowel disease or familial adenomatous polyposis
  - Following subtotal colectomy for slow-transit constipation with concomitant severe pelvic floor dyssynergia
  - Fecal incontinence
  - Congenital anomalies
- Temporary end ileostomies are typically created under the following circumstances:
  - Following subtotal colectomy for acute diverticular bleeding or ulcerative colitis–related toxic megacolon
- Temporary or permanent diverting loop ileostomies are created when diversion of the fecal stream and decompression of the distal bowel are necessary:
  - Following distal ileal or colonic anastomoses at high risk for disruption due to:
    - Malnutrition or immunocompromised status
    - Anastomotic location within an irradiated, inflamed, or contaminated field
    - Low pelvic anastomotic location following sphincter-preserving procedures (e.g., ileal pouch-anal anastomoses, coloanal or low colorectal anastomoses)
  - Disruption of a previously created distal anastomosis
  - Distal bowel perforation
  - Pelvic sepsis
  - Rectal trauma
  - Complicated diverticulitis
  - Following anal sphincter reconstruction
  - Following rectovaginal fistula repair
  - Fecal incontinence
  - Severe radiation proctitis
  - Obstructing or nearly obstructing colorectal cancer, carcinomatosis, and Crohn's disease
  - Sacral decubitus ulcer
  - Necrotizing perineal and gluteal soft tissue infections.

Preoperative Planning

- The ideal stoma has no necrosis, prolapse, or retraction. Daily output ranges from 500 to 1000 mL, the appliance does not leak, and the skin is healthy. The importance of appropriate planning to ensure an optimal ileostomy location and to maximize the opportunity for creation of a viable, tension-free, and well-functioning ileostomy cannot be overemphasized. Attention to these principles will decrease the time required for stoma management and minimize patient frustration.

- A comprehensive discussion with the patient about the proposed ileostomy procedure, alternatives, and postoperative lifestyle is imperative.
- Most stoma patients are elderly and many have their stoma care performed by a spouse, offspring, or caretaker; it is thus critical to involve these providers in the stoma education process.
- Ideally, patients must be mentally and physically ready for a stoma and must therefore be informed as early as possible in their course of the disease regarding the potential need for a stoma. For many patients, though, an ileostomy is created in an acute setting at the end of a long, often life-saving procedure.

Stoma Education

- A comprehensive perioperative educational program decreases readmissions and complications related to dehydration and appliance problems and optimizes postoperative patient satisfaction and participation in activities of daily life.
  - Wound ostomy continence nurse (WOCN) or enterostomal therapy (ET) nurse
    - Optimal stoma management begins with preoperative patient education in regard to diet, activities, clothing, and sexuality. The nurse can provide emotional and physical support. The patient must be informed that self-care may be awkward initially but that it can be learned and mastered.
  - Patient support groups, United Ostomy Association visitor
    - Patients should be introduced to other individuals with ileostomies who have similar socioeconomic and disease backgrounds. These encounters and relationships can help to improve morale and can reassure patients that they can have a satisfactory quality of life. Meetings should occur pre- and postoperatively (particularly during the first 3 to 6 months).
  - Stoma preparedness literature
    - The American College of Surgeons has created a comprehensive stoma preparedness kit including an educational DVD and manual, a stoma model, and stoma appliance samples.

Stoma Site Marking

- The stoma location must be carefully planned to minimize complications and to prevent leakage.
- The patient may wear the stoma appliance faceplate prior to the operation. The optimal location of the stoma should be assessed with the patient standing, sitting, and bending. Where does the patient wear the waist of the pants? Range of motion and physical limitations must be evaluated to determine if the patient can visualize the stoma and can manipulate the appliance (e.g., the site may be placed higher on the abdomen for a wheelchair-bound patient). Care must be taken to avoid stoma placement beneath an abdominal pannus to ensure that the stoma remains visible and easy to access for the patient or caretaker.
- In general, the ileostomy should be placed through the rectus muscle (to minimize parastomal herniation), at the summit of the right paramedian infraumbilical fat pad. The umbilicus, bone, scars, skin folds, and abdominal panni should be avoided (**FIG 1**). The skin site can be identified with a permanent marker and a scratch can be made with a small needle.

Intraoperative Positioning

- Supine or lithotomy position may be used based on the need for an adjunctive procedure for assessment of the colon, rectum, or perineum prior to ileostomy creation (e.g., colonoscopy).

Antibiotic Prophylaxis

- Intravenous antibiotics must be given prior to the incision.

FIG 1 ● Preoperative marking of the ileostomy site. The ileostomy is placed in the right lower quadrant of the abdomen in a right paramedian, infraumbilical position.

CREATION OF AN END ILEOSTOMY

- Meticulous construction of an end ileostomy is paramount because the ileal contents are liquid, bilious, and voluminous. An everted, spout-shaped end ileostomy (Brooke ileostomy) is best suited to address these challenges.

Abdominal Wall Skin Incision for Exploratory Laparotomy and/or Bowel Resection

- If an abdominal incision for bowel resection is necessary, a left paramedian skin incision can be made and angled toward the midline. The abdomen can then be entered through the linea alba. This approach maximizes the distance and amount of skin between the ileostomy and the skin incision.

Ileal Mobilization

- The ileum is prepared by releasing the lateral attachments along the pelvic brim and by fully mobilizing the embryonic root of the terminal ileal mesentery to the level of the duodenum.

Stoma Site Skin Incision

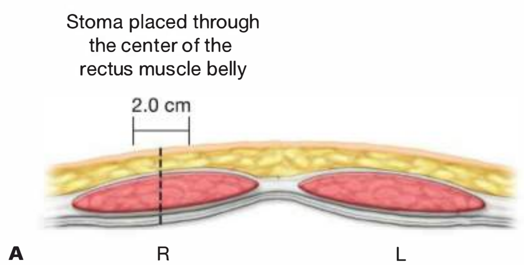
- Following the intestinal resection, the skin opening is created in the right lower quadrant at the premarked site. The skin is grasped with a Kocher clamp and a circular skin incision of 2 cm in diameter (**FIG 2A**) is made tangentially beneath the Kocher clamp with a no. 10 blade. The excised skin disc is removed.

Abdominal Wall Aperture Creation for the Stoma

- Bovie electrocautery is used to perpendicularly divide the subcutaneous fat in the right paramedian plane at the ileostomy site. Handheld retractors can be gently used. The subcutaneous fat should be preserved as much as possible.
- The anterior rectus sheath is identified and incised in a cruciate fashion for approximately 1 cm in both directions. (The horizontal limb should not be placed too close to the midline.)
- Mayo clamps are used to split the rectus muscle bluntly in order to expose the posterior rectus sheath and peritoneum. The rectus muscle fibers are not divided (**FIG 2B**).
- The surgeon places one hand into the abdominal cavity behind the marked stoma site to protect the abdominal contents.
- The abdominal cavity is entered through the stoma incision with a thin-point clamp (e.g., Schnidt or tonsil clamp).
- The defect in the posterior rectus sheath and peritoneum is widened to allow for passage of the ileum without compromising its mesenteric blood supply. The appropriate defect size is obtained by digitally dilating the stoma site with the tips of two digits to create an approximately 2-cm aperture (**FIG 2C**).

Ileal Limb Preparation and Placement

- At least 6 cm of viable distal or terminal ileum with the adjacent marginal artery should be preserved to maintain an optimal blood supply. The mesentery should not be stripped (**FIG 2D**). The ileal limb preparation should be performed as early as possible during the course of the operation to allow for sufficient time to observe and assess the ileum's vascularity. The mesentery must be handled gently to avoid hematomas and mesenteric vascular injury.
- The ileum is gently advanced (pushed rather than pulled) through the split muscle and the abdominal wall to about 4 cm beyond the skin level (using a Babcock clamp to grasp the ileum only if necessary). If the ileum and adjacent tissues are too bulky to pass easily through the aperture, the epiploic fat can be excised.
- To facilitate a future ileostomy reversal procedure, an adhesion barrier (e.g., Seprafilm®) can be used at the time of ileostomy creation. The adhesion barrier is wrapped around the ileal limb used for the ileostomy, extending along the intraabdominal ileal segment for approximately 5 cm.
- The ileal mesentery may be secured to the peritoneum over a length of 3 to 4 cm if a permanent stoma is planned. (This step may prevent torsion, retraction, and prolapse of the ileum.)



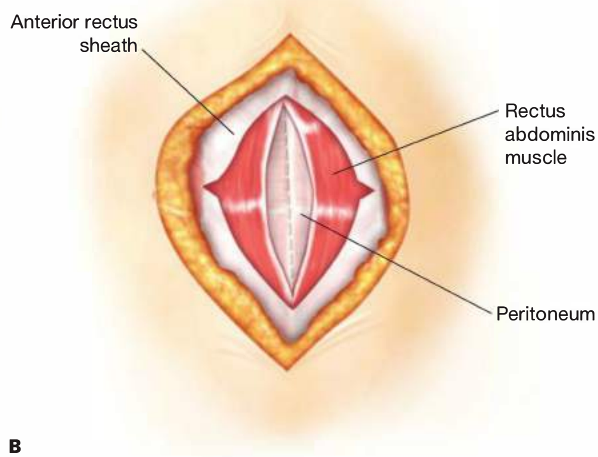


FIG 2 ● Creation of an end ileostomy. **A.** A circular skin incision for the ileostomy is made over the center of the rectus muscle belly and carried through the subcutaneous fat. **B.** A cruciate incision is made in the anterior rectus sheath to expose the underlying rectus muscle. The rectus muscle is split bluntly along the direction of its fibers to expose the posterior sheath and peritoneum. *(continued)*

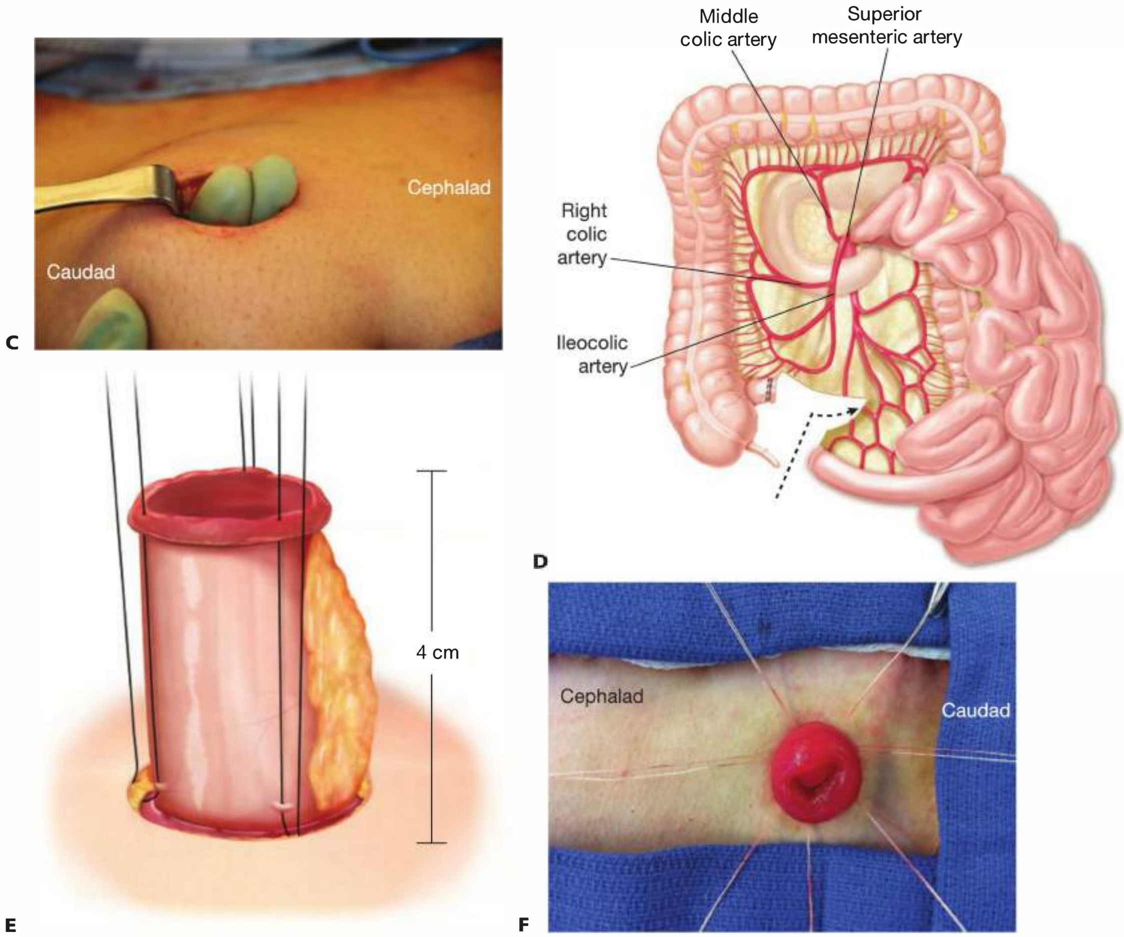

FIG 2 ● *(continued)* **C.** The peritoneum is incised longitudinally and the incision is widened by stretching it with two digits to obtain the desired aperture. **D.** The vascular end arcade and the mesentery are preserved on the ileal segment that is to be used for the end ileostomy *(dotted arrow)*. **E.** The ileum is advanced through the abdominal wall stoma aperture so that it protrudes for about 4 cm beyond the skin level. Following removal of the staple line, three-point sutures are placed through the end of the ileum (full thickness), the seromuscular layer at the base of the stoma 4 cm from the end of the ileum, and the dermis, respectively. No epidermis should be included in stitch. **F.** The sutures are placed circumferentially. They are only tied after all of them have been placed, everting the ileum to create a 2-cm–high ileostomy.

- Both edges of the rectal stump (or other potentially remaining distal bowel segment) are tagged with polypropylene suture to facilitate identification of the distal intestinal segment for potential ileostomy reversal.
- To prevent wound contamination, the surgical abdominal incision is closed next and then covered with a protective wound dressing prior to maturing the stoma.

Stoma Maturation

- The staple line is removed from the ileum.
- 3-0 absorbable (e.g., Vicryl®) interrupted stitches are placed (but not immediately tied), with the stitches running through the following three points (**FIG 2E**):
  - end of the ileum (full-thickness)
  - skin-level base of the stoma (4 cm from the end of the ileum) (seromuscular layer)
  - Dermis (large bites of the subcuticular layer should be avoided to prevent "buttonholing" and mucosal islands).
- One stitch is placed in each quadrant followed by one stitch between each quadrant stitch for a total of seven to eight stitches. Ensure that one stitch is on each side of, and adjacent to, the mesentery (but not through the mesentery).
- To allow for more precise placement, each stitch should be individually tagged and tied only when all stitches have been placed. The subcutaneous and mesenteric fat can be tucked in as each suture is tied. The goal is to create a stoma with a spout that protrudes about 2 cm beyond the skin level when completed (**FIG 2F**).
- The ileostomy appliance is placed over the stoma. Waterproof, nonallergenic tape can be used to further secure the edge of the appliance to the skin.

CREATION OF A LOOP ILEOSTOMY

Stoma Site Skin Incision and Abdominal Wall Aperture Creation

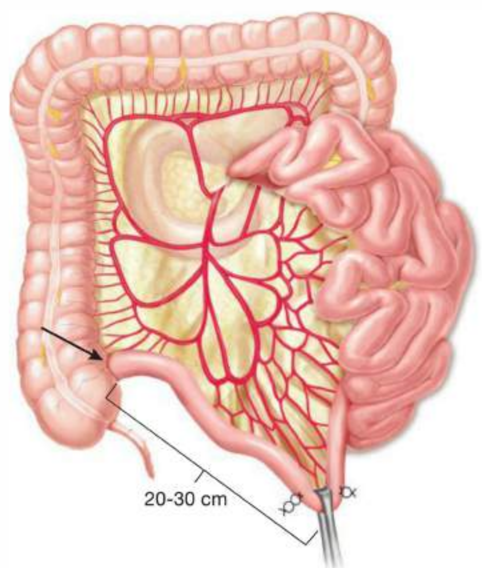
- The skin incision for a loop ileostomy is similar to the incision for an end ileostomy, except that it can be made slightly longer and slightly oblong. In obese patients, some of the subcutaneous tissues may have to be excised down to the fascia in the shape of a cone (apex at skin level) so as to not constrict the afferent and efferent limbs of the loop ileostomy.

Ileal Limb Preparation and Placement

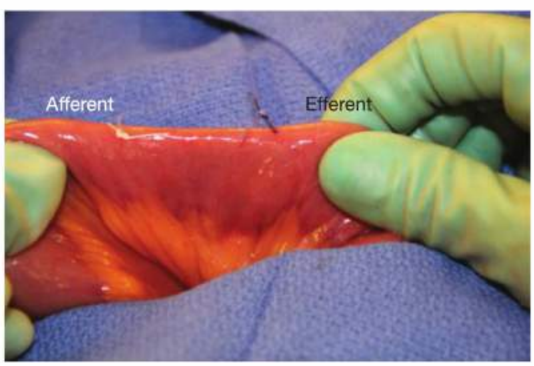
- An ileal segment 20 to 30 cm proximal to the ileocecal valve is identified. The segment is selected so as to maximize mesenteric pedicle length and to avoid compromising the ileocecal valve. The segment's mesentery and vasculature are preserved (**FIG 3A**).
- Two different orienting sutures are placed on the antimesenteric side of the ileum to mark the afferent and efferent side of the ileal segment (e.g., by using sutures of different colors, or sutures with one knot for the afferent segment and two knots for the efferent segment) (**FIG 3B**).
- An umbilical tape is passed behind the ileum at the ileal-mesenteric interface. The ileal loop is advanced through the abdominal wall using the umbilical tape as a guide, taking care to maintain proper orientation and to avoid torsion.
- The afferent (productive) limb of the loop ileostomy is placed inferiorly so that its spout will be located on the caudal aspect of the stoma. This requires a partial (about 90 degrees) twist for correct orientation. Alternatively, the afferent limb can be placed on the medial or superior side of the stoma site, depending on surgeon preference and amount of tension on the ileostomy.
- Optionally, sutures may be placed between the ileal mesentery and peritoneum to maintain the appropriate rotation specially in obese patients.
- The umbilical tape is removed and may optionally be replaced with a supporting rod or a 6-cm segment of red rubber catheter (which may be looped and sutured to itself above the loop ileostomy or secured to the skin).
- To prevent contamination of the laparotomy incision, the surgical abdominal incision (midline or left paramedian) is closed next and a protective wound dressing is placed prior to stoma maturation.

Stoma Maturation

- It is important to create an adequate spout on the afferent bowel limb.
- First, the efferent (distal) limb of the ileum is transversely incised 1 cm above the skin surface for approximately 75% of the circumference of the ileum to allow for appropriate stoma eversion (**FIG 3C**). This allows for a large "hood" and for the os on the afferent productive limb to be larger (encompassing 80% to 90% of the ileostomy) than the os of the efferent limb.



A



B

FIG 3 ● Creation of a loop ileostomy. **A.** An ileal segment that is 20 to 30 cm proximal to the ileocecal junction *(arrow)* is identified. The segment's mesentery and vasculature are preserved. **B.** Marking sutures (e.g., sutures of different colors or with differing numbers of knots) are placed on the afferent and efferent limbs. The ileum is advanced through the abdominal wall stoma aperture so that it protrudes for about 3 to 4 cm beyond the skin level. *(continued)*

TECHNIQUES

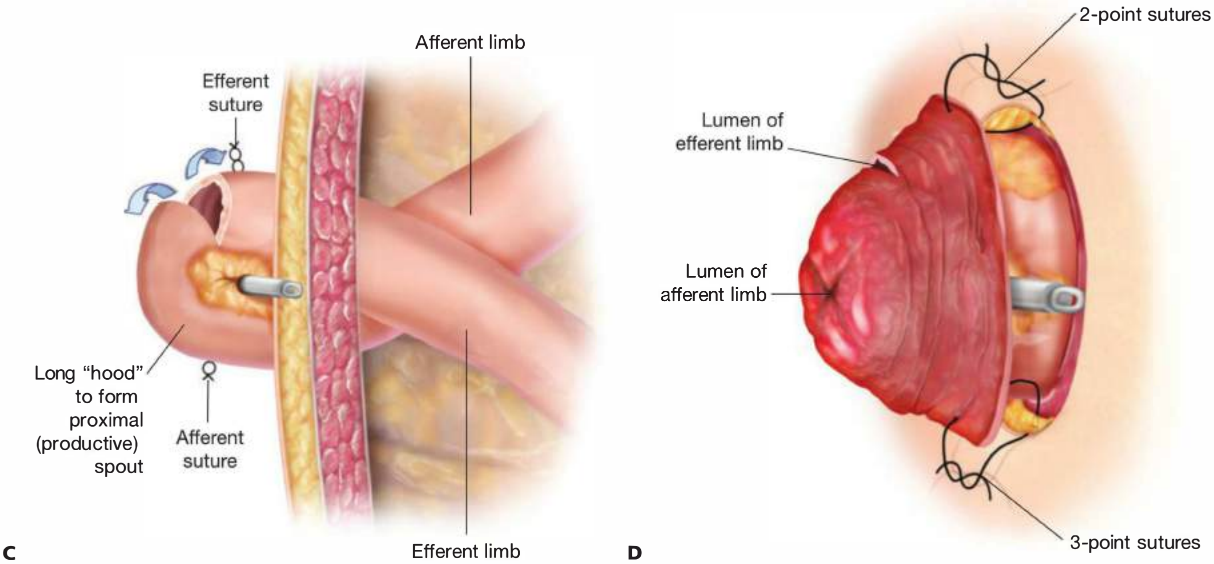


FIG 3 ● *(continued)* **C.** The ileum is incised 1 cm above the skin level on the efferent limb side for 75% of the circumference to create a large afferent spout. **D.** The loop ileostomy is matured by placing two-point sutures (full thickness through the end of the ileum and the dermis) on the efferent limb and three-point sutures (full thickness through the end of ileum, the seromuscular layer at the base of stoma, and the dermis) on the afferent limb to evert the ileum.

- The stoma is created and matured with 3-0 absorbable suture (e.g., Vicryl®). First, the efferent stoma is sewn flush with the dermis by using a two-point suturing technique, with each stitch taking a full-thickness bite through the cut edge of ileum and then through the dermis. Next, the afferent stoma is matured with a three-point suturing technique as already described in principle for the end ileostomy (**FIG 3D**). The main difference with an end ileostomy is that for a loop ileostomy, the seromuscular stitches at the base of the afferent stoma are closer to the stoma's os (about 3 to 4 cm) and the stoma spout may thus not protrude quite as much as with an end ileostomy. Also, sutures cannot be placed on the posterior bridge of ileum that joins the afferent and efferent limbs.
- Optionally, as the sutures are tied, the spout can be formed over a supporting rod (or catheter), which is left in place for 3 to 5 days postoperatively.
- The edge of the aperture in the ileostomy faceplate is placed beneath the rod or catheter.

CREATION OF A DIVIDED LOOP ILEOSTOMY

- A divided (or separated) loop ileostomy is an alternative technique for creating a protecting loop ileostomy; it may result in a more complete fecal diversion.

Stoma Site Skin Incision and Abdominal Wall Aperture Creation

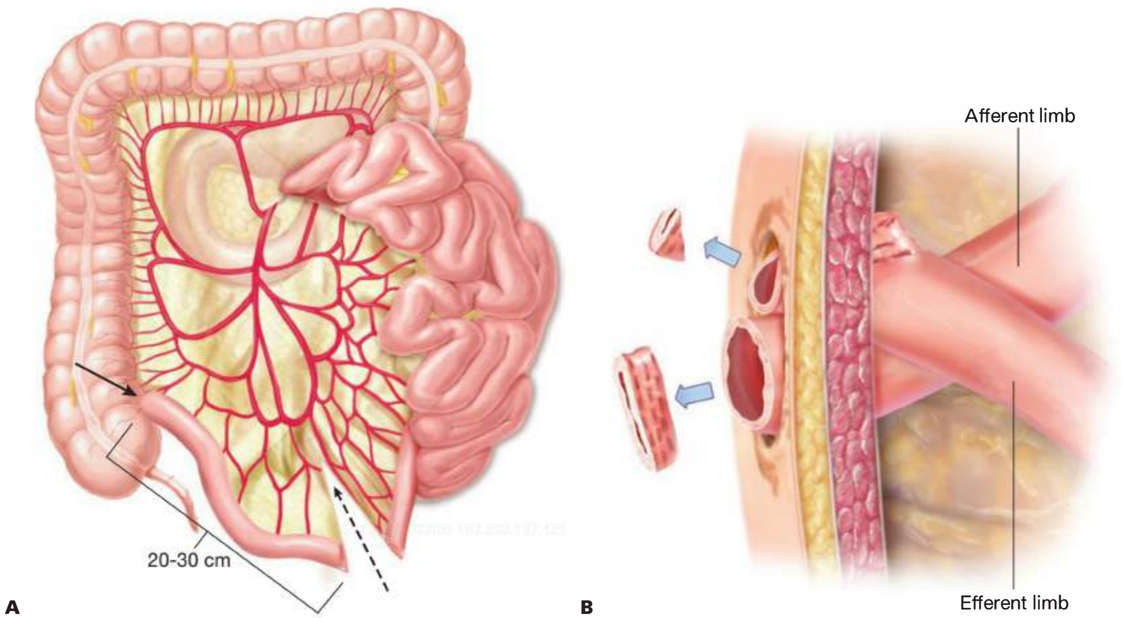
- The skin incision and abdominal wall aperture are created as for a loop ileostomy.

Ileal Limb Preparation and Placement

- The ileum is divided with a linear cutting stapler 20 to 30 cm proximal to the ileocecal valve. The mesentery and vasculature are only minimally divided (**FIG 4A**).
- The stapled afferent limb is advanced through the abdominal wall aperture so that it protrudes 4 cm beyond the skin and the staple line is removed. Only the antimesenteric corner of the efferent limb is externalized, thus minimizing the need for division of the mesentery (**FIG 4B**).

Stoma Maturation

- Afferent limb—The stoma is constructed in the same manner as described for an end ileostomy, using a three-stitch technique (**FIG 4C**).
- Efferent limb—The antimesenteric corner is excised to decompress the distal bowel if desired. A two-stitch technique is then used, placing sutures that encompass the full-thickness edge of the ileum and the dermis. Alternatively, the efferent limb can remain stapled closed if complete fecal diversion is desired.



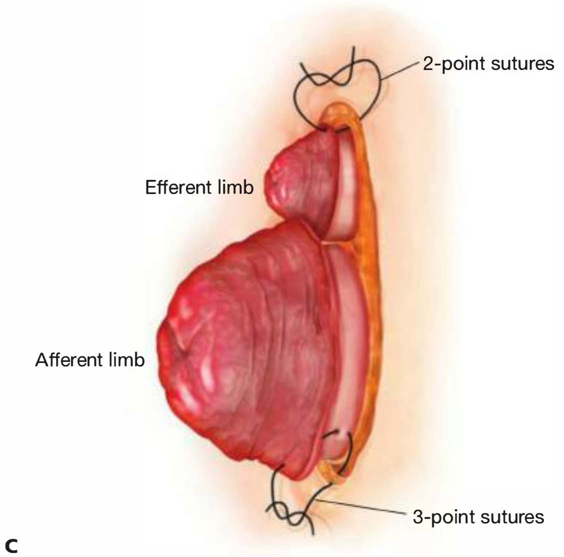


FIG 4 ● Creation of a divided loop ileostomy. **A.** The ileum is divided using a linear cutting stapler, 20 to 30 cm proximal to the ileocecal valve *(solid arrow)*. The mesentery and vasculature are only minimally divided *(dotted arrow)*. **B.** The stapled afferent limb is advanced through the abdominal wall aperture so that it protrudes for about 4 cm beyond the skin level, and the entire staple line is then cut off. Optionally, if distal decompression is desired for the efferent limb, only the antimesenteric corner is externalized, excised, and matured. The staple line may also be left intact on the efferent limb for total diversion. **C.** The afferent limb of the ileostomy is matured with three-point sutures. The efferent limb can be matured with two-point sutures.

CREATION OF AN END-LOOP ILEOSTOMY

- An end-loop (or loop-end) ileostomy is functionally not different from an end ileostomy, but the stoma maturation is akin to the technique for a loop ileostomy. An end-loop ileostomy allows for preservation of an adequate mesenteric blood supply when the mesentery would otherwise be too short for adequate advancement through the abdominal wall (e.g., in case of a shortened mesentery or a thickened abdominal wall). This technique is often used in obese patients and those with prior operations.

Stoma Site Skin Incision and Abdominal Wall Aperture Creation

- The skin and stoma site are prepared as described for a loop ileostomy.

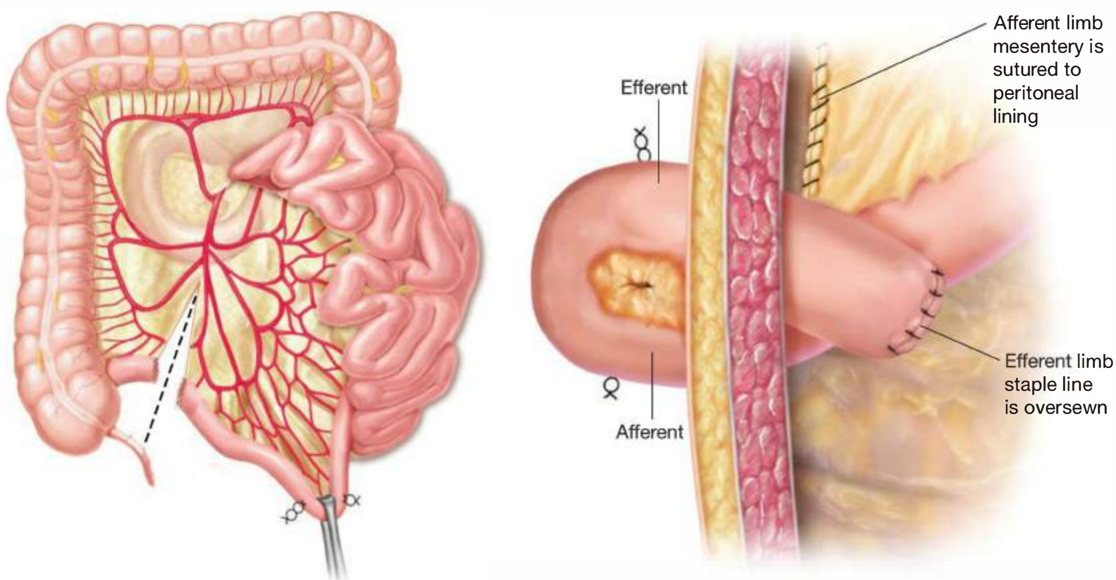
Ileal Limb Preparation and Placement

- The mesentery and vasculature are divided to obtain as much length as possible (FIG 5A).
- Following the distal intestinal resection or division, the staple line at the end of the ileum is oversewn.

- The segment of ileum to be used for the stoma creation is typically located about 10 cm proximal to the oversewn ileal staple line. The segment must have adequate mobility to reach the proposed stoma site without tension. Within the abdominal cavity, the afferent limb is oriented inferiorly and the efferent limb superiorly. The segment of ileum to be used for the stoma is then advanced through the abdominal wall as for a loop ileostomy (**FIG 5B**).
- Optionally, a supporting rod or catheter can be passed behind the ileum at the ileal-mesenteric interface.
- Optionally, the intraabdominal ileal mesentery may be sutured to the peritoneum.

Stoma Maturation

- The end-loop ileostomy is matured as described for a loop ileostomy (**FIG 3C,D**).



A **B**

FIG 5 ● Creation of an end-loop ileostomy. **A.** The mesentery and vasculature are divided proximally to obtain as much length as possible. **B.** Marking sutures are placed on the afferent and efferent limbs. The staple line closing off the ileum is oversewn with Lembert sutures and remains in the abdomen. A more proximal segment of ileum to be used for the ileostomy, approximately 10 cm proximal to the oversewn ileal staple line, is externalized so that the afferent limb is in the inferior position on the abdominal wall. The mesentery may be affixed to the abdominal wall to prevent stoma prolapse, torsion, or an internal hernia.

LAPAROSCOPIC CREATION OF AN ILEOSTOMY

- The laparoscopic approach can be used for temporary and permanent end ileostomies, loop ileostomies, divided loop ileostomies, and end-loop ileostomies.
- The entire abdominal cavity can be visualized and inspected, which can be beneficial as it allows for assessment of the underlying disease and the extent of adhesions. Additionally, laparoscopy allows for precise identification of the ileal segment to be used for the stoma and can help to ensure its proper orientation.
- The laparoscopic approach may not be feasible if the patient has extensive adhesions from prior operations or an insufficient intraabdominal domain due to intestinal dilatation.
- Laparoscopic ileostomy creation may result in shorter total incision length, shorter operative time, decreased pain, fewer wound complications, more rapid return of bowel function, and shorter hospital stay.

Stoma Site Skin Incision and Port Placement

- The 2-cm skin incision for the stoma site can be made prior to insufflation at the time of port site creation or after diagnostic laparoscopy and selection of the ileal segment to be externalized (see "Abdominal Wall Aperture Creation for the Stoma").
- A 5-mm or 10-mm port is placed through the upper midline for the camera.
- A 10-mm port is placed through the intended ileostomy site.
- A 5-mm port is placed in the left lower quadrant for bowel manipulation and adhesiolysis as necessary.
- An additional 5-mm port may be placed in the left suprapubic region if needed.

Ileal Limb Preparation and Placement

- The most distal segment of ileum that can reach the intended stoma site without tension is identified laparoscopically.
- For loop ileostomies, sutures or clips are placed to mark the afferent and efferent ileum prior to externalization.
- A laparoscopic bowel clamp is placed through the 10-mm port at the stoma site to grasp the ileum.
- The pneumoperitoneum is released.
- To facilitate the passage of the loop of ileum, the anterior rectus sheath can be further stretched or incised with a cruciate incision.
- The ileum, bowel clamp, and 10-mm port are pulled out of the abdomen.

Laparoscopic Confirmation of Proper Stoma Orientation

- Adequate stoma loop orientation and hemostasis are confirmed after reestablishing pneumoperitoneum.
- All ports are removed and the skin incisions are closed with reabsorbable suture.

Stoma Maturation

- The stoma is matured as described for the open technique.

PLACEMENT OF THE ILEOSTOMY APPLIANCE

- Most appliances are disposable and available as one-piece or two-piece products. A basic appliance consists of an adhesive faceplate with a central opening and a collection bag. When cutting out the definitive stoma aperture in the appliance faceplate, the stoma aperture is cut offset (i.e., medially in relation to the precut stoma aperture) so as to shift the entire appliance laterally on the patient. As a result, the portion of the appliance directly over any midline incision can be minimized. The edges of the cut-out area of the appliance should be 1 to 2 mm away from the edges of the ileostomy to avoid appliance trauma to, and leakage from, the ileostomy (**FIG 6**).

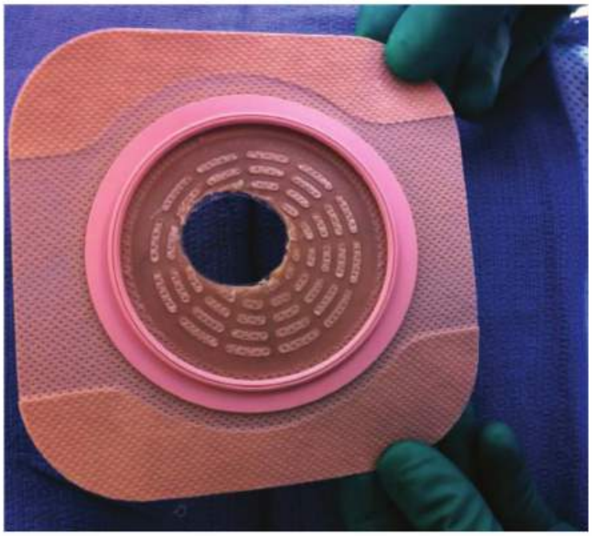


FIG 6 ● Ileostomy appliance. The faceplate stoma aperture is cut off-center in a medial direction to minimize the portion of the faceplate that lays directly over a midline incision (allows for a shift laterally off of the midline if an incision if present).

END AND DIVERTING LOOP ILEOSTOMIES: REVERSAL

DEFINITION

- Ileostomy reversal (synonyms: ileostomy takedown or closure) is a procedure that reestablishes intestinal continuity in a patient with an ileostomy.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Reversal of a temporary ileostomy is usually performed at the earliest 2 to 3 months after ileostomy creation in order to allow for optimal healing of the area from which the enteric contents were diverted (e.g., distal anastomosis, bowel repair) or to allow for the distal inflammation to subside. An end ileostomy following subtotal colectomy may be reversed if the rectal and anal complex are healthy and without disease or malfunction.
- Modifiable risk factors (e.g., malnutrition) must be optimized and any chemotherapy and radiation should be completed.
- Reversal may be necessary at an earlier date for selected patients in the presence of an ileostomy complication such as prolapse or recurrent serious fluid and electrolyte abnormalities.
- Ileostomy reversal can be associated with considerable morbidity.
- Up to 30% of patients with potentially reversible ileostomies never have their ileostomies reversed due to underlying health issues, underlying disease prognosis, or patient preference.

PREOPERATIVE IMAGING AND OTHER DIAGNOSTIC STUDIES

- The indications for preoperative imaging and diagnostic (e.g., functional) studies must be individualized for each patient.
- The routine use of contrast studies prior to ileostomy takedown to assess the distal bowel or anastomosis for stricture, obstruction, leak, recurrence of disease, or to assess pouch anatomy is controversial. If a study is performed, the contrast can be instilled through the efferent limb of a loop ileostomy or per anum, depending on the location of the area to be studied.
- An examination under anesthesia and an endoscopic assessment may be performed to ascertain that a J-pouch is intact, to ensure that a distal anastomosis or repair has healed, and to ensure that a malignancy has not recurred.

- If the anal sphincter was involved in the disease or repair, an anal manometry or endoscopic ultrasonography may be helpful to evaluate the sphincter.

SURGICAL MANAGEMENT

Preoperative Planning

- Ileostomy reversal is not a minor operation and sometimes requires a full laparotomy.
- A loop ileostomy often facilitates subsequent ileostomy reversal by potentially obviating the need for a full laparotomy.
- The groundwork for successful ileostomy reversal is laid at the time of the construction of the ileostomy. To facilitate the ileostomy takedown procedure, an adhesion barrier should be placed at the time of ileostomy creation.
- Bowel preparation for the proximal intestine consists of 24 hours of clear liquids.
- Bowel preparation distal to the ileostomy is optional but is strongly recommended if no formal bowel preparation was performed prior to creation of ileostomy (e.g., in case of an emergency operation). Bowel preparation can be achieved under those circumstances as follows:
  - Patients with an end ileostomy and a rectal stump: transanal enema
  - Patients with a loop ileostomy: irrigation through the efferent limb or transanal retrograde enema, depending on the location of disease, repair, or anastomosis.
  - The radiologist can be asked to irrigate the diverted segment (efferent limb or colon) with saline solution at the completion of a contrast study.
  - Ureteral stents should be strongly considered if the patient has had significant pelvic inflammation.

Positioning

- The patient is placed in lithotomy position if an endoscopic assessment or exam under anesthesia is required, if the rectal vault requires irrigation and evacuation of inspissated mucus secretions, or if an ileorectal or ileoanal anastomosis is to be created.
- Supine position is adequate if no access to the anus or rectum is required.

TECHNIQUES

END ILEOSTOMY REVERSAL

Stoma Closure

- The stoma is closed with a running 0-silk suture.

Mobilization and Resection of Ileostomy

- A circumferential skin incision is made sharply around the closed ileostomy just peripheral to the mucocutaneous junction.
- Sharp dissection is used next to the bowel wall, with judicious use of electrocautery, to release the stoma from the subcutaneous fat, rectus muscle, and rectus sheath (**FIG 7**). Caution is used to avoid an injury to the bowel wall or mesentery. Eastman or Army-Navy retractors can facilitate exposure and visualization.
- Any adhesions to the abdominal wall adjacent to the internal aspect of the ileostomy site are lysed circumferentially to clear the peritoneal surface for safe subsequent reapproximation and closure of the abdominal wall defect. A wound protector is placed to minimize wound contamination.
- The ileostomy is excised with its fibrofatty tissue and a viable segment of ileum with intact serosa and adequate blood supply is prepared for the anastomosis. If a stapled anastomosis is planned, the anvil from the circular stapler is placed and secured in the ileum.

FIG 7 ● Skin incision and stoma mobilization for reversal of an end or loop ileostomy. A circumferential skin incision is made directly adjacent to the closed ileostomy. The incision is deepened across all abdominal wall layers down to the level of the abdominal cavity. The ileostomy and adherent fibrofatty tissues are resected.

Preparation of the Distal Bowel Segment

- Typically through a laparotomy, the distal bowel segment to which the ileum is to be anastomosed (usually the rectum) is carefully mobilized and prepared for anastomosis. The intestinal segment must be viable and of adequate length.

Anastomosis after Takedown of the End Ileostomy

- A standard ileorectal (or ileoanal or ileocolic) anastomosis can be created with a stapler (e.g., by using a circular end-to-end anastomosis [EEA] stapler) or a hand-sewn technique (**FIG 8**).
- A leak test is performed. Water is poured into the pelvis until the anastomosis is submerged. The bowel is occluded proximal to the anastomosis. Air is insufflated per anum with a proctoscope.
  - Small leaks can be oversewn and the leak test is repeated. If the leak test remains positive, the anastomosis can be redone with a low threshold for the placement of a proximal diverting loop ileostomy and a pelvic drain.
  - Small leaks low in the pelvis or large leaks should be repaired or the anastomosis should be redone.

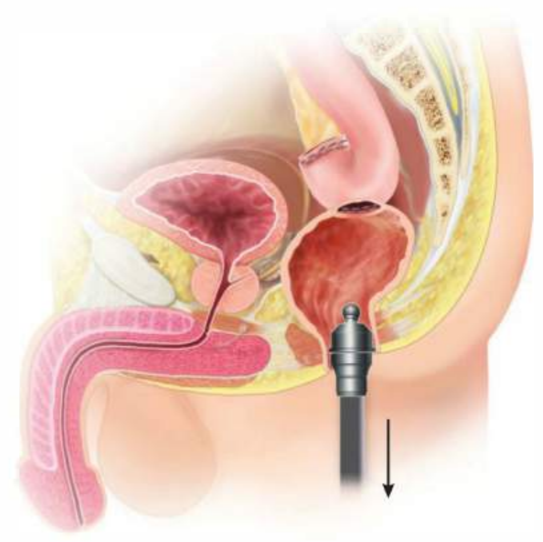

FIG 8 ● Reversal of an end ileostomy. Intestinal continuity is restored with a circular cutting stapler (e.g., by creating an ileorectal anastomosis).

Creation of a proximal diverting loop ileostomy and insertion of a pelvic drain should be strongly considered under those circumstances. The omentum should be wrapped around the anastomosis.

- Alternatively, the anastomosis can be visualized endoscopically (with or without injection of intravenous fluorescein to assess the intestinal blood supply).

Fascial Closure

- The abdominal wall stoma defect is closed without tension in two layers with running or interrupted 1-polydioxanone (PDS) suture. Omentum is placed between the anastomosis and the fascial closure, if available.
- If the fascia is of poor quality, a biologic mesh can be used for reinforcement.

Stoma Site Skin Closure

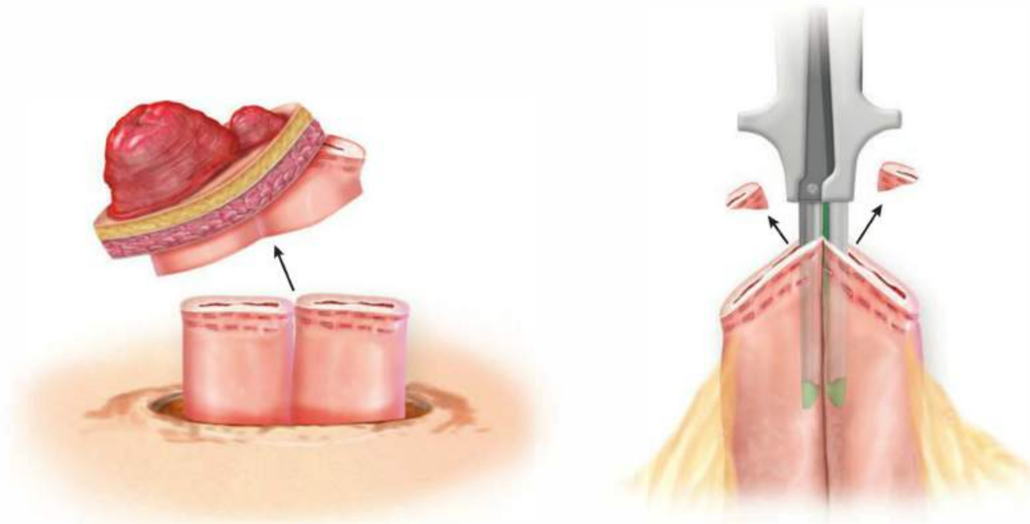
- The skin can be closed with numerous different techniques, but in principle, the closure should not be watertight. Options include the following:
  - Primary skin closure
    - Loose skin closure with interrupted 2-0 nylon sutures or staples. Wound fluid drainage should be facilitated, for instance, by application of wicks made of Kendall Telfa® dressing pads (the wicks should be removed on postoperative day 2 or 3).
    - Delayed primary closure (performed on postoperative day 2 or 3).
    - Purse-string closure. Loose circular (purse-string) skin closure with 2-0 running, subcuticular polypropylene. The approximately 1 to 1.5 cm remaining central opening is packed with moist gauze that is first removed on postoperative day 2 and then exchanged daily. The suture is removed on postoperative day 21. The purse-string closure may be associated with a lower surgical site infection rate than a primary closure.
- Wound healing by secondary intention. The wound is left open and wet-to-dry dressing changes are initiated.

REVERSAL LOOP ILEOSTOMY

- The ileostomy closure can usually be performed through the ileostomy site, without requiring a complete laparotomy.
- The steps leading up to the anastomosis are the same as for the reversal of the end ileostomy discussed earlier.
- A wound protector is placed to minimize wound contamination.

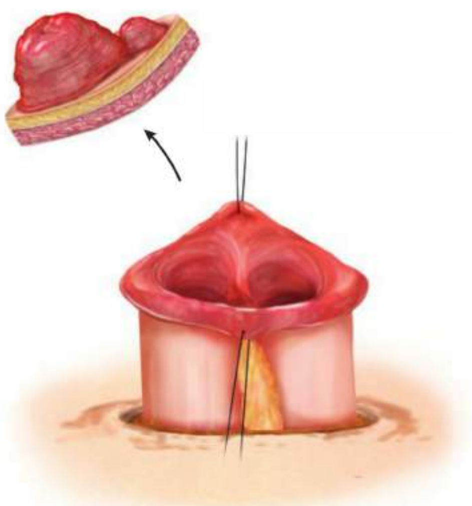
Anastomosis after Takedown of Loop Ileostomy

- The anastomosis between the proximal (afferent) and distal (efferent) ileal limbs can be either hand-sewn or stapled.
- The stoma and fibrofatty tissues are resected with a linear cutting stapler to a level where there are two distinct ileal limbs (FIG 9A).
  - For a stapled side-to-side anastomosis, the antimesenteric corner of each ileal end is cut and removed.
  - A side-to-side, functional end-to-end anastomosis is created with a linear cutting stapler (FIG 9B). The enteric defect is closed with a linear stapler or a hand-sewn technique.
  - The anastomosis can also be constructed with a circular stapler or hand-sewn.
- Alternatively, a direct transverse closure of the enteric defect at the stoma site can be performed. With this technique, the stoma and fibrofatty tissues are resected sparingly so that the connecting bridge of intestinal wall on the posterior (mesenteric) aspect of the loop stoma remains intact (FIG 10A).
  - The antimesenteric defect can then be closed either by a hand-sewn technique (double layer technique consisting of 3-0 absorbable full-thickness sutures [e.g., Vicryl®], followed by 3-0 nonabsorbable Lembert seromuscular sutures [e.g., silk]) (FIG 10B) or stapled technique (with a linear stapler) with optional oversewing of the staple line (FIG 10C).

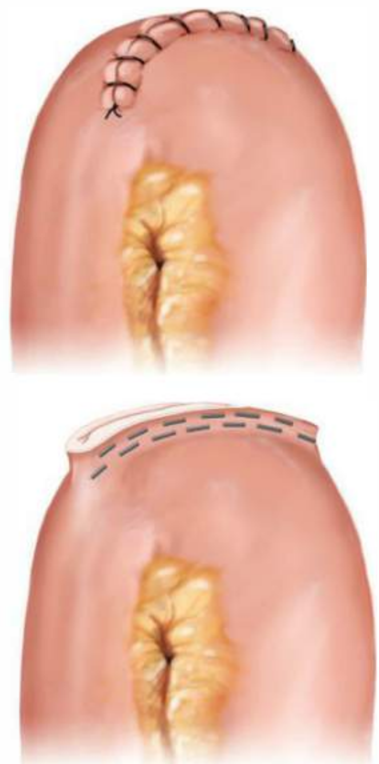


A B

FIG 9 ● Reversal of a loop ileostomy: option 1 (results in larger anastomotic cross section). **A.** The ileum is mobilized from the abdominal wall. The stoma itself (including the staples in case of a divided loop ileostomy) and adjacent fibrofatty tissues are resected with a linear cutting stapler to a level where both limbs are completely separated. **B.** A side-to-side (functional end-to-end) stapled anastomosis is created with a linear cutting stapler inserted into the antimesenteric aspect of each ileal limb. The remaining ileal opening is closed off with a linear stapler application or by using a hand-sewn technique.



A



B

C

FIG 10 ● Reversal of a loop ileostomy: option 2. **A.** The ileum is mobilized from the abdominal wall. The stoma itself and adjacent fibrofatty tissues are resected sparingly so that the connecting bridge of ileum on the posterior/mesenteric aspect of the loop ileostomy is left intact. **B.** The ileal defect is closed with a transverse two-layer hand-sewn technique or **(C)** with a linear stapler.

PEARLS AND PITFALLS

Ileostomy Creation	
Indications	■ A diverting ileostomy may prevent morbidity by preventing a distal anastomotic disruption in high-risk patients.
Preoperative education	■ Stoma education is crucial to familiarize the patient with the impending stoma and to minimize potential complications.
Stoma placement	■ Preoperative ileostomy site determination and marking is critical. The stoma must be placed away from bony prominences, panni, and scars to create a viable, tension-free ileostomy with a reliable appliance seal.
Orientation of loop ileostomy	■ Use marking sutures on afferent and efferent limbs. Avoid torsion and mesenteric vascular compromise during stoma creation.
Stoma maturation	■ Creation of a 2-cm Brooke ileostomy (end or diverting loop) minimizes the morbidity that stems from the ileostomy effluent.
Follow-up	■ Close follow-up and the use of ileostomy care pathways are critical to recognize and address stoma-site problems and to minimize readmissions for dehydration and electrolyte abnormalities.
Ileostomy Reversal	
History and physical	■ Ileostomy reversal is usually an elective procedure. Allow the patient to attain an optimal health status before undertaking reversal.
Diagnostic tests	■ Consider diagnostic studies to assess the distal bowel or anastomosis prior to closure. These studies may prevent morbidity and improve outcome.
Preparation of the ileum for takedown	■ Dissect the ileum to viable, healthy ileum with adequate blood supply. Avoid tension on the anastomosis.
Skin closure	■ Healing by secondary intention predictably prevents wound infections and typically has similar cosmetic outcomes compared to primary closure. "Purse string" closure is an increasingly used as skin closure option.
Follow-up	■ Patients undergoing ileostomy reversal are at risk for major morbidity and mortality and must be followed closely postoperatively.

POSTOPERATIVE CARE

For Ileostomy Creation Patients

- Creation of an ileostomy results in the loss of the ileocecal valve and of the colonic water reabsorption, leading to dehydration and electrolyte abnormalities. Postoperatively, the newly created ileostomy begins to function within 72 hours, often with high output (>1 L) per day. Within weeks, the proximal small bowel adapts at least partially as water absorption increases and the effluent thickens. Ideal daily effluent volume after adaptation is 500 to 1000 mL.
- Appropriate hydration and electrolyte levels (sodium, potassium, magnesium, and calcium) must be maintained, using electrolyte solutions (e.g., Pedialyte®) and oral or intravenous sodium chloride. After discharge, the patient must contact his or her medical provider if the ileostomy output is greater than 1 L per day for 2 consecutive days.
- Psyllium (e.g., Metamucil®) can be used to thicken the enteric contents.
- Anticholinergic agents, opioid receptor agonists (e.g., loperamide), bile acid binders (e.g., cholestyramine), and narcotic agents (e.g., tincture of opium, codeine) can be used to decrease ileostomy output.
- Vitamin B_{12} is administered subcutaneously as needed.
- Support belts may be helpful for securing poorly fitting appliances, especially in obese patients.
- Maintaining a healthy skin around the stoma is paramount. Allergic reactions to the appliance can occur and may be managed by changing appliance type or manufacturer.
- Pooling of ileal effluent must be avoided by frequent appliance changes or bag emptying. The appliance should be changed immediately postoperatively if the patient experiences leakage or peristomal skin problems.

For Ileostomy Reversal Patients

- The patients must be followed closely postoperatively to identify problems and complications after ileostomy takedown. This is especially important in high-risk patients.
- Dehydration and electrolyte abnormalities may persist after ileostomy takedown.

OUTCOMES

- Dietary indiscretion (e.g., high glucose, high fat) and alcoholic beverages may result in diarrhea and dehydration. Dehydration contributes to readmission rates that can be as high as 20%.
- An "ileostomy care pathway," including a standardized set of perioperative patient education tools, direct patient engagement with stoma care, strict monitoring of stoma output postdischarge, and visiting nurse involvement, may all positively impact overall readmission rates (e.g., 35% prepathway implementation vs. 21% postpathway implementation)

and may decrease or even eliminate readmissions for dehydration (e.g., 15.5% prepathway implementation vs. 0% postpathway implementation).[1]

- The use of a sodium hyaluronate and carboxymethylcellulose-based bioabsorbable membrane can significantly decrease adhesion formation around a loop ileostomy as identified at the time of ileostomy reversal (e.g., no Seprafilm® vs. Seprafilm® around stoma, 30.6% vs. 14.1%).[2]
- In patients requiring a diverting loop ileostomy, a bridge (rod) does not significantly impact retraction or leakages.[3]
- Laparoscopic creation of an ileostomy is safe and effective and should be considered for patients.[4]
- Over 10% of patients require ileostomy-related reoperations. Obesity is an independent risk factor for ileostomy complications and, along with smoking history, is associated with a lower likelihood of subsequent ileostomy reversal.[5]
- Handsewn vs. stapled ileo-ileostomy anastomoses for ileostomy closure have similar major complications such as bowel obstruction (in about 15% of cases) and anastomotic leak (in about 2% of cases), with stapled anastomoses resulting in shorter operation times.[6]

COMPLICATIONS

Ileostomy Creation Patients

- Over 80% of patients experience one or more stoma-related complications. Common problems include skin irritation (in up to 60%), fixation problems (in up to 50%), and peristomal leakage (in up to 40%). Superficial necrosis, bleeding, and retraction can occur in up to 20%, 15%, and 10% of patients, respectively. Stoma-related complications are even more common for stomas in suboptimal locations.
- Parastomal hernia
- Parastomal fistula
- High-output ileostomies may result in dehydration, electrolyte abnormalities, and fat/fat-soluble vitamin malabsorption.

Ileostomy Reversal Patients

- An analysis of the National Surgical Quality Improvement Program (NSQIP) demonstrated that following elective ileostomy closure, 9.3% of patients had major complications (e.g., mortality, sepsis, return to the operating room, renal failure, major cardiac, neurologic, or respiratory episode) and 8.4% had minor complications (e.g., wound infection or urinary tract infection within 30 days). Mortality was 0.6%. Independent predictors of major complications were American Society of Anesthesiologists (ASA) physical status classification system score, functional status, history of chronic obstructive pulmonary disease (COPD), dialysis, disseminated cancer, and prolonged operative time.
- Hand-sewn ileo-ileostomy and stapled ileo-ileostomy anastomoses for ileostomy closure have similar major complication rates e.g., bowel obstruction in about 15% of cases and anastomotic leak in about 2% of cases.
- Wound infections following ileostomy reversal are significantly lower in patients undergoing delayed versus primary closure (0% vs. 24%) with similar cosmetic outcomes.

Chapter 5

Jejunostomy Tube

Rebecca L. Wiatrek Lillian S. Kao

DEFINITION

- A jejunostomy feeding tube is a tube placed into the proximal jejunum and brought out through the skin to allow for feeding distal to the stomach. Jejunostomy tubes are indicated in patients who are unable to maintain adequate nutrition orally and who are unable to be fed via the stomach. Examples of conditions that may require a jejunostomy tube include, but are not limited to, gastric outlet obstruction, esophageal perforation, gastroparesis, or recurrent aspiration. Jejunostomy tubes may be placed via a nasojejunal or percutaneous route; the latter can be approached via interventional radiology, via laparoscopic or open surgery, or via endoscopy, as an extension through a percutaneous gastrostomy tube.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A complete surgical history should be elicited, focusing on prior abdominal operations.
- A complete abdominal examination should be performed, noting prior incisions and hernias.
- Because malnutrition may be an indication for placement of a jejunostomy tube, a complete nutritional history should be obtained including recent weight loss.
- Physical examination should be focused on signs of severe malnutrition such as loss of subcutaneous fat, muscle wasting, and/or presence of edema and ascites.
- The Subjective Global Assessment Score combines the history and physical examination to provide a rating from A (*well nourished*) to C (*severely malnourished*).

IMAGING AND OTHER DIAGNOSTIC STUDIES

- A nutritional assessment should be performed. Severe malnutrition may be a reason for placement of a jejunostomy tube, such as prior to major elective surgery. Indicators of preoperative malnutrition include weight loss greater than 10% to 15% over the previous 6 months, body mass index less than 18.5 kg/m^2, Subjective Global Assessment Grade C, and/or serum albumin less than 3 g/dL.[1]
- Electrolytes should be checked and replaced prior to surgery. An electrocardiogram should also be checked in order to rule out cardiac abnormalities and arrhythmias.
- Additional studies and radiologic imaging should be based on the primary diagnosis. In patients with underlying malignancy, staging studies should be recent enough to ensure that there are no changes in the cancer status that may affect the operative plan.

SURGICAL MANAGEMENT

Preoperative Planning

- Although enteral feeding is preferred to the parenteral route, the surgeon should ensure that there are no contraindications to enteral nutrition such as distal obstruction, ileus, high-output enterocutaneous fistula, or shock.
- Alternatives to jejunostomy tubes include temporary nasally inserted feeding tubes and gastrostomy tubes. Temporary feeding access can be achieved using a nasogastric or a nasojejunal feeding tube; the latter can be placed with the assistance of fluoroscopy or endoscopy. Smaller diameter feeding tubes may be more comfortable for the patient but also may be more prone to clogging. Gastrostomy tubes for longer term feeding access can be placed endoscopically, radiologically, or surgically.
- If enteral access is not the primary indication for surgery, then the complete operative plan should be considered. The anticipated duration of inability to take in oral nutrition or of inadequate nutrition (<60% of caloric requirement) should be taken in consideration when deciding whether or not to place a feeding jejunostomy tube as well as in deciding the route of placement (nasojejunal vs. surgical).[1] In cancer patients, whether the goal of surgery is curative or palliative should be considered. A temporary feeding jejunostomy tube may be indicated after resection of cancer of the esophagus, stomach, or pancreas to allow continued distal enteral nutrition in the event of an anastomotic leak.
- Palliative care may include placement of a surgical jejunostomy tube. Cancer patients who are not candidates for curative treatment should be assessed for their preferences, quality of life, and resources. The risks of surgical intervention should be weighed against the potential benefits of enteral nutrition. A candid discussion should be held with the patient regarding advanced directives and end-of-life care.
- When enteral access is the primary indication for surgery, the surgeon should discuss the planned operative approach with the patient. When a laparoscopic jejunostomy tube is planned, the surgeon should discuss the possibility of conversion to open. If the jejunostomy tube is palliative, the surgeon should discuss the possibility of aborting the procedure when the risks outweigh the benefits (i.e., in the setting of carcinomatosis and inability to safely dissect the proximal jejunum).
- Although no randomized trials exist regarding antibiotic prophylaxis prior to jejunostomy tube placement, there is high-quality evidence that antibiotic prophylaxis reduces surgical site infections across procedures and baseline risks.[2] In addition, a meta-analysis of randomized controlled trials of antibiotic prophylaxis to prevent peristomal infection after percutaneous endoscopic gastrostomy demonstrated a significant risk reduction with cephalosporin and penicillin-based prophylaxis.[3]

Positioning

- The patient should be positioned in the supine position. This is required for both laparoscopic and open techniques. For the laparoscopic approach, it is important to secure the patient to the bed with straps or tapes to allow for safe manipulation of the operating table.

OPEN JEJUNOSTOMY FEEDING TUBE PLACEMENT

First Step—Placement of Skin Incision

- A limited midline incision, approximately 5 cm in length, is made above the umbilicus. This allows for identification of the ligament of Treitz. A larger incision may be needed if the patient has had multiple prior operations requiring adhesiolysis.
- Once the abdomen is entered, the omentum can be followed to the transverse colon, which is retracted cephalad. The ligament of Treitz is located at the base of the transverse mesocolon to the left of the fourth portion of the duodenum (**FIG 1**) and is identified by visualization and palpation. A segment of jejunum distal to the ligament of Treitz is identified. A distance of 15 to 20 cm from the ligament of Treitz will allow the jejunum to reach the abdominal wall without tension, while also providing for enough length for a proximal revision of the jejunal segment, should one be necessary in the future.
- An exit site is identified in the skin of the left upper quadrant, several centimeters lateral from the midline. A stab incision is made at this level, and tonsil clamps are used to deliver the jejunostomy tube into the abdominal cavity.

Second Step—Choice of Tubes

- The type of jejunostomy tube used can be as simple as a 10- or 12-French red rubber catheter or a silicone jejunostomy tube similar to those used in laparoscopic cases. Silicone tubes may have more longevity.[4] Avoid using balloon-tipped catheters (i.e., Foley catheters) or, alternatively, ensure that the ability to inflate the balloon has been disabled to prevent future attempts at insufflating the balloon that could lead to subsequent bowel obstruction.
- If using a red rubber catheter, the tip may be cut off, which allows for exchange over a wire should the tube become clogged. Additional side holes may also be cut at the distal end of the tube in order to improve flow through the catheter.

Third Step—Suturing Tube into the Bowel

- The previously chosen site of proximal jejunum is delivered into the wound. The site of entry of the tube should be on the antimesenteric side of the jejunum. Once this is identified, a 3-0 silk is used to create a diamond-shaped purse-string suture. A small opening is made inside the purse-string suture with cautery, only large enough to allow for the tube to be inserted into the bowel.
- The tube is placed into the bowel and advanced into the distal portion of the jejunum. The length of advancement into the jejunum should be long enough to prevent backflow of feeds into the proximal small intestine.
- The purse-string suture is secured, and the tube is placed along the proximal bowel wall. The Witzel technique is then used to prevent extravasations of enteric feeds at the jejunostomy tube entrance site. In this technique, 3-0 silk seromuscular sutures are placed perpendicularly on the antimesenteric border of the bowel on both sides of the feeding tube (Lembert sutures) in order to imbricate the bowel wall over the feeding tube, creating a serosal tunnel (**FIG 2**). This should be approximately 2 to 3 cm in length and care should be taken to not narrow the lumen

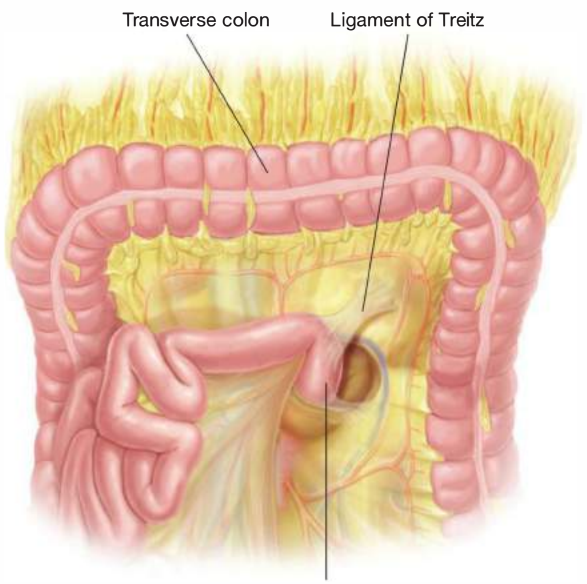

FIG 1 ● Identification of the ligament of Treitz. With the transverse colon retracted superiorly, the ligament of Treitz can be easily identified at the base of the transverse mesocolon and to the left of the fourth portion of the duodenum.

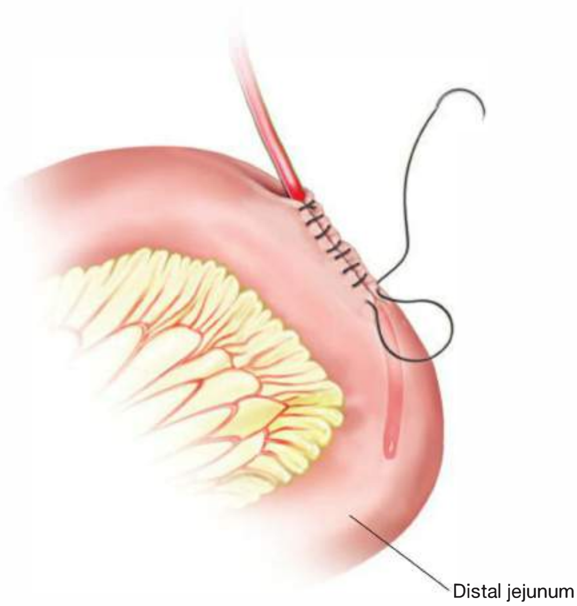

FIG 2 ● The open Witzel technique. 3-0 silk seromuscular sutures are placed perpendicularly on the antimesenteric border of the bowel on both sides of the feeding tube (Lembert sutures) in order to imbricate the bowel wall over the feeding tube, creating a serosal tunnel.

of the bowel or tube with these sutures. Care should also be taken to avoid perforating the feeding tube during the placement of these sutures, as this could lead to extravasation of the enteric feeds into the abdominal cavity.

Fourth Step—Suturing the Tube to the Abdominal Wall

- The tube should then be secured with 3-0 silk seromuscular sutures to the abdominal wall parietal peritoneum in four quadrants around the exit point of the tube just proximal to the last Witzel suture. Care should be taken to avoid perforating the feeding tube during the placement of these sutures, as this could lead to extravasation of the enteric feeds into the abdominal cavity. One additional suture can be used to tack the jejunum to the abdominal wall distal to the tube entrance site to prevent kinking or volvulus of the jejunum around the tube site.

LAPAROSCOPIC JEJUNOSTOMY FEEDING TUBE PLACEMENT

First Step—Laparoscopic Port Placement

- The abdomen may be entered either by a cut-down technique, by use of an insufflation needle followed by entry with an optical access trocar, or with an optical access trocar alone. One 5-mm port should be placed periumbilically and two additional 5-mm ports should be placed in a triangulated fashion to allow for manipulation of the jejunum; these should be placed under direct visualization to prevent bowel injury. These are traditionally placed in the right upper and left lower quadrants.

Second Step—Identification of the Ligament of Treitz

- The patient is placed in a Trendelenburg position and is rotated to the right side in order to facilitate identification of the ligament of Treitz.
- The transverse colon is elevated with an atraumatic grasper to identify the ligament of Treitz, located at the base of the transverse mesocolon and to the left of the fourth portion of the duodenum (**FIG 1**). A segment of jejunum approximately 15 to 20 cm distal from the ligament that will easily allow the jejunum to reach the abdominal wall without tension is identified.

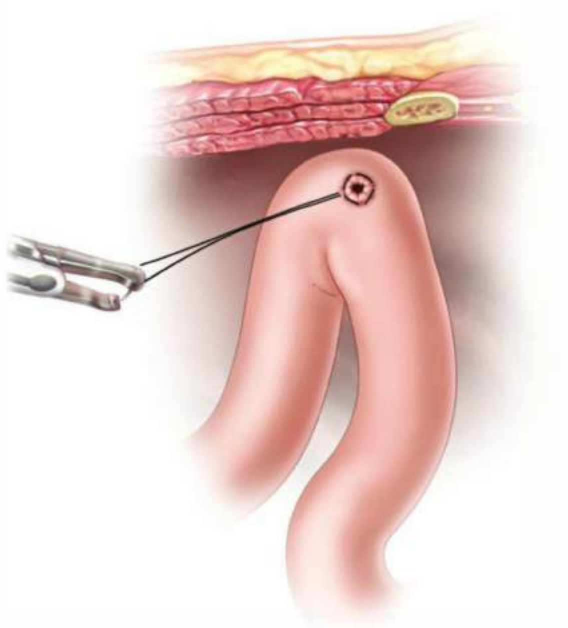

FIG 3 ● A purse-string suture of 3-0 silk is placed with an endoscopic sewing device in a circular manner at the site where the feeding tube will be inserted.

Third Step—Placing the Tube in the Jejunum

- A purse-string suture of 3-0 silk can be placed with a laparoscopic needle driver or with an endoscopic sewing device in a circular manner, in the same fashion as performed in open cases (**FIG 3**). Using electrocautery, make an opening in the small bowel and deliver the feeding tube through the opening and into the distal jejunum. The purse-string suture is tied intracorporeally.
- Lembert sutures are placed to create a Witzel serosal tunnel around the feeding tube. The jejunostomy tube is then tacked to the anterior abdominal wall with a four-quadrant suture placed intracorporeally proximally to the Witzel tunnel.
- If using a laparoscopic jejunostomy tube kit that provides T-fasteners, the jejunum is grasped with two atraumatic graspers and the percutaneous T-fastener is placed through the skin and into the bowel just proximal to where the tube will enter the jejunum. Care should be taken not to place the needle through and through the bowel (back-wall perforation) that would lead to leakage of tube feeds and enteric contents into the abdominal cavity postoperatively. Once the needle is inside the bowel, the T-fastener is released by pushing in the stylet (**FIG 4**). The needle is then removed, and a hemostat is used to pull up on the suture in order to pull the jejunum up flushed to the abdominal wall. Additional T-fasteners are placed in a diamond shape around the planned insertion site.
- The jejunum is then accessed with a needle, and a guidewire is threaded into the bowel (**FIG 5**). The wire is followed laparoscopically to ensure it is going down the distal jejunal limb. A skin incision is made at the guidewire exit site and the dilator is placed over the wire and into the jejunum. The dilator is exchanged for the peel-away sheath. The wire is removed and the tube is placed through the peel-away sheath. The sheath is then peeled away from the catheter (**FIG 6**).
- Confirmation that the tube is in the bowel lumen can be achieved by injecting air into the tube and observing the bowel distend.

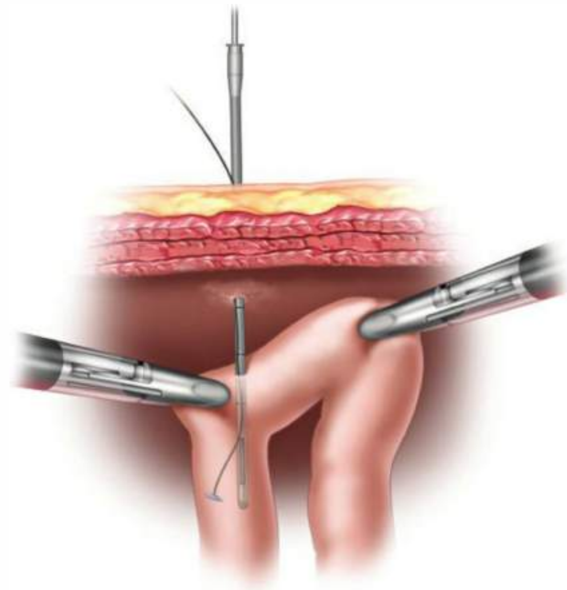

FIG 4 ● Laparoscopic jejunostomy kit technique. Once the needle is inserted inside the bowel, pushing in the stylet deploys the T-fastener.

Fourth Step—Securing the Jejunum to the Abdominal Wall

- The bowel can be fastened to the abdominal wall in four corners with 3-0 silks using laparoscopic needle drivers (**FIG 3**). An alternative method is to place sutures on all four quadrants around the purse-string site and deliver them through the abdominal wall with a suture passer.
- If T-fasteners are used, they are then secured by crimping the metal fasteners above the bolsters with a straight hemostat, thus approximating the jejunum to the abdominal wall. An additional T-fastener can be used to tack the jejunum to the abdominal wall distal to the tube insertion site to prevent volvulus (**FIG 7**).
- Inject a small amount of saline or air into the tube after it has been secured to the abdominal wall to ensure there is no leak and that the tube is patent.

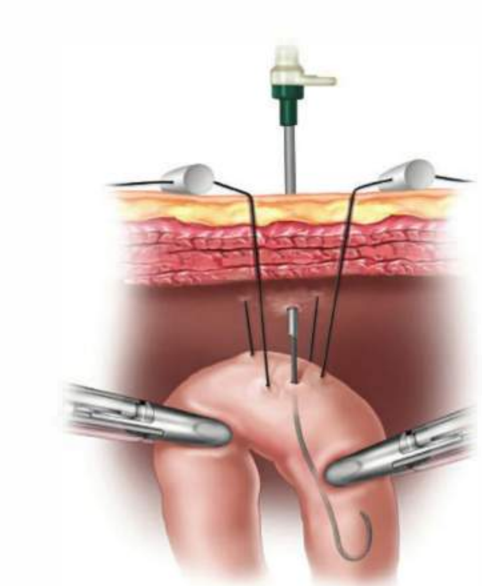

FIG 5 ● Laparoscopic jejunostomy kit technique. The jejunum is then accessed with a needle and a guidewire is threaded into the bowel.

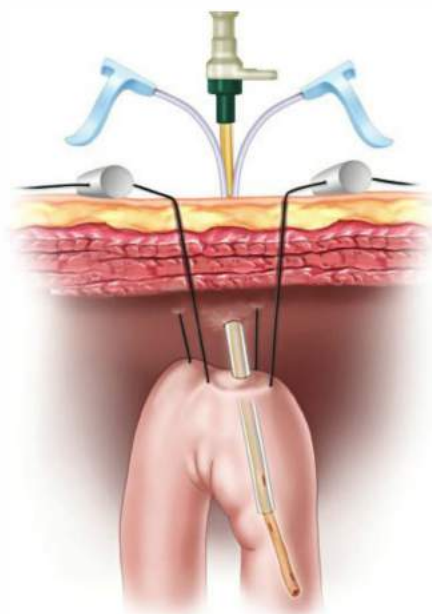

FIG 6 ● Laparoscopic jejunostomy kit technique. The jejunostomy tube is placed through the peel-away sheath and into the distal jejunal limb.

FIG 7 ● Laparoscopic jejunostomy kit technique. **A.** The T-fasteners have been secured by crimping the metal fasteners above the bolsters, thus approximating the jejunum to the abdominal wall at the jejunostomy site. **B.** An additional T-fastener was placed to tack the jejunum to the abdominal wall distal to the tube insertion site to prevent volvulus.

PEARLS AND PITFALLS

Technique	
Open jejunostomy tube placement	
Creating the serosal tunnel	■ When creating the Witzel tunnel, it is possible to cause narrowing of the proximal bowel. The sutures should be carefully placed close to the feeding tube to avoid this problem.
Laparoscopic jejunostomy tube placement	
Using T-fasteners	■ Care should be taken not to place the needle through and through the bowel (avoid back-wall perforation of the bowel). ■ When crimping the T-fasteners, ensure that the jejunum is flush to the abdominal wall. However, do not indent the skin significantly, which can cause necrosis of the skin and cause the patient significant pain. ■ Fasteners should be carefully planned as kits only carry five fasteners and once through the skin and fascia, the fastener is not reusable.
Wire placement	■ Ensure that the wire is traveling distally when placed. ■ Ensure that the wire is freely mobile in the bowel and has not dissected into the layers of the intestinal wall.
Confirmation of tube placement	■ Ensure that the dilator and tube are visualized laparoscopically while entering into the distal aspect of the jejunum. ■ Inject a small amount of saline or air into the tube after it has been secured to the abdominal wall to ensure there is no leak and that the tube is patent.

POSTOPERATIVE CARE

- Postoperatively, the patient's jejunostomy tube can be used immediately.
- The jejunostomy tube should be flushed daily, before and after administration of medications, and after stopping tube feeds to prevent clogging and to ensure patency.
- If a laparoscopic jejunostomy kit was used, the T-fasteners can be cut at the skin level 2 weeks after tube placement.
- Nutritional consultation should be considered in order to determine the patient's caloric needs. Nutritionists may also assist in the choice of enteral formula. There is data from meta-analyses of randomized trials suggesting a benefit to using immunonutrition in perioperative head/neck and gastrointestinal cancer patients.[5,6]
- In malnourished patients who are at high risk for refeeding syndrome, nutritional support should be started slowly.[7] Fluid and electrolyte imbalances should be corrected. In addition, high-risk patients should be monitored closely in terms of their vital signs, electrolytes, weight, and neurologic signs and symptoms. Patients should be monitored for hypophosphatemia, hypokalemia, hypomagnesemia, hyperglycemia, and hyponatremia upon initiation of feeds. Because of the risk of arrhythmias, telemetry may be indicated in severe cases.
- Diarrhea is a common side effect of enteral nutrition. High-quality data on preventive interventions are lacking.[8]

Persistent diarrhea (>72 hours) should trigger evaluation for *Clostridium difficile* infection, rectal examination to rule out fecal impaction, cessation of laxatives, and restoration of fluid and electrolyte balance. Addition of soluble fiber or modification of the composition of the enteral formula may reduce diarrhea.[8]

- Nonocclusive bowel necrosis is a rare but devastating complication of enteral feeding. Tube feed tolerance should be monitored closely, particularly among patients with preexisting impaired gastrointestinal function. Signs of intolerance may be nonspecific such as nausea, diarrhea, bloating, and abdominal pain. Mechanisms that may contribute to nonocclusive bowel necrosis include mesenteric hypoperfusion, bacterial contamination, and hyperosmolarity of the tube feeds. Unfortunately, due to the rarity of nonocclusive bowel necrosis, specific risk factors cannot be identified.[9] Therefore, a low threshold for diagnosis should be maintained and early reexploration performed when suspected.

OUTCOMES

- Outcomes after jejunostomy tube placement are dependent on the primary diagnosis.
- In cancer patients undergoing curative treatment, enteral nutrition improves the tolerance and response to therapy.[10,11] In cancer patients undergoing palliative treatment, enteral nutrition may improve symptoms and quality of life while reducing loss of autonomy.[10]

COMPLICATIONS

- Diarrhea
- Dermatitis
- Infection
- Tube leakage (peristomal or intraperitoneal)
- Small bowel perforation
- Displacement of the jejunostomy tube
- Enterocutaneous fistula
- Refeeding syndrome
- Mechanical small bowel obstruction at the jejunostomy tube site
- Volvulus around the jejunostomy tube site
- Nonocclusive bowel necrosis

Chapter 6

Appendectomy: Open Technique

James Suliburk David Berger

DEFINITION

- Open appendectomy is defined as removal of the appendix via an incision in the abdominal wall without use of a camera. Prior to laparoscopy, it was the most commonly performed emergency general surgery operation in the United States.
- Open appendectomy has been replaced in frequency by laparoscopic appendectomy as the most common emergency general surgery operation performed.
- Laparoscopic appendectomy is not always possible, and an open approach may be preferred in patients who have had extensive abdominal or pelvic surgery. Additionally, it may be necessary to convert to an open technique from an initial laparoscopic approach due to technical or anatomic reasons. Open appendectomy can also be the preferred approach in patients who are pregnant in which the gravid uterus precludes laparoscopy.

DIFFERENTIAL DIAGNOSIS

- Patients presenting with appendicitis may have any number of conditions mimicking the classic right lower quadrant (RLQ) pain of appendicitis. Conditions that have to be considered in the differential diagnosis of acute appendicitis can be broken down in categories, including the following:
  - Gastrointestinal: gastroenteritis, mesenteric lymphadenitis, Meckel's diverticulum, intussusception, cholecystitis, inflammatory bowel disease, diverticulitis, perforated cancers, and perforated peptic ulcers
  - Gynecologic: ectopic pregnancy, salpingitis, endometriosis, ovarian torsion, tuboovarian abscess
  - Urologic: urinary tract infection, nephrolithiasis

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients most commonly present with appendicitis between the ages of 10 and 40 years. Approximately 75% of patients will present with pain of less than 24 hours duration. Classically, the pain is described as starting at the umbilicus and then migrating over several hours' time to the RLQ as the stimulus changes from the visceral to somatic nerves. However, this classic migration is not always present, and nearly 40% of patients will have atypical pain, with only vague abdominal pain or even flank pain.
- Atypical pain can frequently be caused by subtle variation in the appendix location with right upper quadrant pain being caused by an anteriorly located appendix on a high-riding cecum, tenesmus triggered by an inflamed appendix tip in the pelvis, and flank pain triggered by a retrocecal appendix.
- Nausea, vomiting, and anorexia are classically associated with appendicitis but are variably present. Of these, the sequence of having anorexia and/or abdominal pain preceding vomiting is more consistent with appendicitis. When vomiting is the first symptom elicited, the diagnosis of appendicitis is questionable. Diarrhea is fairly nonspecific.
- Physical exam findings consistent with appendicitis are dependent on the location of the appendix. Because the appendix may be located anywhere on the cecum, signs are extremely variable. Classic RLQ point tenderness at McBurney point is present in the normal anterior location of the appendix. Rovsing's sign (RLQ pain when left lower quadrant is pressed) may also be present.
- When the appendix is located in a retrocecal position, a positive psoas sign (pain with extension of the right thigh with the patient lying on the left side) can be elicited.
- When the inflamed appendix is in the pelvis, the classic obturator sign (pain with internal rotation of the flexed thigh in the supine position) may be positive.
- Additional tests for subtle peritoneal irritation, including gently shaking the hospital stretcher or having the patient walk, cough, or jump to determine if this exacerbates pain, are nonspecific for appendicitis and simply indicate peritoneal irritation.
- Diffuse peritonitis is consistent with ruptured appendicitis and intraabdominal sepsis. These patients usually present with temperature greater than 39°C and tachycardia.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Laboratory studies and radiologic studies can be complementary to history and physical exam in establishing the diagnosis. A mild leukocytosis is generally present. Occasionally, a "left shift" with normal leukocyte count is seen. Fewer than 5% of patients presenting with acute appendicitis will have both a normal white blood cell (WBC) count and no shift.
- Urinary analysis may show a few white or red cells but should not reflect bacteriuria.
- Serum chemistry testing for amylase and lipase and liver function tests are useful in cases where the history of presentation and physical exam findings are not classic and there is an atypical presentation.
- Imaging studies have come to the forefront of appendicitis diagnosis in recent years. Computed tomography (CT) enhanced with intravenous (IV) and enteral contrast is the gold standard for evaluation of appendicitis. Case series differ slightly in their reports, but a reasonable estimation is that CT is 90% sensitive and 95% specific for detection of appendicitis.
- Widespread use of CT has been shown to reduce the incidence of negative appendectomy.[1] Furthermore, findings of phlegmon or abscess on CT may prompt the surgeon to undertake an alternate approach in treating complex cases of appendicitis with percutaneous drainage and IV antibiotic therapy as the first step of therapy in order to minimize morbidity to the patient.
- Ultrasound remains an imaging modality that is operator dependent. In skilled centers, it can be especially helpful in pediatric patients and in early pregnancy.

- Plain abdominal radiographs should not be considered routine or mandatory in the specific evaluation of appendicitis but can be used as an initial test in patients presenting with diffuse peritonitis and signs of intraabdominal sepsis.

SURGICAL MANAGEMENT

- The bulk of surgical treatment should be discussed in the "Techniques" section. Here, consider indications and other more general concerns, such as discussed in the following sections.

Preoperative Planning

- Patients should receive adequate preoperative fluid resuscitation prior to operation in order to restore urine output. This is especially important for patients who show systemic signs of inflammation (systemic inflammatory response syndrome [SIRS]: fever, tachycardia, increased respiratory rate, WBC count $\geq$12,000/mm^3 or $\leq$4,000/mm^3, or >10% bands).
- Evidence-based studies clearly indicate that as soon as the decision to operate on the patient is made, IV antibiotics covering facultative, gram-negative, and anaerobic flora should be promptly administered in an effort to reduce surgical site infection (SSI).[2] If simple (nonruptured) appendicitis is encountered at operation, there is no benefit in administration of postoperative antibiotics.

Positioning

- The patient is positioned on a supine position with the arms extended or tucked depending on surgeon preference. A Foley catheter can be inserted at the surgeon's discretion.

TECHNIQUES

OPEN APPENDECTOMY FOR PRIMARY TREATMENT OF APPENDICITIS

First Step—Skin Incision

- A McBurney (oblique) or Rocky Davis (transverse) incision is made in the RLQ, slightly superior to the point of maximal tenderness found during preoperative exam, and centered on the midclavicular line (**FIG 1**).

Second Step—Abdominal Wall

- There are three muscle layers in the lateral abdominal wall. As these are encountered when entering the abdomen, these are the external oblique, the internal oblique, and the transversus abdominis muscles.
- Each muscle aponeurosis is cut in the direction of the muscle fibers.
- A muscle-splitting technique is used to spread apart each muscle layer along the orientation of the muscle fibers (**FIG 2**) until the peritoneum is reached.
- The peritoneum is then grasped with forceps in order to assure no bowel is adherent and is incised with scissors to enter the abdominal cavity (**FIG 3**).
- An appropriate retractor is placed to enhance operative exposure. This can be either a Balfour or a Bookwalter retractor.

Third Step—Exposure of the Appendix

- After the peritoneum is entered, the cecum is identified. Sponge sticks can be helpful to sweep the small bowel in a lateral to medial direction in order to expose the cecum.

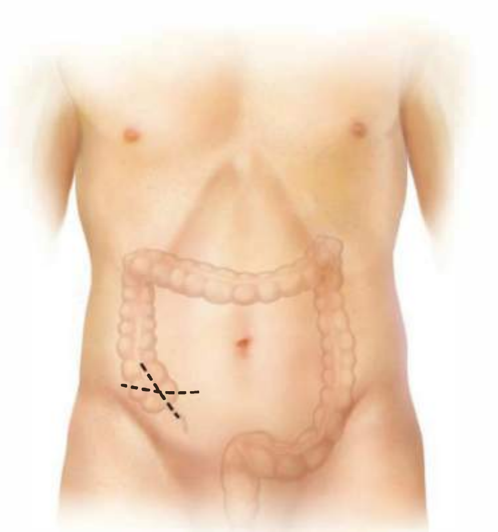

FIG 1 ● Incision placement. A Rocky Davis (transverse) or McBurney (oblique) incision is used. The midpoint of the incision should be centered over the maximal point of tenderness.

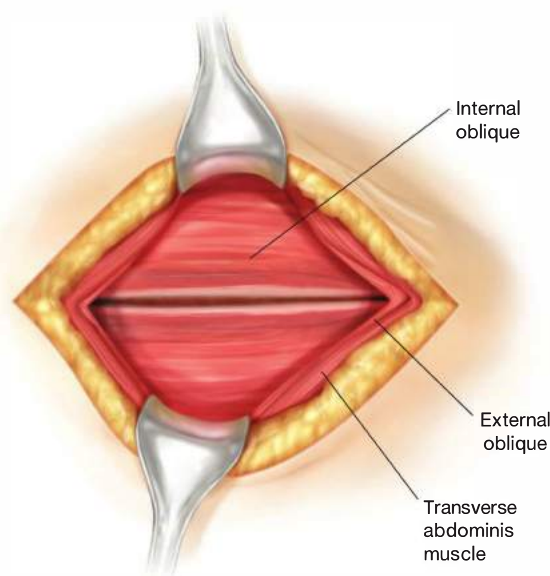

FIG 2 ● Abdominal wall opening. A muscle-splitting technique is used to spread apart each muscle layer along the orientation of the muscle fibers.

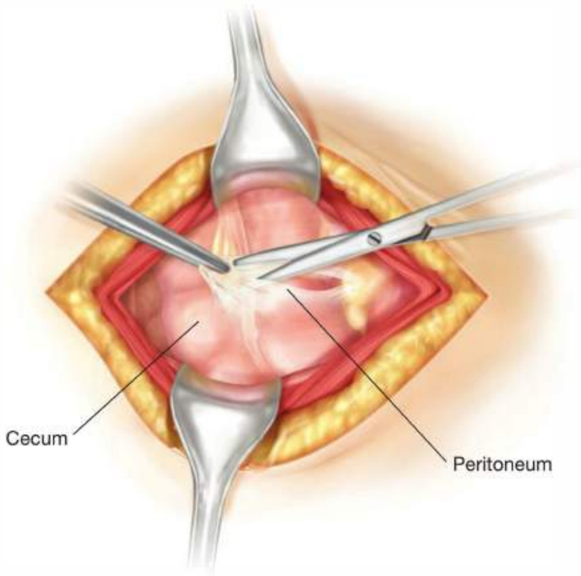

FIG 3 ● Abdominal wall opening. The peritoneum is then grasped with forceps in order to assure no bowel is adherent and is incised with scissors to enter the abdominal cavity.

- Once the cecum is identified, the anterior taenia is identified. The cecum is then mobilized, following the anterior taenia to its confluence with the appendiceal base (**FIG 4**).
- The convergence of all three teniae coli allows for the correct identification of the base of the appendix. This is critical to ensure that the entire appendix is removed.
- Failure to remove the base of the appendix may cause a closed loop obstruction between a persistent fecalith at the base of the appendix and the stump staple line. This may lead to an appendiceal stump blowout postoperatively.
- In cases of retrocecal appendicitis, the cecum will need to be fully mobilized in a lateral to medial fashion so that it is completely reflected from the retroperitoneum in order to find the appendix.

Fourth Step—Ligation and Resection

- The appendix and cecum are gently pulled into the wound. The mesoappendix is transected and ligated between clamps (**FIG 5**).
- Absorbable suture ties are placed at the appendiceal base, and the appendix is then transected (**FIG 6**). There is no supporting data for electrocautery ablation of the appendiceal mucosa at the ligated stump, and this common practice clearly puts at risk the security of the suture used to ligate the appendiceal stump.
- Inversion of the appendiceal stump may be performed if the surgeon desires. Commonly, a "Z-stitch" is used for this purpose (**FIG 7**).
- In the Z-stitch, the upper bite is placed as a Lembert suture and then brought below the base of the appendiceal stump and a second seromuscular stitch is placed. The base of the appendix is then inverted using forceps and the ends of the suture tied down over the inverted stump (**FIG 7**).
  - In cases of severe appendiceal stump edema and inflammation, a gastrointestinal stapler may be used to transect the base of the appendix, even including a segment of healthy cecal base in the resection; be careful to avoid impingement of the ileocecal valve when firing the stapler (**FIG 8**).

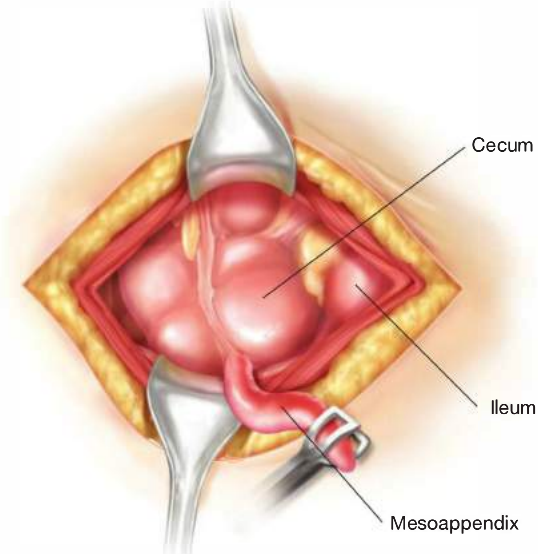

FIG 4 ● Delivery of the appendix into the wound. Once the cecum is identified, the anterior teniae coli is identified. The cecum is then mobilized following the anterior taenia to its confluence with the appendiceal base.

FIG 5 ● Clamping and ligation of the mesoappendix. The appendix and cecum are gently pulled into the wound. The mesoappendix is transected and ligated between clamps.

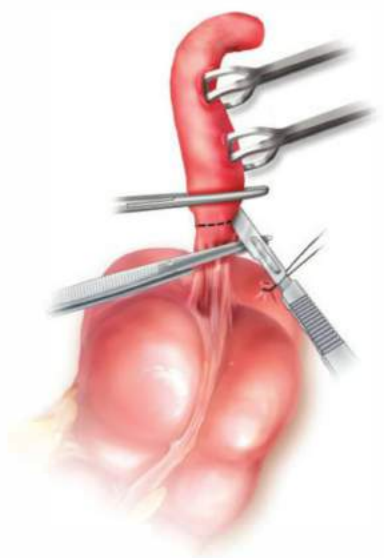

FIG 6 ● Ligation of the appendiceal base. Absorbable suture ties are placed at the appendiceal base, and the appendix is then transected.

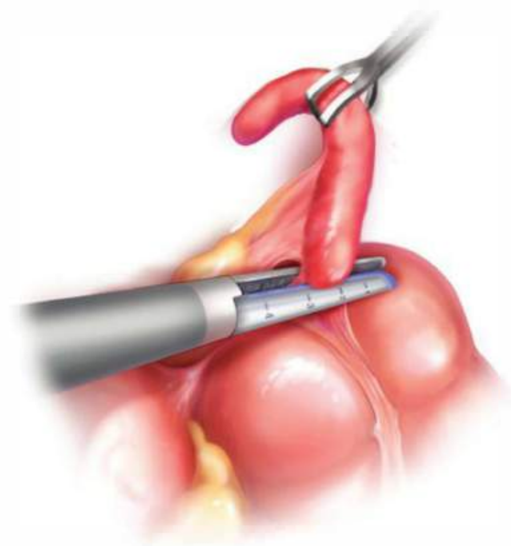

FIG 8 ● Use of gastrointestinal stapler to transect the appendiceal base.

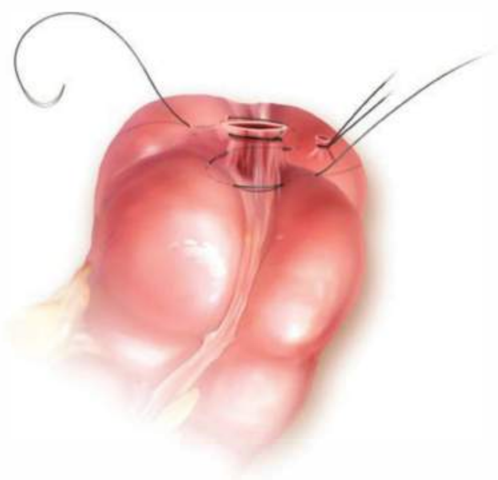

FIG 7 ● Inversion of the appendiceal stump. The appendiceal stump is inverted into the cecum with the placement of a Z-stitch.

- Irrigation of the surgical field is of unclear benefit. There are limited data in adults. A randomized prospective study in children failed to show any change in intraabdominal abscess whether irrigation was used or not used.[3]

Fifth Step—Closure

- All three muscle layers are closed separately with running absorbable suture.
- The skin can be closed, left open, or loosely approximated, depending on the severity of contamination encountered during the case.
- For gangrenous or perforated appendicitis, considered delayed primary closure or placement of a negative pressure wound therapy device to minimize superficial surgical site infection.
- No drain is indicated in simple appendicitis. Drain placement in cases of complicated appendicitis is also not supported by clinical trials.

OPEN APPENDECTOMY FOR APPENDICEAL NEOPLASMS

- Occasionally, the surgeon may encounter an appendiceal neoplasm as the cause of the suspected appendicitis. Overall, this happens in approximately 1% of cases of suspected appendicitis.
    - Appendiceal tumors encountered may include carcinoid tumor, mucinous neoplasm, or appendiceal/cecal adenocarcinoma. In these cases, it is essential to understand what operation needs to be done for the patient. **FIG 9** is shown as a quick reference guide.
    - For carcinoid tumors less than 1 cm in size, a simple appendectomy is sufficient.
    - For carcinoid tumors between 1 and 2 cm in size, surgical treatment will depend on the tumor location. If the carcinoid tumor is at the base of the appendix or if the tumor invades the mesoappendix, then a right hemicolectomy is indicated to obtain an

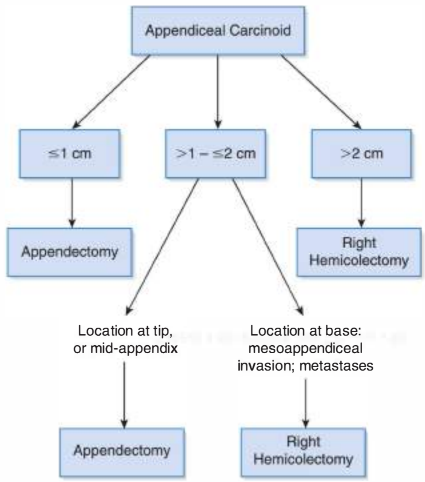

FIG 9 ● Management of appendiceal carcinoid.

adequate lymphadenectomy. Otherwise, a simple appendectomy is sufficient.

- For carcinoid tumors greater than 2 cm in size, a right hemicolectomy with a high ileocolic lymphovascular pedicle transection is indicated due to the higher incidence of metastatic disease observed in the nodal basin in these patients.[4]
- In cases where right hemicolectomy is indicated, it is prudent to close the RLQ incision and convert to a midline laparotomy.
- For mucinous appendiceal neoplasms, the extent of resection will be dictated by the degree of invasion. Intraoperatively, special attention should be given to not rupturing an intact mucinous neoplasm.
- If rupture of a mucinous neoplasm has occurred, then the surgeon should examine if mucin coats peritoneal surfaces. If mucin is diffusely coating the abdomen, then right hemicolectomy is indicated. If there is no mucin contamination, appendectomy with clear margins will suffice. Pathology must then be followed up to determine if the lesion was malignant or not.
- If malignancy is identified, refer to a specialty center for consideration of right hemicolectomy (if not originally performed). Debulking and intraperitoneal chemotherapy is also indicated in cases of diffuse mucin coating of the abdominal surfaces.[5]
- Nonmucinous appendiceal adenocarcinoma warrants a right hemicolectomy with a high ileocolic lymphovascular transection in order to perform an adequate lymphadenectomy.
- For the technical description on how to perform an open right hemicolectomy, please refer to the description of this technique elsewhere in this textbook.

CONVERSION TO OPEN APPENDECTOMY AFTER FAILED ATTEMPT AT LAPAROSCOPIC APPENDECTOMY

First Step—Skin Incision

- When converting to an open procedure from laparoscopy, a lower midline laparotomy incision is preferred. The incision may be extended above the umbilicus if additional exposure is required.

Second Step—Abdominal Wall

- It is essential to stay in the midline, along the linea alba, during the fascial incision in order to facilitate optimal closure and to prevent ventral incisional hernia formation. Care should be taken not to extend the incision too far inferiorly as the bladder is at risk of injury (especially in cases where no Foley catheter is present).

Third Step—Appendiceal Resection

- Once the peritoneum is entered, any adhesions are lysed sharply and an appropriate retractor is placed to enhance operative exposure. This can be either a Balfour or a Bookwalter retractor.
- At this point, the cecum is mobilized and the appendix is exposed. The mesoappendix is then divided and tied between clamps.
- The base of the appendix, identified by the convergence of the teniae coli at the base of the cecum, is ligated with sequential absorbable suture ties as described.
- If the base is easily identified at the beginning of the case, it may be helpful to perform a "retrograde" dissection of the appendix. In this technique, the appendiceal base is transected first. The mesoappendix is then sequentially transected from the appendiceal base to its tip (**FIG 10**). This technique can be useful when the mesoappendix is severely adhered to the cecum.
- If inflammation is severe, an ileocecectomy may be required or even partial colectomy. If inflammation is so severe as to preclude mobilization of the cecum and terminal lieum, a cecostomy maybe created. Please refer to the description of this technique described elsewhere in this textbook.

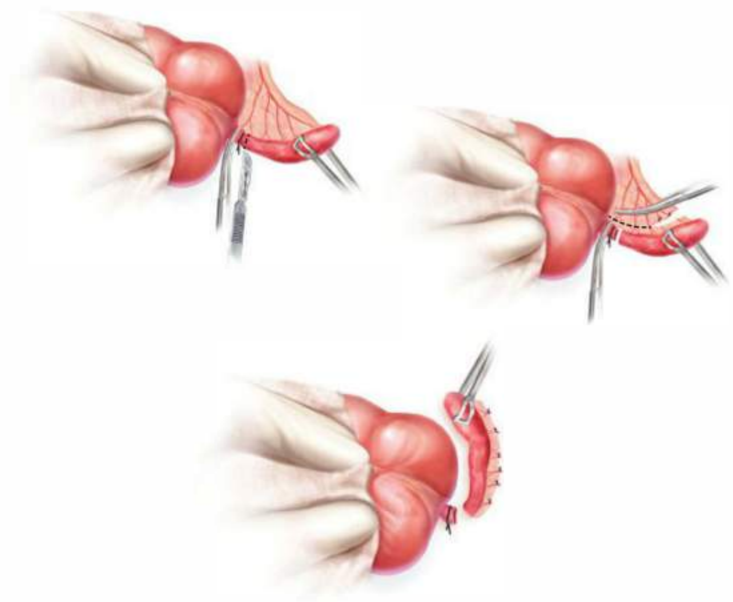

FIG 10 ● "Retrograde dissection" of the appendix. In this technique, the appendiceal base is transected first. The mesoappendix is then sequentially transected from the appendiceal base to its tip. This technique can be useful when the mesoappendix is severely adhered to the cecum.

PEARLS AND PITFALLS

Indications	■ Beware of atypical pathology in the atypical patient clinical presentation.
Placement of incision	■ Midline incision is preferred when converting from laparoscopic to open surgery. ■ For primary open RLQ incision approach, place the incision slightly higher than the maximal point of tenderness.
Exposure	■ Use sponge sticks to sweep the bowel out of the way and to expose the cecum. ■ *Gently* use Babcocks to pull the cecum and appendix into the wound.
Resection	■ Proper identification of the appendiceal base by the convergence of the teniae coli at the base of the cecum is critical to prevent incomplete resection and possible appendiceal stump blowout postoperatively. ■ If the base of the appendix is severely inflamed, use a gastrointestinal anastomosis (GIA) stapler to transect, including a segment of healthy cecal base in the resection (be careful to avoid impingement of the ileocecal valve). ■ Consider performing a retrograde appendectomy in cases where the appendix is densely adhered to the cecum.
Closure	■ For gangrenous or perforated appendicitis, considered delayed primary closure or placement of a negative pressure wound therapy device to minimize superficial surgical site infection.

POSTOPERATIVE CARE

- For cases of simple appendicitis, antibiotics should be stopped within 24 hours of surgery. There is no evidence supporting improved outcomes with additional antibiotics beyond 24 hours of surgery end time.
- In cases of gangrenous or perforated appendicitis, empiric antibiotic therapy should be continued with coverage for facultative, gram-negative, and anaerobic bacteria. Endpoints of duration of IV antibiotic coverage include WBC count less than 12,000/mm^3, less than 10% bands, return of bowel function, and temperature lower than 38°C. If these criteria are not reached by postoperative day 6, then a CT scan of the abdomen and pelvis with contrast is obtained to evaluate for potential intraabdominal and/or pelvic abscess.

COMPLICATIONS

- Appendectomy for simple appendicitis is performed with very low complication rate. Patients may be discharged home within 24 to 48 hours with no additional antibiotics needed.

- Appendectomy for complicated appendicitis carries significantly increased morbidity and mortality rates as compared to simple appendectomy.
  - Postoperative ileus is common, and diet should be initiated when clinical signs of return of bowel function exist.
  - SSI is also a common complication. SSI is lower in children than adults, and as such, primary closure after perforated open appendectomy is indicated in this setting.
  - Primary wound closure in adults should be done with caution as wound infection rates can approach 30%.[6]
- Intraabdominal abscess is treated with image-guided drainage and culture and IV antibiotic therapy tailored toward microbiology of the abscess. If the abscess is not accessible via percutaneous approach, a surgical drainage of significant collections via a laparoscopic or open approach is indicated.
- Append the seal stop blowout: Oftentimes, this is associated with incomplete resection of the appendix and may lead to severe peritonitis, necessitating repeat exploratory laparotomy. In these cases, an ileocecectomy and a possible performance of a temporary ileostomy should be considered. If inflammation is so severe as to preclude mobilization of the cecum and terminal lieum, a cecostomy tube maybe placed through the hole where the base of the appendix connected to the cecum in order to created a controlled fistula that may be treated at a later date.
- Incisional hernia: Incidence is higher with midline incisions.
- Postoperative small bowel obstruction

Chapter 7

Appendectomy: Laparoscopic Technique

Roosevelt Fajardo

DEFINITION

- Acute appendicitis is the most frequent cause of acute surgical abdominal pain seen in the emergency services around the world. Close to 7% of the total world population will suffer from appendicitis at some point in their lives. Although it may occur at any age, its incidence is higher in childhood, with a peak incidence between 10 and 30 years of age. It is more frequent in men, with a male-to-female ratio of 1.4:1. Advances in laparoscopic surgery around the world have made laparoscopic appendectomy a safe and simple procedure.

DIFFERENTIAL DIAGNOSIS

- Urinary tract infection
- Intestinal obstruction
- Acute cholecystitis
- Mesenteric adenitis
- Meckel's diverticulitis
- Colonic diverticulitis
- Right ureteric colic
- Ectopic pregnancy
- Salpingitis, pelvic inflammatory disease
- Ruptured ovarian follicle
- Gastroenteritis
- Terminal ileitis

PATIENT HISTORY AND PHYSICAL FINDINGS

- Despite advances in diagnostic imaging, diagnosis of acute appendicitis continues to be predominantly clinical. A good clinical history and a thorough physical examination should provide the surgeon with a high degree of suspicion. The characteristic clinical picture is one of abdominal pain that exacerbates with movement, starting in the periumbilical region and then migrating to the right lower quadrant. Fever, anorexia, nausea, and vomiting are frequent.
- The Alvarado score, a clinical scoring system used in the diagnosis of appendicitis, assigns points to six clinical items and two laboratory measurements with a maximum possible total of 10 points. With scores greater than 5, the probability of acute appendicitis increases.
- A popular mnemonic used to remember the Alvarado score factors is **MANTRELS**: **M**igration to the right iliac fossa, **A**norexia, **N**ausea/Vomiting, **T**enderness in the right iliac fossa, **R**ebound pain, **E**levated temperature (fever), **L**eukocytosis, and **S**hift of leukocytes to the left. Due to the popularity of this mnemonic, the Alvarado score is sometimes referred to as the MANTRELS score.
- The location of the appendix may change the clinical presentation. With the appendix in a retrocecal location, patients may present with right flank pain. With an appendix in a pelvic location, patients typically present with urinary symptoms and diarrhea.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- The hemogram typically shows a leukocytosis, with a left-sided shift. Female patients in fertile age should have a pregnancy test prior to surgery.
- Ultrasound (**FIG 1**) has shown to have 86% sensitivity and 81% specificity for the diagnosis of acute appendicitis and has the benefit of not being invasive, but it is operator dependent.
- Computerized axial tomography (CAT; **FIG 2**) scan, with a 94% sensitivity and a 95% specificity, has been shown to be the most accurate imaging study for the diagnosis of acute appendicitis but is expensive and may delay surgical intervention.
- Magnetic resonance imaging (MRI) is reserved for patients who cannot be exposed to radiation, such as pregnant women suspected of having appendicitis.

SURGICAL MANAGEMENT

Indications

- Same indications than for open appendectomy
- Any patient with diagnosis of appendicitis who can tolerate pneumoperitoneum and general anesthesia, provided that trained staff and the necessary equipment for a safe procedure are available

Preoperative Planning

- Appropriate prophylactic antibiotic should be administered 30 minutes before surgery.
- Decompression of the bladder by voiding before surgery or by using a Foley catheter may avoid injury of the bladder during trocar placement.

Patient and Team Positioning

- The patient is secured to the table with the arms padded and tucked to the side.
- The surgeon and the camera operator stand on the patient's left side (**FIG 3**).
- The monitor is placed in front of the surgeon (at eye level) on the patient's right side.

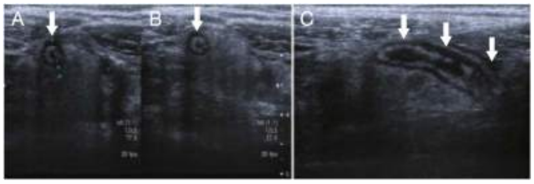

FIG 1 ● Ultrasound imaging in appendicitis. *Arrows* show a distended appendix with a thickened wall. **A** and **B** show transverse views of the appendix. **C** shows a longitudinal view of the appendix.

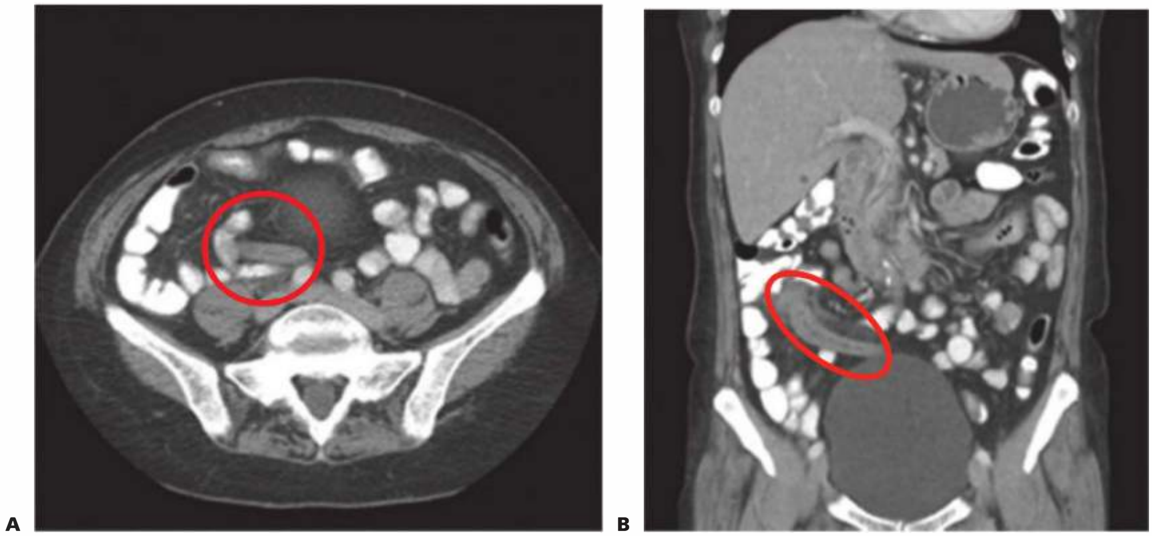

FIG 2 ● CAT scan imaging in appendicitis. **A:** Axial view. **B:** Coronal view. Red circles show acute appendicitis with periappendiceal inflammation.

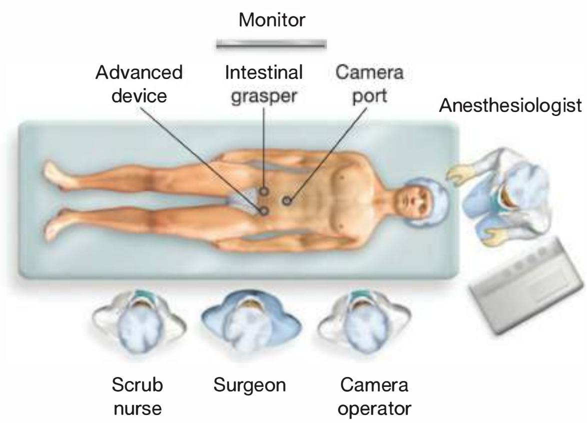

FIG 3 ● Patient, port, team, and operating room setup.

Port Placement

- A traditional laparoscopic appendectomy is performed using a three-port system (**FIGS 3** and **4**). The surgeon should be able to work two-handed.
- The ports are triangulated to enhance maneuverability and exposure.
- A 10-mm Hasson trocar is inserted in the umbilicus. This trocar will be used for CO_2 insufflation and also as a camera port.
- A 12-mm trocar is inserted in the left lower quadrant. In addition to being the main dissection port, this port will be used for the stapler and also as an extraction site. If a good quality 5-mm camera is available, then a 5-mm port can be inserted in this location; in this alternative setup, the specimen would be retrieved through the umbilical port site.
- A 5-mm trocar is inserted in the right lower quadrant. This trocar will be used to help retract and expose. Placement of a urinary catheter may be required before introducing the lower abdominal trocars in order to reduce the risk of bladder perforation during this step of the procedure.

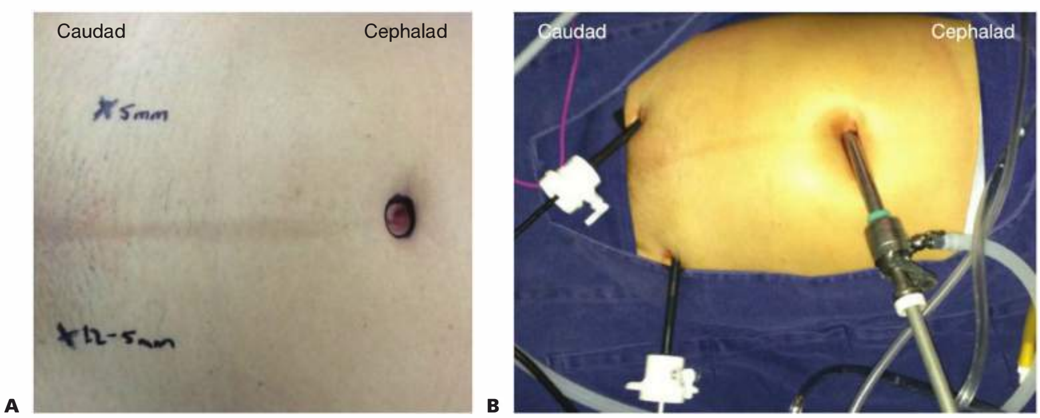

FIG 4 ● **A,B.** Port placement. The three ports are triangulated to enhance maneuverability and visualization.

STEP 1. EXPOSURE OF THE APPENDIX AND IDENTIFICATION OF THE APPENDICEAL BASE

- The patient is placed in a Trendelenburg position and rotated with the right side up to help mobilize the small bowel out of the field of view and to enhance operative exposure.
- The fold of Treves (an antimesenteric fat fold also known as the sail sign) allows for identification of the terminal ileum (**FIG 5**). Following the terminal ileum distally to the ileocecal junction facilitates identification of the cecum. The appendix can usually be seen at the base of the cecum.
- In retrocecal appendicitis cases, the cecum may have to be mobilized medially by transecting its lateral peritoneal attachments in order to expose the appendix.
- The base of the inflamed appendix is localized by identifying the convergence of the three teniae coli at the base of the cecum (**FIG 5**).

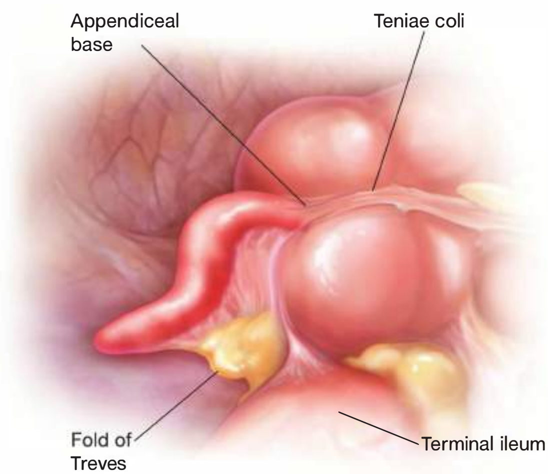

FIG 5 ● The appendiceal base can be identified by the convergence of the teniae coli at the base of the cecum. Identifying the ileocecal junction, with the fold of Treves in the antimesenteric aspect of the terminal ileum, facilitates identification of the cecum and the appendix in patients with severe inflammation.

STEP 2. DIVISION OF THE MESOAPPENDIX

- Once identified, the tip of the appendix is pulled up with a grasper introduced through the right lower quadrant port site. This allows for the exposure of the triangular-shaped space between the appendix, the cecum, and terminal ileum, where the mesoappendix can be readily identified (**FIG 6**).
- The mesoappendix can then be sequentially transected with an advance energy device (LigaSure or a Harmonic) (**FIG 7**) very close to the appendix. Transection of the mesoappendix is carried down to the base of the appendix (**FIG 8**). Alternatively, the mesoappendix may be transected with a linear vascular load stapler.

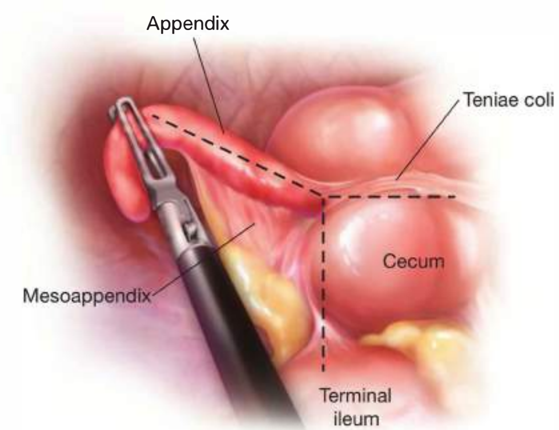

FIG 6 ● Exposure of the mesoappendix. Pulling up on the tip of the appendix exposes the triangular space between the appendix, the cecum, and terminal ileum, where the mesoappendix can be readily identified.

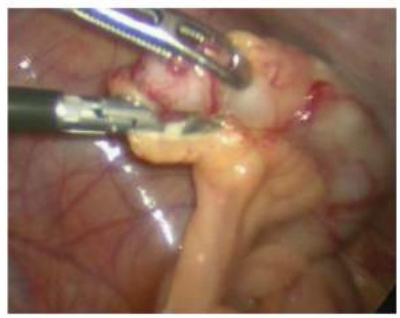

FIG 7 ● Transection of the mesoappendix with an energy device.

FIG 8 ● The appendix has been completely skeletonized by transecting the mesoappendix down to the level of the appendiceal base. The appendix is now ready for transection.

STEP 3. TRANSECTION OF THE APPENDIX

- The appendix is transected at its base, flush to the cecal wall.
- This is critical to avoid, potentially leaving a fecalith impacted in a retained, long appendiceal stump. In this situation, a dead space will be left between the stapled transected end of the appendix and the persistent luminal obstruction produced by the fecalith at the base of the appendix. Progressive fluid and gas accumulation in this dead space could lead to a "blown" appendiceal stump and the development of severe peritonitis postoperatively.
- If the base of the appendix is sufficiently narrow, it may be ligated with 8- to 10-mm Hem-o-Lok clips (**FIG 9**) or with a pretied Roeder's endoloop. In cases where the appendix is thicker and inflamed, a linear 30- or 45-mm stapling device (introduced through the right lower quadrant port site) may be used to transect the appendix at its base (**FIG 10**).

A

B

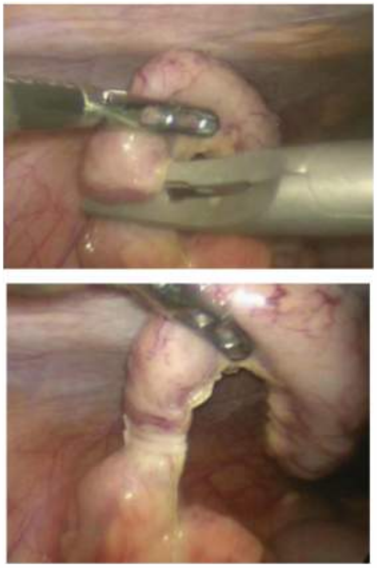

FIG 9 ● **A,B.** Ligation of the appendiceal base with Hem-O-Lock clips. This is only possible when the appendiceal base is sufficiently narrow.

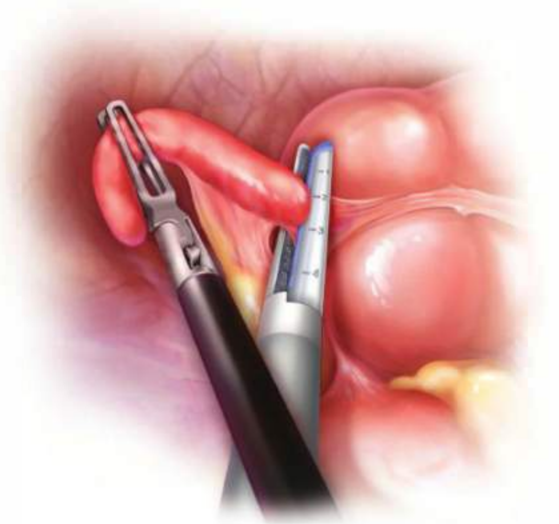

FIG 10 ● In cases with a thick appendix with severe inflammation, the appendix is transected at its base with a linear stapler device.

STEP 4. RETRIEVAL OF THE SPECIMEN

- With the appendix transected, the appendiceal stump staple line is checked for integrity and hemostasis (**FIG 11**).
- The appendix may be then retrieved through the 12-mm trocar site using an endoretrieval bag (**FIG 12**).

FIG 11 ● With the appendix transected, the appendiceal stump staple line is checked for integrity and hemostasis.

FIG 12 ● The appendix may be then retrieved through the 12-mm trocar site using an endoretrieval bag.

STEP 5. CLOSURE

- The operative site is irrigated with sterile normal saline solution.
- A drain is placed by the appendiceal stump only in cases of perforated appendicitis.
- The pneumoperitoneum is evacuated.
- All ports are removed.
- The skin incisions are closed with reabsorbable subcuticular sutures.

PEARLS AND PITFALLS

Localization on the appendix	■ By identifying the cecum and following the teniae coli distally or using the terminal ileum as a guide to reach the ileocecal valve
Transection of the mesoappendix	■ Stay close to the appendix; this will minimize cumbersome bleeding and will facilitate the extraction of the specimen from the abdominal cavity.
Transection of the base of the appendix	■ It is imperative to transect the base of the appendix to prevent a potential blown appendiceal stump syndrome. ■ If the base of the appendix is too thick, use a linear stapling device.
Extraction from the abdominal cavity	■ Use an endoretrieval bag to protect the wound. You may need to expand the 12-mm trocar site if the appendix is bulky.
Use of drainage	■ Only leave a closed drainage in cases of perforation of the appendix.

POSTOPERATIVE CARE

- This procedure, done through laparoscopy, is less painful, and it may be done as an outpatient procedure in most cases of uncomplicated appendicitis. The patient can resume oral feeding within a few hours of the surgery and go back to routine activities sooner than with traditional open surgery.
  - Patients with perforated or complicated appendicitis are generally admitted for intravenous (IV) antibiotics until they are afebrile with a normal white blood cell count. Antibiotics are usually targeted toward gram-negative and anaerobic organisms. As with patients with simple appendicitis, discharge criteria include ability to tolerate oral intake and appropriate pain control. If patients continue to have abdominal pain, develop leukocytosis, or become febrile after undergoing appendectomy for perforated or complicated appendicitis, their symptoms may be signs of an intraabdominal abscess. Image-guided percutaneous drainage may be needed for resolution.

OUTCOMES

- Laparoscopic appendectomy has been shown to have multiple advantages over the open procedure, including a lower rate of wound site infection, although there are reports in the literature of an increased rate of residual abscesses when compared with open appendectomy.

COMPLICATIONS

- Complications of acute appendectomy are relatively rare, and they are more frequently associated with the disease status or the presence of perforation.
- In nonperforated appendicitis, reported mortality is 0.8 per 1,000, and it increases to 5.1 per 1,000 in cases of perforation.
- Wound infection may vary from 5% to 50% in cases of perforated appendicitis.

- Surgical site infection is directly related to the status of the disease, and it increases by up to 20% in cases of perforated appendicitis. With the advent of laparoscopic appendectomy, this rate of infection has dropped dramatically.
- Hematoma
- Appendiceal stump leak/blowout
- Port site hernia

Chapter 8

Appendectomy: Single-Incision Laparoscopic Surgery Technique

Reshma Brahmbhatt   Mike K. Liang

DEFINITION

- Single-incision laparoscopic surgery (SILS) appendectomy is defined as laparoscopic removal of the appendix using a single skin incision. The entire procedure, including an intracorporeal appendectomy, is performed laparoscopically. This is in contrast to other methods of single-incision appendectomy, which use a single port/incision for dissection but then proceed to pull the appendix out of the incision and essentially perform an open appendectomy. The addition of an additional port distant from the single incision (usually the suprapubic region) is called a SILS plus one (SILS +1) appendectomy.

DIFFERENTIAL DIAGNOSIS

- The differential diagnosis for acute appendicitis in the healthy adult patient includes gastroenteritis, colitis, cystitis/pyelonephritis, inflammatory bowel disease, and diverticulitis.
- Female patients have an expanded differential diagnosis, which can include pelvic inflammatory disease, ovarian pathology, ectopic pregnancy, endometriosis, and mittelschmerz.
- Pediatric patients can have acute mesenteric adenitis, especially following an upper respiratory tract illness, that can mimic acute appendicitis.
- Immunosuppressed patients may have opportunistic infections that present in a similar fashion to acute appendicitis, and consideration should be given to a full infectious workup.

PATIENT HISTORY AND PHYSICAL FINDINGS

- For patients to undergo SILS appendectomy, they must be candidates for traditional laparoscopic appendectomy. Patients with previous midline abdominal surgery or large ventral hernias may present a relative contraindication to SILS appendectomy due to adhesions and potential difficulty with abdominal entry.
- A thorough history and physical examination is necessary to carefully select patients for SILS appendectomy. Pediatric, elderly, and pregnant patients are appropriate for SILS appendectomy.[1] Absolute and relative contraindications to SILS appendectomy are listed in Table 1.

Table 1: Absolute and Relative Contraindications to Single-Incision Laparoscopic Surgery Appendectomy

Absolute contraindications	• Hemodynamic instability • Inability to undergo general anesthesia • Inability to tolerate abdominal insufflation
Relative contraindications	• Generalized peritonitis • History of midline laparotomy or umbilical hernia repair with prosthetic material • Large midline ventral hernia • Surgeon inexperienced with single-incision laparoscopic procedures

- A thorough history should be performed, including location and duration of symptoms, previous history of similar episodes, and detailed past medical and surgical history. A short (1 to 2 days) history of nausea/vomiting, anorexia, fevers, and periumbilical or right lower quadrant pain in a previously healthy patient is suspicious for acute appendicitis. A longer (5 to 7 days) history of nausea/vomiting, malaise, fevers, and right lower quadrant pain may be consistent with perforated appendicitis and abscess formation.
- A complete physical examination should be performed. Particular attention should be paid to the patient's vital signs and abdominal examination. The patient will often be ill appearing and prefer to lie still.
- Classic abdominal findings of appendicitis include tenderness in the right lower quadrant with localized guarding and rebound. The abdomen is often soft with minimal to no distention.
- Female patients of childbearing age should undergo a bimanual vaginal examination to evaluate for gynecologic conditions, such as pelvic inflammatory disease or adnexal abnormalities, which may mimic appendicitis.
- Atypical presentations of acute appendicitis can include suprapubic pain, right flank pain, and right upper quadrant pain, depending on where the appendix may be located.
- Anatomic variations may cause pain in the right flank (retrocecal appendix) or even the absence of abdominal pain (pelvic-lying appendix). Right-sided pain on rectal examination may point toward an appendix hanging in the pelvis.
- It is also important to note that with very early appendicitis, the patient will often have mild (or even absent) signs and symptoms. These clinical variations should be kept in mind while evaluating the patient for acute appendicitis.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Standard laboratory studies ordered in the evaluation of acute appendicitis include a complete blood count, basic metabolic panel or electrolytes, and urinalysis and urine pregnancy test.
- An elevated white blood cell count suggests an inflammatory response such as appendicitis.
- Electrolyte derangements due to dehydration or vomiting should be corrected prior to surgical management.
- A urinalysis may show a urinary tract infection or cystitis to be the source of the patient's symptoms rather than appendicitis; however, identifying leukocytes in the urine is not uncommon with acute appendicitis.
- A positive urine pregnancy test should prompt further evaluation of another diagnosis (such as ruptured ectopic pregnancy) and will affect the medications and anesthesia used during the procedure.
- Clinical scoring systems, such as the Alvarado score or the appendicitis inflammatory response score use various laboratory and clinical findings to assess a patient's likelihood of having acute appendicitis.[2–3]

- Computed tomography (CT) is the most ordered radiologic study in the evaluation of acute appendicitis. The scan should be ordered as a CT abdomen/pelvis with intravenous (IV) and oral or rectal contrast.
- CT findings consistent with appendicitis include appendiceal dilation, failure of appendiceal opacification with oral or rectal contrast, presence of a fecalith, periappendiceal fat stranding and enhancement, and pelvic free fluid. CT is excellent in visualizing perforated appendicitis with an abscess and should be considered in any patient where the diagnosis of complicated appendicitis is entertained. Additionally, CT can provide information on other intraabdominal and pelvic structures/pathology (**FIG 1**).
- Transabdominal ultrasonography can be used to evaluate for appendicitis as a nonradiating alternative to CT scans. Findings consistent with appendicitis include a thickened appendiceal wall, appendiceal dilation, identification of a fecalith, periappendiceal fluid, and a "target sign." Limitations to ultrasonography include operator dependence and difficulty in appendiceal visualization in patients with higher body mass index (BMI) (**FIG 2**). Ultrasonography is most often used in children and pregnant patients.
- Focused magnetic resonance imaging (MRI) has been used in specific cases as an alternative to CT scan and ultrasound. Pregnant women and children may benefit from this nonradiating imaging modality, but MRI may not be as readily available as ultrasound and CT scan in all centers. The need for MRI should be evaluated on a case-by-case basis.
- Women of childbearing age may require evaluation of their adnexal structures via CT scan or transvaginal/transabdominal ultrasonography to rule out differential diagnoses.
- In adult male patients with a classic presentation of appendicitis, radiologic studies are not necessarily indicated and are used only at the discretion of the surgeon.

FIG 1 ● CT scan demonstrating acute appendicitis. The appendix is dilated, thick-walled, and enhances with IV contrast *(arrow)*, suggesting inflammation. There is also stranding/thickening around the adjacent cecal wall.

FIG 2 ● Ultrasound examination demonstrating acute appendicitis. The appendix is noncompressible and contains a visible fecalith *(arrow)*.

SURGICAL MANAGEMENT

Preoperative Planning

- Preoperative antibiotics, with gram-negative and anaerobic coverage, should be administered before the incision is made.
- A Foley catheter should be placed to ensure bladder decompression.
- Patients with large midline laparotomy scars or periumbilical hernia repairs may have significant adhesions or prosthetic material at the level of the umbilicus, making safe abdominal entry potentially difficult. The surgeon should use his or her discretion at proceeding with a SILS appendectomy in these particular patients and should have a low threshold for adding additional ports (SILS +1 appendectomy) for improved exposure and visualization.

Positioning

- SILS appendectomy is performed from the left side of the patient, similar to traditional laparoscopic appendectomy. The patient should be positioned in a supine position, with the left arm tucked to provide adequate space for the surgeon and the assistant (**FIG 3**).

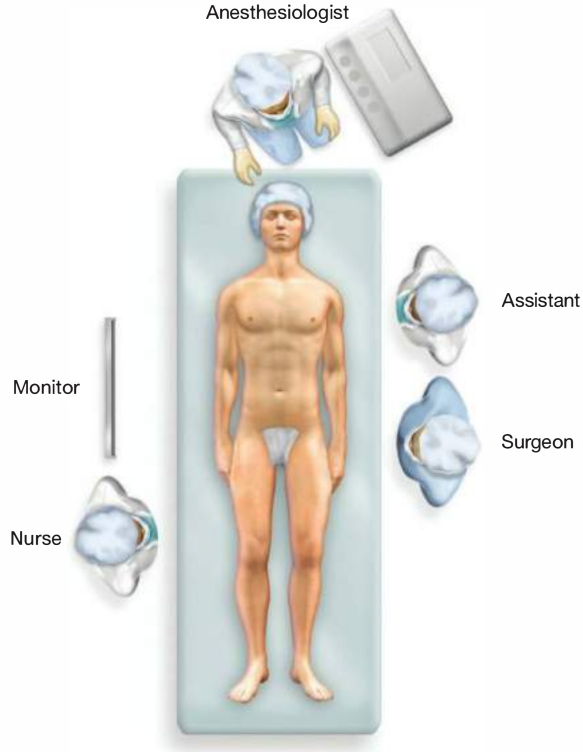

FIG 3 ● Patient, team, and operating room setup. The surgical team stands at the patient's left side. The patient is positioned in a supine position, with the left arm tucked to provide adequate space for the surgeon and assistant. The laparoscopic monitor should be positioned at the right side of the patient.

- The patient's abdomen should be prepped and draped from the xiphoid to the pubis, allowing for possible conversion to a traditional laparoscopic or open appendectomy if indicated.
- The laparoscopic monitors should be positioned at the right side of the patient or at foot of the operating table (**FIG 3**).

SKIN INCISION AND PORT PLACEMENT

- A 12- to 20-mm incision should be made adjacent to or through the umbilicus, with consideration for the potential need to extend the incision if conversion to an open appendectomy is needed (**FIG 4**). In patients with previous periumbilical or midline laparotomy scars, the surgeon should consider alternative methods of abdominal entry

FIG 4 ● Placement of the incision. A 12- to 20-mm incision should be made adjacent to or through the umbilicus, with consideration for the potential need to extend the incision if conversion to an open appendectomy is needed.

(Veress needle insufflation through the left upper quadrant, trocar insertion in left upper quadrant, etc.) or alternate placement of the SILS port (supraumbilical, left lateral abdomen). Although these methods may result in a SILS +1 appendectomy or in a more challenging closure of the incision, they may allow safer entry into the peritoneal cavity.

- The umbilical skin incision should be taken down through the subcutaneous tissues. The midline fascia close to the umbilicus (umbilical stalk) should be incised in a longitudinal manner.
- Once safe access into the peritoneal cavity is confirmed, the port should be placed through the incision following the port manufacturer's instructions.
- There are many types of SILS ports currently available; the type of SILS port used is left to the discretion of the surgeon (**FIG 5**). An alternative to the placement of a SILS port is to insert multiple standard ports through a single skin incision.
- Prior to port placement, a surgical sponge may be introduced into the abdominal cavity to facilitate retraction later in the procedure.
- Port placement varies depending on the single-port device used. Once the port is placed, pneumoperitoneum is created and the laparoscopic camera and instruments are introduced. It is advisable to triangulate the ports to minimize instrument conflict.

FIG 5 ● SILS port placed via umbilical incision.

- A 30-degree camera and traditional straight laparoscopic instruments are used. Alternatively, articulated instruments may be employed.
- In order to afford maximal operative reach and to avoid internal and external instrument conflict, bariatric and standard length instruments may be used simultaneously. Moreover, a right-angle light cord adaptor may be used to further decrease conflict.
- The patient is placed in a Trendelenburg position with the left side down to help move the small bowel into the left upper quadrant, enhancing exposure of the cecum and the appendix.

APPENDICEAL IDENTIFICATION

- The right lower quadrant should be examined closely (**FIG 6**). Significant fluid or abscess collections should be carefully aspirated to allow for visualization of the right lower quadrant.
- The presence of significant adhesions may require additional port placement or conversion to traditional laparoscopic appendectomy (or open procedure) to allow for appropriate visualization and/or adhesiolysis.
- The appendiceal base should be identified using the convergence of the teniae coli at the base of the cecum as a landmark.
- The surgeon's right-hand instrument should grasp and elevate the appendix. The left-hand instrument should bluntly dissect any adhesions, allowing for full visualization of the appendix, from tip to base.
- If the appendix appears to be completely normal, the right lower quadrant should be closely investigated for other potential sources of the patient's symptoms. Any diagnosis other than appendicitis should prompt appropriate management by the surgeon and may require conversion to a traditional laparoscopic or open procedure. Appendectomy may be performed at the same time, as per the surgeon's discretion.

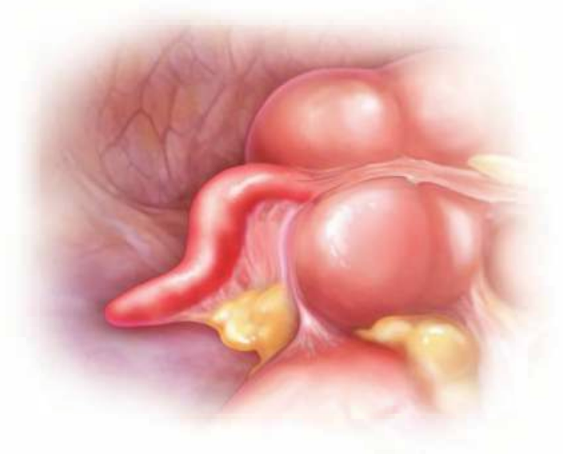

FIG 6 ● Examination of right lower quadrant showing inflamed appendix.

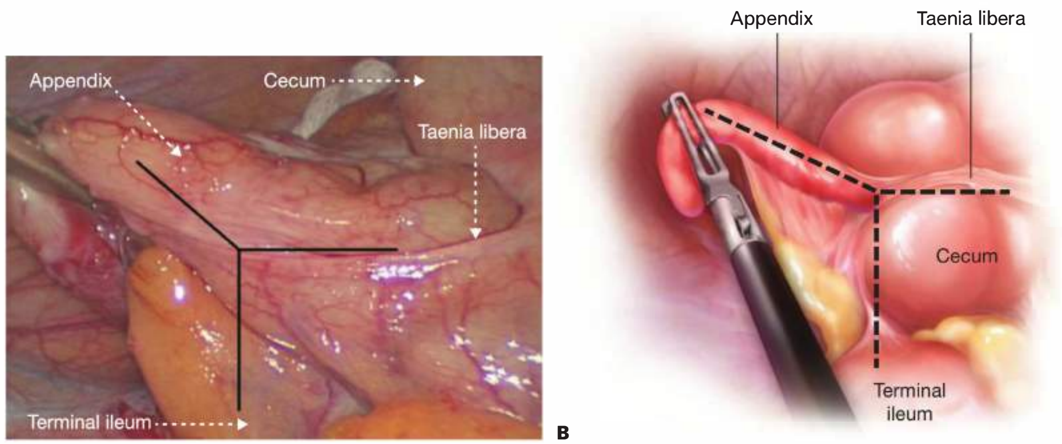
APPENDICEAL CRITICAL VIEW[4]

- The appendix should be retracted to the 10 o'clock position, the terminal ileum should be placed in the 6 o'clock position, and the taenia libera (anterior band of the teniae coli) should be positioned in the 3 o'clock position (**FIG 7**). This allows for clear identification of the appendiceal base and associated anatomy prior to appendiceal transection.
- If the critical view cannot be obtained, or the appendiceal base is not easily identified, a suprapubic port can be placed to allow for further dissection/retraction (SILS +1 appendectomy). If the anatomy still remains unclear, the procedure can be converted to a traditional laparoscopic appendectomy or to an open appendectomy, as per the surgeon's discretion.

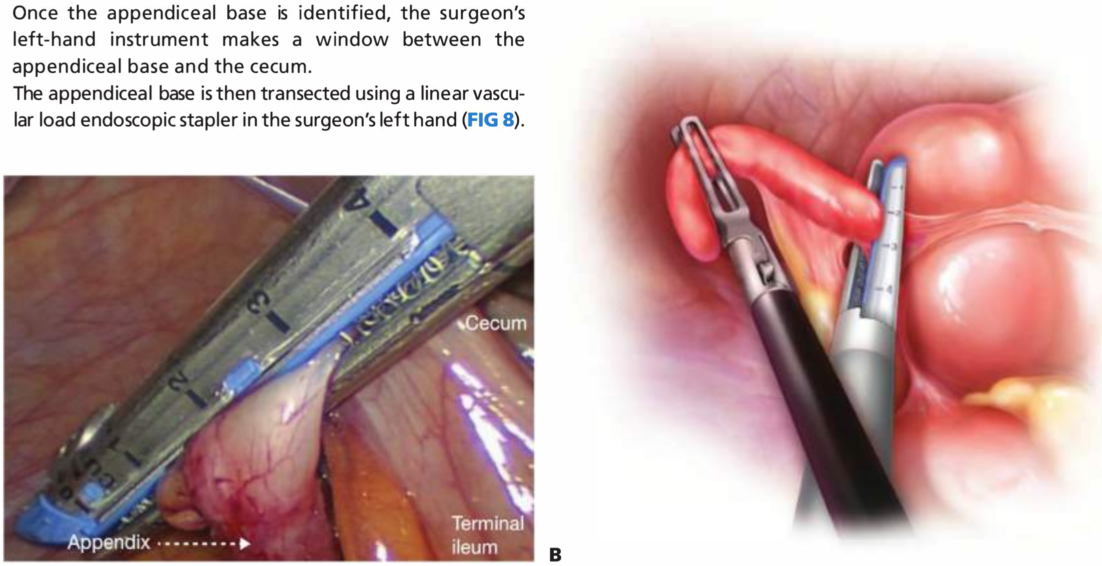


A B

FIG 7 ● **A.** The appendiceal critical view. The appendix is retracted to the 10 o'clock position, the terminal ileum is placed in the 6 o'clock position, and the taenia libera (anterior band of the teniae coli) is positioned in the 3 o'clock position. The terminal ileum can be identified by the fold of Treves (fatty fold in the antimesenteric border of the terminal ileum), also known as the "sail sign." **B.** Illustration of this step.

APPENDICEAL TRANSECTION

- Once the appendiceal base is identified, the surgeon's left-hand instrument makes a window between the appendiceal base and the cecum.
- The appendiceal base is then transected using a linear vascular load endoscopic stapler in the surgeon's left hand (**FIG 8**).



A B

FIG 8 ● **A.** Appendiceal base transection by an endoscopic stapler. **B.** Illustration of this step.

- The appendiceal mesentery is similarly transected using a linear vascular load endoscopic stapler.
- Alternatively, similar to traditional laparoscopic appendectomy, energy devices and endoloops may be used as per the surgeon's discretion.
- The appendix is then placed in a retrieval bag, if desired, and removed via the port site. The specimen should be sent for pathologic evaluation and assessment. A proportion of appendectomies (up to 1%) have associated tumors or malignancies.

PORT SITE CLOSURE

- Once the appendix has been removed from the abdominal cavity, operative field is examined for hemostasis. Minor bleeding from the mesenteric staple line can be controlled with electrocautery. The appendiceal stump should be examined to ensure a complete staple line (**FIG 9**). Any blood or purulent material should be aspirated out of the abdominal cavity. Drains should not be placed under routine circumstances.

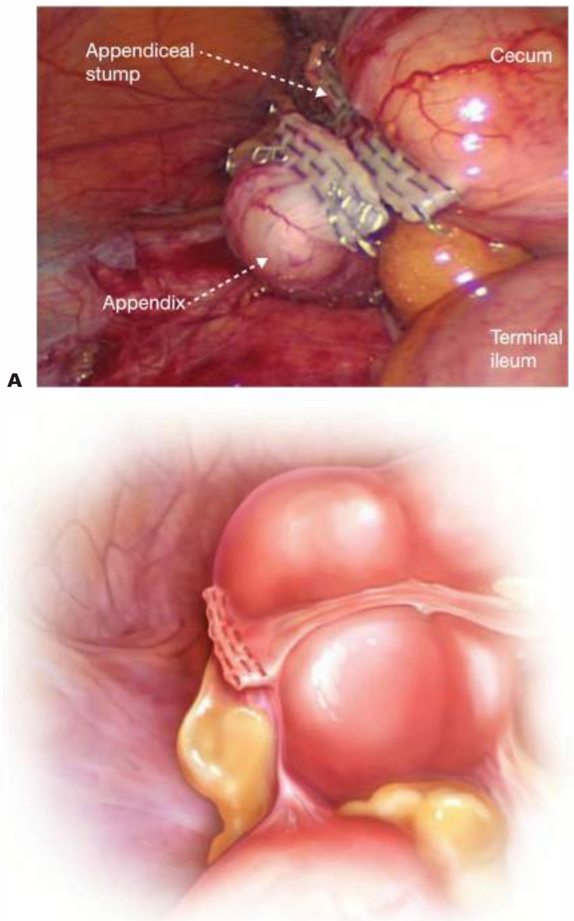


FIG 9 ● **A.** After transection, the operative field is inspected to ensure adequate hemostasis and an intact appendiceal stump staple line. **B.** Illustration of this step.

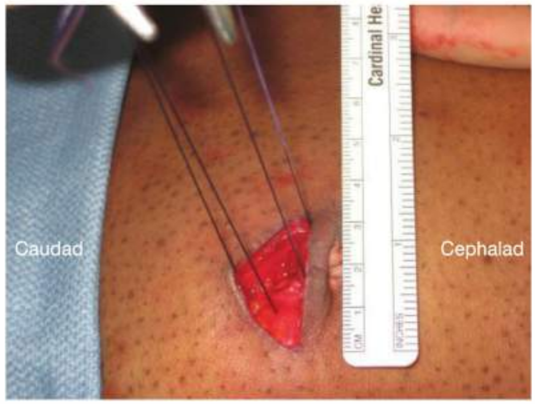

FIG 10 ● The fascial defect is closed with interrupted absorbable figure-of-eight sutures.

- Any additional ports are removed under direct visualization and the abdomen is desufflated. The SILS port is removed according to the port manufacturer's instructions.
- The fascial defect is closed with interrupted absorbable figure-of-eight sutures (**FIG 10**). The subcutaneous tissues are irrigated and the skin is closed with a subcuticular stitch (**FIG 11**).
- If the incision was made through the umbilicus, care should be taken to sew the umbilicus down to the fascia and to reapproximate the umbilical skin well to allow for an aesthetically pleasing closure and to prevent seroma formation.

FIG 11 ● The subcutaneous tissues are irrigated and the skin is closed with a subcuticular stitch.

PEARLS AND PITFALLS

Indications	■ A complete history and physical examination and review of available imaging should take place to confirm the diagnosis of appendicitis and to assure the patient is a suitable candidate for SILS appendectomy.
Abdominal entry	■ If a safe periumbilical entry is questionable, alternate port site placement, or additional ports, may be placed to assist in SILS port placement.
Critical view	■ The appendix should be retracted to the 10 o'clock position, the terminal ileum should be placed in the 6 o'clock position, and the taenia libera (anterior band of the teniae coli) should be positioned in the 3 o'clock position. ■ Complete visualization of the appendiceal base is mandatory prior to transection. If this is not possible, conversion to a SILS +1 or to a traditional laparoscopic appendectomy may be required.
Closure	■ If the incision was transumbilical, the umbilicus should be tacked back down to the fascia.

POSTOPERATIVE CARE

- Patients with simple or uncomplicated appendicitis are usually discharged home after a 23-hour observation period, during which the patient is confirmed to tolerate oral intake and to have appropriate pain control.[5,6]
- Recent studies advocate for same-day discharge for this patient population; discharge timing remains up to the discretion of the surgeon.
- Patients with perforated or complicated appendicitis are generally admitted for IV antibiotics for 3 to 7 days or until they are afebrile and with a normal white blood cell count. Antibiotics are usually targeted toward gram-negative and anaerobic organisms.
- As with patients with simple appendicitis, discharge criteria include ability to tolerate oral intake and appropriate pain control.
- If patients continue to have abdominal pain, develop leukocytosis, or become febrile after undergoing appendectomy for perforated or complicated appendicitis, their symptoms may be signs of an intraabdominal abscess. Image-guided percutaneous drainage is usually needed for resolution.
- Pathology results should be concordant with the diagnosis of acute appendicitis. A negative appendectomy should prompt further workup as required.
- A pathologic diagnosis of appendiceal tumor or malignancy is present in 1% of specimens removed for acute appendicitis.

OUTCOMES

- Although long-term studies evaluating SILS appendectomy are not currently available due to the new nature of the approach, reviews and pooled analyses show no difference in complications and outcomes compared to traditional laparoscopic appendectomy.[7–11]
- A recent prospective randomized controlled trial comparing SILS appendectomy to traditional laparoscopic appendectomy showed no difference in complications, outcomes, or cosmetic and pain results between the two approaches (follow-up of 14 days).[12]
- Further research, ideally as prospective randomized trials, will allow a better comparison of outcomes to traditional laparoscopic appendectomy.
- Although recent studies on SILS procedures show a possible increase in incisional hernias after the SILS procedure, currently available studies show no significant benefit or drawback for the SILS technique for appendectomy.[13,14]

COMPLICATIONS

- Surgical site infection: superficial, deep, organ/space
- Hematoma
- Stump appendicitis/incomplete appendectomy
- Appendiceal stump leak/blowout
- Port site hernia
- Ileus and small bowel obstruction

Chapter 9

Right Hemicolectomy: Open Technique

Somala Mohammed Kathleen R. Liscum Eric J. Silberfein

DEFINITION

- Right hemicolectomy refers to the removal of the cecum, the ascending colon, the hepatic flexure, the proximal portion of the transverse colon, and part of the terminal ileum (**FIG 1**). It is the standard surgical treatment for malignant neoplasms of the right colon and involves ligation of the ileocolic, right colic, and right branch of the middle colic vessels.

DIFFERENTIAL DIAGNOSIS

- Various benign and malignant conditions require right hemicolectomy. The most common indication is a mass in the right colon. Other indications include neoplasms of the cecum or appendix. Benign conditions for which right hemicolectomy is performed include adenomatous polyps that cannot be removed endoscopically, cecal volvulus, inflammatory bowel disease, and right-sided diverticulitis, among others.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history and physical examination is mandatory.
- Findings such as ascites or diffuse adenopathy may result in additional diagnostic workup to rule out metastatic disease and this may alter the overall care plan for the patient.
- A baseline nutritional and functional status should also be ascertained in the preoperative setting.
- Previous abdominal surgeries should be noted.
- A thorough family history, including history of colonic polyps and cancers, should be obtained.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- A full colonoscopy should be obtained to examine the remainder of the colon, which has up to a 5% chance of synchronous disease. Colonoscopy can also allow for India ink tattooing of the lesion to facilitate accurate intraoperative localization (**FIG 2**).
- Preoperative imaging also includes high-quality dual phase computed tomography (CT) imaging of the abdomen and pelvis to not only assess for metastatic disease but also to evaluate the primary tumor's relationship to nearby structures such as the kidney, ureter, duodenum, and nearby vessels such as the vena cava, superior mesenteric vessels, and middle colic vessels. Tumors that involve adjacent organs require additional preoperative planning and consultation with ancillary services may be necessary. Attempts at en bloc resection should be made in cases where the tumor involves adjacent organs or structures.
- Additional workup includes a CT of the chest, complete blood cell count, and comprehensive metabolic panel. A baseline carcinoembryonic antigen (CEA) level should be obtained to assist with postoperative surveillance for recurrence. Positron emission tomography (PET)-CT is not routinely indicated.

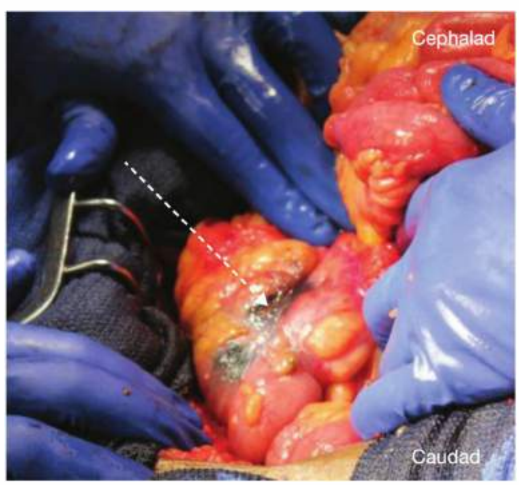

FIG 2 ● Tattooed lesion in the cecum.

SURGICAL MANAGEMENT

Preoperative Planning

- Preoperative bowel preparation is not mandatory but it may make manipulation of the colon more manageable. If intraoperative colonoscopy is required, a prepped colon would also be preferred.
- Preoperative antibiotic prophylaxis for skin and bowel flora is recommended. Intravenous broad-spectrum antibiotics that contain second- or third-generation cephalosporins (such as cefoxitin or ceftriaxone) or fluoroquinolones (such as ciprofloxacin) along with metronidazole will adequately cover gram-negative and anaerobic pathogens. Alternatively, ertapenem, a carbapenem with activity against gram-positive, gram-negative, and anaerobic flora, can be used. Prophylactic antibiotics should be at therapeutic bloodstream levels at the time of incision. Redosing the antibiotic should be considered when taking into account the length of the operation, the estimated blood loss, and the half-life of the antibiotic.
- Venous thromboembolic prophylaxis for patients undergoing right hemicolectomy includes both mechanical interventions, such as pneumatic compression devices, and pharmacologic interventions, such as low-molecular-weight heparin or unfractionated heparin. These agents should be delivered prior to induction of anesthesia as the dramatically decreased level of vascular tone associated with anesthesia results in venous stasis and risks thrombosis. Patients on preoperative warfarin should be transitioned to either low-molecular-weight or unfractionated heparin.
- Preoperative thoracic epidural placement for postoperative pain control should be offered to patients without contraindications to this form of analgesia. Epidural pain control reduces narcotic requirements postoperatively and decreases risk of postoperative ileus and pulmonary complications. Otherwise, patient-controlled analgesia is preferred. Intravenous nonsteroidal antiinflammatory drugs (NSAIDs) should also be considered in the perioperative period to decrease the use and side effects of narcotic analgesia.
- Ancillary surgical services may be required to assist in the patient's care for procedures such as preoperative placement of ureteral stents or assistance in resection or reconstruction of involved adjacent organs, such as the kidneys, ureters, or the duodenum.

ANESTHESIA AND PATIENT POSITIONING

- General endotracheal anesthesia is preferred for right hemicolectomy. However, spinal anesthesia alone is feasible if necessary.
- The patient is placed supine with or without the arms tucked.
- After induction of anesthesia, the bladder is catheterized and an orogastric tube is placed.
- The entire abdomen is prepped and draped.
- The surgeon stands on the patient's right and the first assistant on the left.

INCISION

- A midline laparotomy is made.
- Upon entering the abdominal cavity, inspect for evidence of metastatic disease. The liver should be palpated for masses and biopsied as needed, and the small bowel eviscerated and inspected from the ligament of Treitz to the ileocecal valve. The colon and rectum should be inspected and palpated. The omentum and peritoneum should be evaluated for tumor implants or carcinomatosis. In women, the ovaries should also be inspected for abnormalities.

RIGHT COLON MOBILIZATION

- Placement of self-retaining retractors, such as a Balfour, may be used to improve exposure. Otherwise, the abdominal wall is retracted with handheld instruments.
- The cecum and ascending colon are freed from the peritoneal reflection by incising along the white line of Toldt (**FIG 3**). The terminal ileum is also freed from the retroperitoneum and mobilized by incising the peritoneum along the root of the mesentery.
- As the colon and terminal ileum are reflected anteriorly and medially, the right gonadal vessels and right ureter should be identified in the retroperitoneum and not mobilized anteriorly so as to avoid injury.
- The lateral dissection is carried sharply up and around the hepatic flexure in the avascular, embryologic plane between the mesocolon and the duodenum. The second and third portions of the duodenum are identified near the hepatic flexure and injury to this structure must be avoided.
- The hepatocolic ligament is transected (**FIG 4**).
- The gastrocolic ligament, extending from the greater curvature of the stomach to the transverse colon, is divided from left to right to complete the mobilization of the hepatic flexure (**FIG 5**).

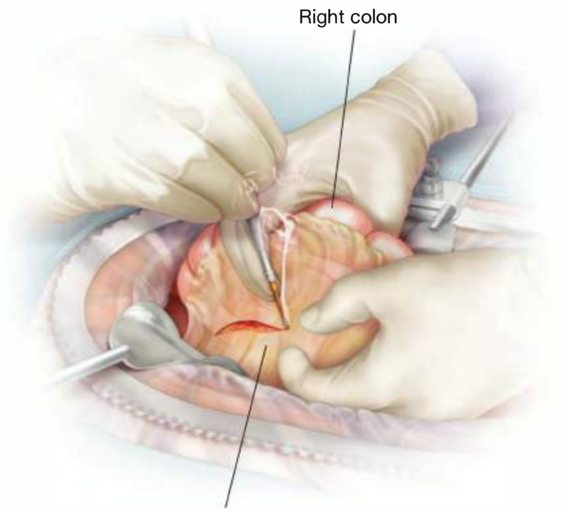

FIG 3 ● Ascending colon mobilization. The surgeon retracts the ascending colon medially. Dissection proceeds along the right paracolic gutter by transecting the white line of Toldt.

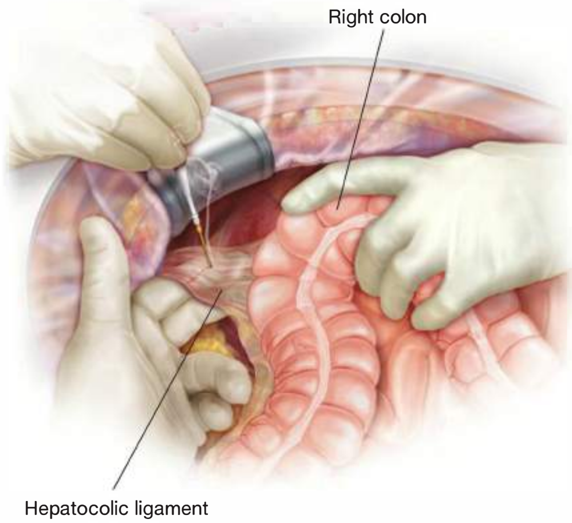

FIG 4 ● Hepatic flexure mobilization. Gentle traction on the hepatic flexure of the colon exposes the hepatocolic ligament, which is then transected with electrocautery.

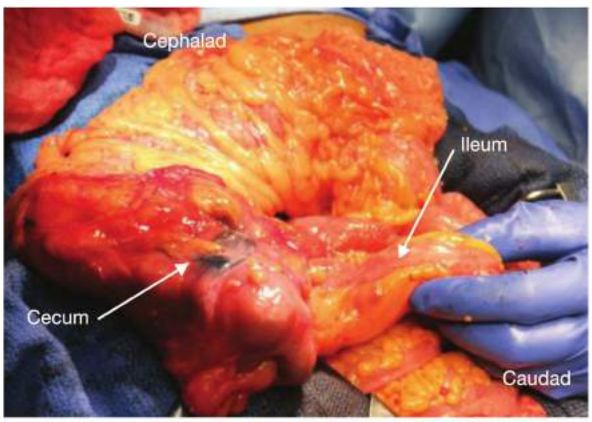

FIG 5 ● Fully mobilized terminal ileum and right colon. The tattooed area can be seen on the surface of the cecum.

VASCULAR PEDICLE TRANSECTION

- For a right hemicolectomy, the vascular arcades of interest include the ileocolic, the right colic, and the right branch of the middle colic vessels.
- An avascular window between the right branch of the middle colic and the right or ileocolic vessel arcade is made (**FIG 6**).
- The right branch of the middle colic is doubly clamped, divided, and tied while the left branch is spared.
- The right colic arcade, if present, is also taken at its origin to ensure adequate resection of lymphatics. This arcade, however, rarely branches directly off the superior mesenteric vessels. It is most often a branch of the ileocolic arcade.
- The ileocolic arcade is therefore ligated at its origin in the majority of circumstances (**FIG 7**).
- The lymphatic drainage pattern mirrors that of the vascular system. There are two possible paths of lymphatic spread: paraintestinal (along the intestine) and central (along the vessels). To reduce the risk of recurrence, an adequate lymph node harvest should be attempted by ligating the required mesenteric vessels at their origin. A minimum of 12 resected nodes is required for American Joint Committee on Cancer for adequate staging of colorectal cancer. Intramural spreading of cancer beyond 2 cm is rare, but an oncologic resection should aim for proximal and distal mucosal margins of at least 5 to 7 cm to ensure adequate harvest of paraintestinal and mesenteric nodes.

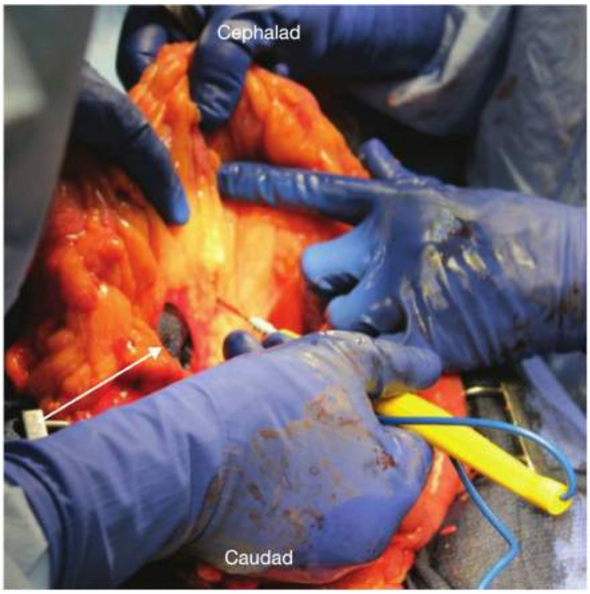

FIG 6 ● Avascular window adjacent to right branch of the middle colic vessels *(arrow)*.

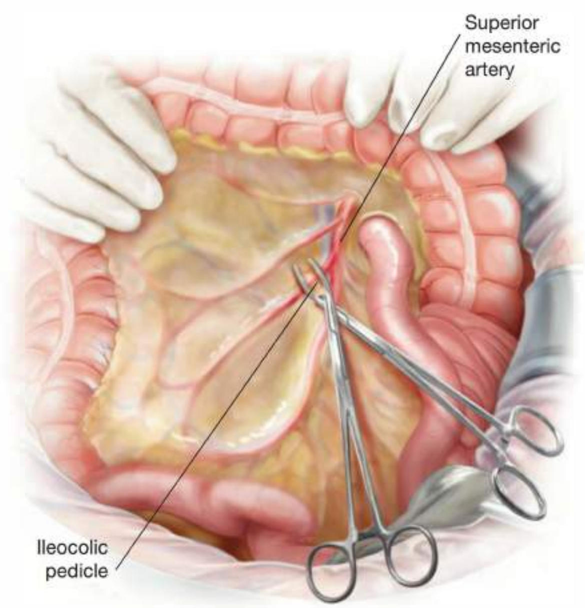
- An extended right hemicolectomy may be performed for lesions located at the hepatic flexure or transverse colon. This procedure involves transection of the middle colic vessels at their origin and an anastomosis of the distal ileum with the distal transverse colon, relying on the margin artery of Drummond for blood supply. If the integrity of this blood vessel is questionable, the resection must be extended to include the splenic flexure and the distal ileum is anastomosed to the descending colon.
- For an extended right hemicolectomy, mobilization of the splenic flexure is required. In order to mobilize the splenic flexure, the splenocolic, phrenocolic, and gastrocolic ligaments must be divided (**FIG 8**). The splenic flexure is then carefully dissected of the tail of the pancreas. Care must be taken to avoid injury to the spleen and the ascending branch of the left colic artery.



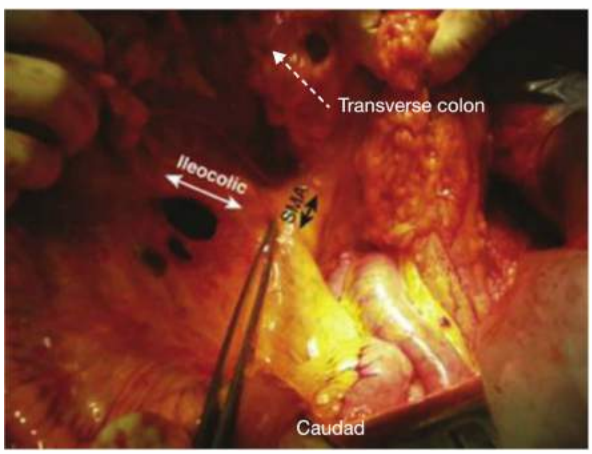


FIG 7 ● Transection of the ileocolic pedicle. The ileocolic vessels are transected at their origin of the superior mesenteric vessels. *SMA*, superior mesenteric artery.

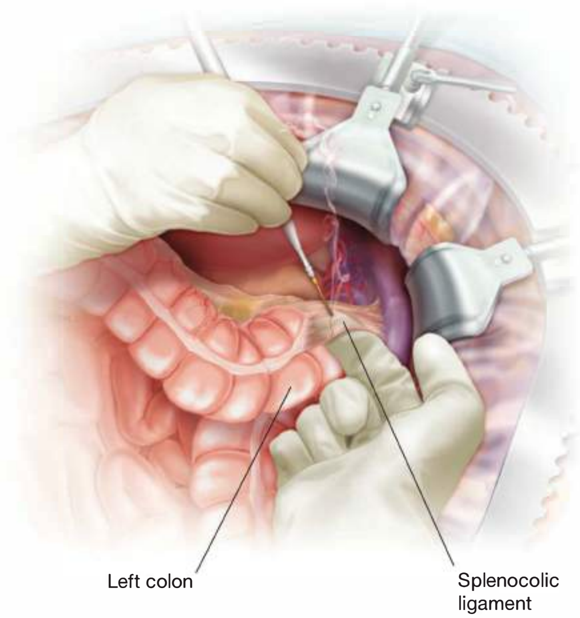

FIG 8 ● Splenic flexure mobilization (for extended right hemicolectomies). After medial and lateral mobilization of the splenic flexure attachments, the surgeon hooks his or her right index finger under the splenocolic ligament, providing good exposure and allowing for a safe transection of this ligament.

BOWEL TRANSECTION

- The colon is cleared of epiploic fat at the proposed site of anastomosis to allow the bowel wall to be visualized, thereby facilitating precise placement of sutures or staplers. The transverse colon is then transected to the right of the middle colic vessels with a linear 75-mm blue load stapler (**FIG 9**).
- The distal ileum is divided approximately 10 cm proximal to the ileocecal valve with a linear 75-mm blue load stapler (**FIG 10**).
- If adjacent organs are involved, every attempt at a complete en bloc resection must be made. The specimen should be assessed with the pathologist to ensure that the diseased segment is acquired and that adequate margins have been obtained. If there is any doubt about margin status, an intraoperative frozen section evaluation should be conducted.

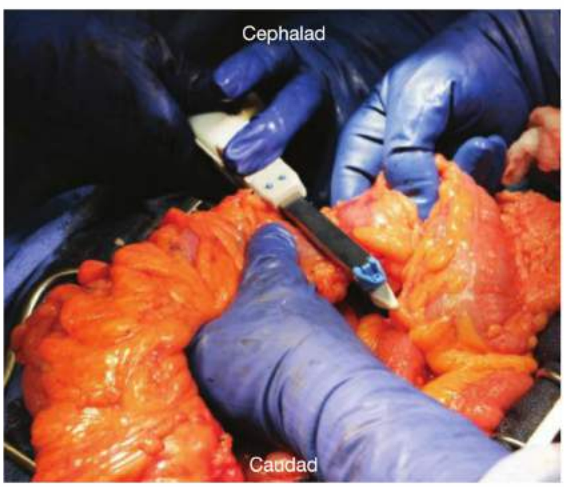

FIG 9 ● Colon transection. The colon is divided to the right side of the middle colic vessels with a linear stapler.

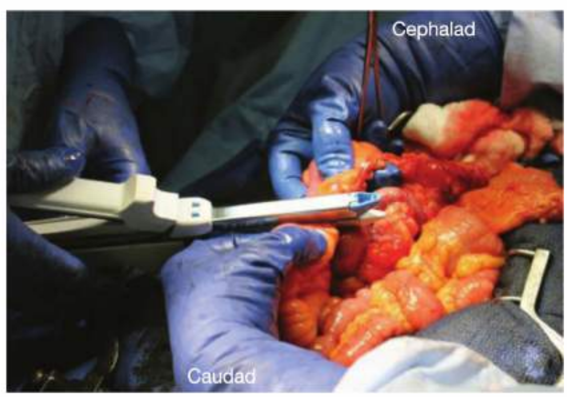

FIG 10 ● Ileal transection. The terminal ileum is divided with a linear stapler.

ILEOCOLONIC ANASTOMOSIS

- After resection, reconstruction proceeds with an anastomosis between the ileum and the transverse colon.
- A primary ileocolic anastomosis is almost always possible. Either a hand-sewn or a stapled anastomosis can be performed in an end-to-end, end-to-side, side-to-side, or side-to-end fashion. The viability of the proximal and distal segments of bowel should be assessed and further resection to well-perfused bowel should be performed if there is any question regarding the viability of the bowel.
- Atraumatic bowel clamps should be placed proximal and distal to the anastomotic site to prevent spillage of bowel contents. Gauze pads should also be placed in the abdomen to protect surrounding structures and the skin from contamination during the process of transecting the colon and creating the anastomosis.
- The ileal and transverse colon segments should be brought into apposition to allow a tension-free anastomosis.
- For the stapled technique, the antimesenteric borders of the bowel segments are approximated with interrupted 3-0 silk sutures. A small enterotomy is made on the antimesenteric border of both the ileum and the transverse colon (**FIG 11**) to allow insertion of a stapling device (**FIG 12**). The stapler is allowed to gently close, bringing together the ileum and transverse colon (**FIG 13**). Once it is assured that the mesentery is clear and the stapler is in good position, the stapling device is fired and then slowly removed.
- This fuses the two previous enterotomies into a single enterotomy. This new enterotomy can be closed either with a stapler, placed at a right angle to the previous staple line (**FIG 14**), or with sutures, in one or two layers (**FIGS 15** and **16**).

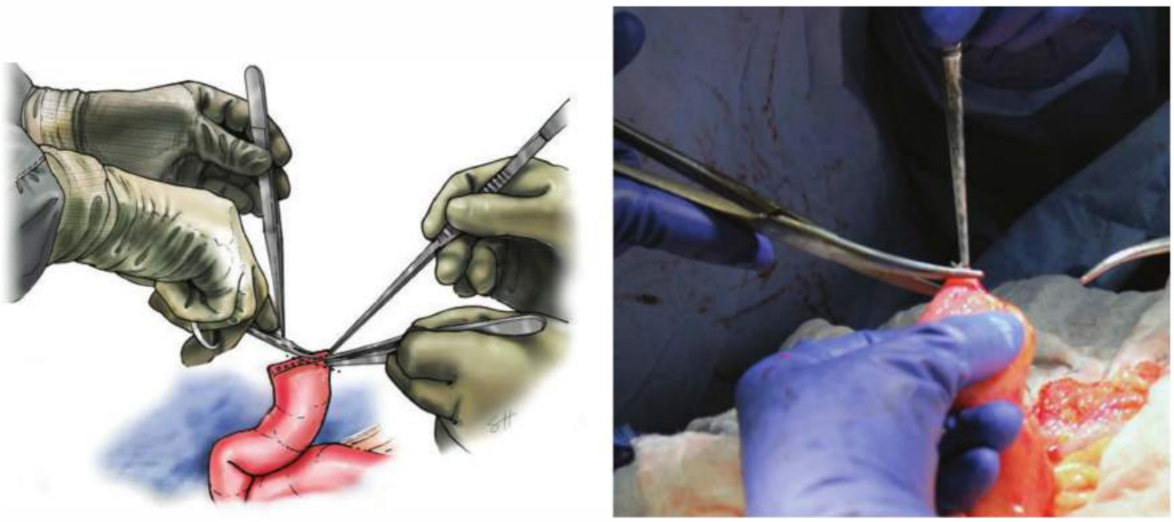

FIG 11 ● Stapled ileocolonic anastomosis. Scissors are used to make a small enterotomy on the antimesenteric border of the bowel. (Printed with permission from Baylor College of Medicine.)

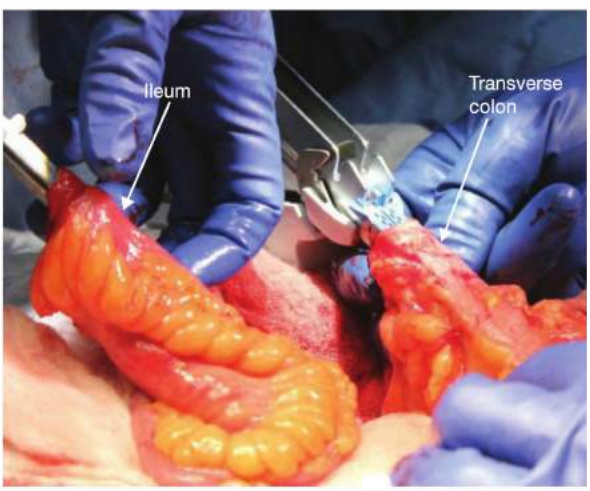

FIG 12 ● Stapled ileocolonic anastomosis: inserting the stapling device into the enterotomy.

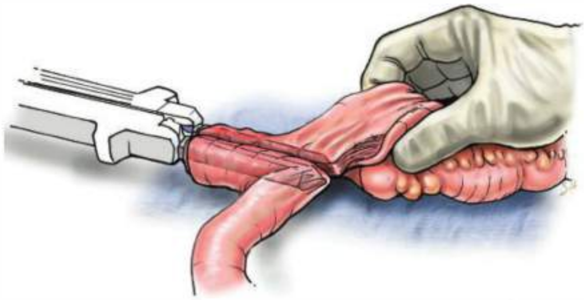

FIG 13 ● Stapled ileocolonic anastomosis. The stapler is inserted in the ileum and transverse colon and is then closed. (Printed with permission from Baylor College of Medicine.)

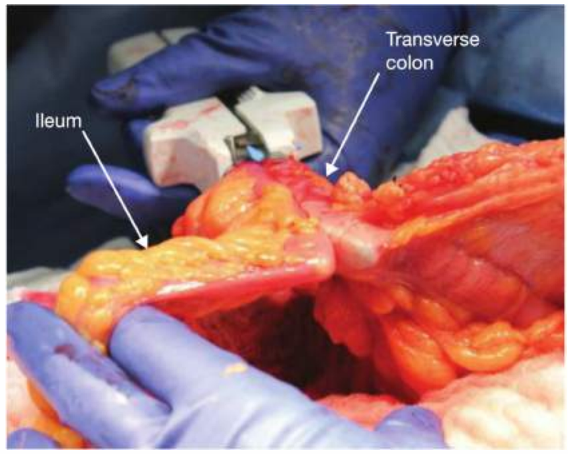

FIG 14 ● Stapled ileocolonic anastomosis: closing the common enterotomy with a stapler. (Printed with permission from Baylor College of Medicine.)

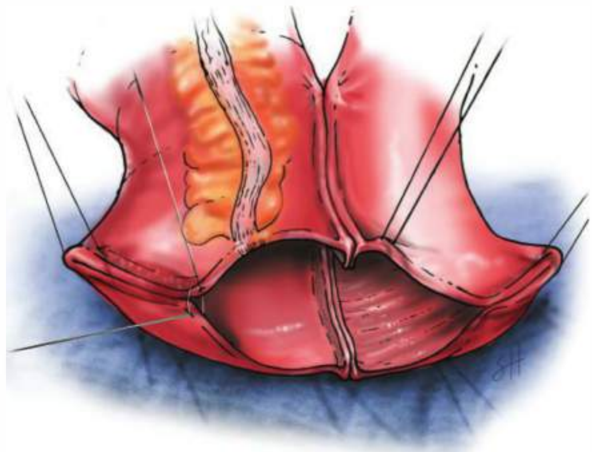

FIG 15 ● Stapled ileocolonic anastomosis: closing the inner layer of the common enterotomy with an absorbable running suture. (Printed with permission from Baylor College of Medicine.)

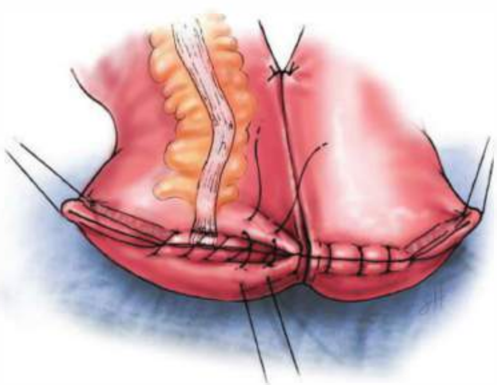

FIG 16 ● Stapled ileocolonic anastomosis: closing the outer layer of the common enterotomy with interrupted Lembert sutures. (Printed with permission from Baylor College of Medicine.)

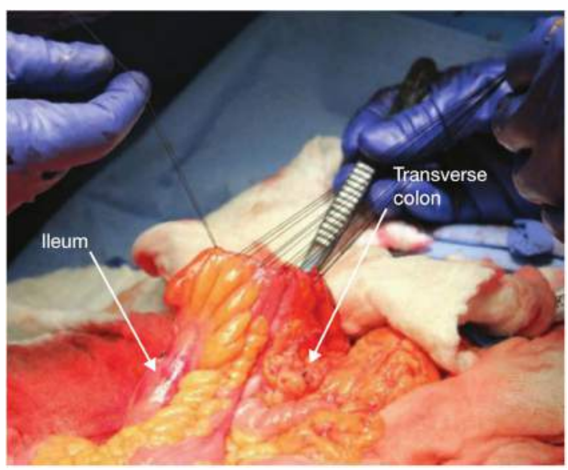

- The completed anastomosis is visually inspected to ensure that it is well perfused and is palpated to check for patency (FIG 17).
- Alternatively, a hand-sewn anastomosis can be performed in either one or two layers. The type of suture (monofilament, braided, absorbable), type of stitch (interrupted, continuous, Lembert), or configuration used is probably not as important as are the principles of approximating well-perfused bowel without tension. The authors prefer a two-layer, side-to-side anastomosis using an outer layer of interrupted Lembert silk sutures and an inner continuous running layer of monofilament absorbable suture.
- Closure of the mesenteric defect is optional and is based on surgeon preference. Oftentimes, the omentum can be placed around the anastomosis.

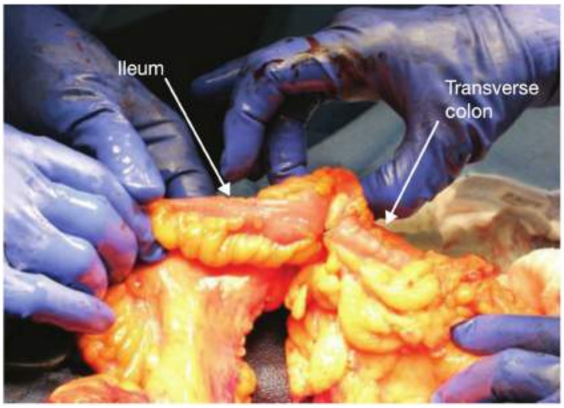

FIG 17 ● The completed ileotransverse colon side-by-side stapled anastomosis. Palpation of the anastomosis between the thumb and index finger shows that the anastomosis is patent. Notice that both the ileal and colonic segment are well perfused. Closure of the mesenteric defect is optional and is based on surgeon preference.

CLOSURE

- Once hemostasis is ensured and the abdomen is irrigated, the abdominal fascia and skin are closed in standard fashion. Drains are not routinely required, although in cases of infection or abscess, a drain may be placed.

PEARLS AND PITFALLS

Colon mobilization	■ The plane between the mesocolon and the retroperitoneum is an avascular embryologic plane that should be dissected sharply. Excess blood loss during this dissection alerts the surgeon that the incorrect plane was entered.
Vascular dissection	■ During dissection of the middle colic vessels, avulsion of the large collateral branch that connects the inferior pancreaticoduodenal vein with the middle colic vein and superior mesenteric vein can result in bleeding that is difficult to control because the vein retracts and cannot be isolated easily. ■ Avoiding excess upward and medial traction of the right colon while mobilizing the hepatic flexure best prevents this. ■ Transillumination of the mesocolon and the mesentery of the terminal ileum can help to identify vascular arcades to minimize iatrogenic injury in patients with thick mesentery and can assure good blood supply to the anastomosis.
Anastomosis	■ A well-vascularized, tension-free anastomosis minimizes the risk of anastomotic breakdown. ■ If there is any doubt regarding the integrity of the anastomosis, the bowel segments should be further resected to healthy, vascularized bowel. ■ Blood supply to the anastomosis can also be further assessed with Doppler ultrasound if necessary.

POSTOPERATIVE CARE

- In the absence of intraabdominal infection, antibiotic therapy does not need to be continued postoperatively.
- A nasogastric tube is not routinely placed.
- The patient should begin ambulating on postoperative day 1.
- The Foley catheter can usually be removed on postoperative day 1 or 2 unless an epidural remains in place.
- The patient can be started on a liquid diet. The diet can be advanced based on clinical progress.
- Deep venous thrombosis (DVT) prophylaxis should be continued until the time of discharge and can be considered as an outpatient in certain subsets of patients.
- The patient should be counseled about the initial changes in bowel habits including more frequent, loose stools and the possible appearance of blood clots in the first few bowel movements.

COMPLICATIONS

- Intraoperative complications include injury to the ureter, duodenum, nearby bowel or colon segments, nearby blood vessels such as the inferior pancreaticoduodenal vessels or the superior mesenteric vessels, or an anastomosis that is poorly vascularized or under tension.
- Early postoperative complications include wound infection, anastomotic leak, or intraabdominal abscess formation
- Late postoperative complications include development of colocutaneous fistulas, recurrence of cancer, anastomotic stricture, incisional or internal hernia, or ureteral stricture from ureteral devascularization.
- An extended right hemicolectomy adds the potential complication of splenic injury, as the splenic flexure must be mobilized to achieve a tension-free anastomosis. Because most of the proximal colon absorbs fecal water, an extended right hemicolectomy also predisposes to postoperative diarrhea.

Chapter **10**

Laparoscopic Right Hemicolectomy

Craig A. Messick   Joshua S. Hill   George J. Chang

DEFINITION

- Right hemicolectomy is defined as the resection of a portion of the terminal ileum, cecum, ascending colon, and portion of the transverse colon. When performed for neoplastic disease, it includes resection of the vascular pedicles including the ileocolic, right colic (when present), and sometimes right branch of the middle colic artery and their associated veins. An extended right hemicolectomy is one in which the middle colic vessels are ligated. Laparoscopic right hemicolectomy has been shown to be a preferred alternative technique in the resection of benign and malignant diseases of the colon and in experienced hands has been shown to have equivalent oncologic outcomes with improvements in speed of recovery when compared to open resection.[1–3]

INDICATIONS

- Right hemicolectomy may be performed for either benign or malignant indications, but the underlying principles of surgical resection apply to both open and laparoscopic approaches. A thorough preoperative workup to define the underlying disease plays a critical role in determining the nature of the operative intervention and optimizing the surgical treatment.
- Benign pathology (common etiologies)
  - Crohn's disease: most frequently occurs in the terminal ileum and may include the ascending colon with associated an associated inflammatory phlegmon or fistula. Right hemicolectomy for Crohn's is performed when the disease is refractory to medical therapy.
  - Right-sided diverticulitis: occurs uncommonly in the U.S. population and it is felt to arise as a congenital lesion occurring more commonly in Asian patients. It is commonly misdiagnosed as acute appendicitis.
  - Ischemic colitis: uncommonly affects the right colon in isolation owing to its collateral blood supply; however may present with abdominal pain, bloating due to stricture, or hematochezia.
  - Cecal volvulus: caused by a twist (typically clock-wise) of the terminal ileum and colonic mesentery around fixed retroperitoneal attachments, presents with acute abdominal pain and obstructive symptoms.
- Neoplastic pathology
  - Endoscopically unresectable polyps should be treated with colectomy. As they have potential to harbor malignant foci not detected on biopsy, they should be managed according to oncologic principles. Right-sided polyps include high-risk adenomas with high-grade dysplasia or villous components, large hyperplastic polyps, or sessile serrated adenoma/polyps (SSA/Ps).
  - Malignancy is the most common indication for laparoscopic right hemicolectomy. Equivalent outcomes to open resection have been demonstrated in large multi-center randomized controlled trials.[2–6] A bulky cancer or one that has invaded into adjacent organs should be resected en bloc with associated tissues and may be considered for open resection.
  - Adenocarcinoma: The location with respect to the anatomy of the blood supply determines the extent of bowel resection.
  - Carcinoid: Right colectomy is indicated for carcinoid tumors of the terminal ileum or appendix when 2 cm or greater. Colectomy is also indicated for adverse features such as goblet cell carcinoid histology or presence of lymphovascular or perineural invasion.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Adenocarcinoma patients are commonly asymptomatic but can present with anemia, melena, altered stool patterns (diarrhea), pain, and weight loss.
- A thorough history and physical examination is essential for identifying candidates for laparoscopic surgery. Several patient factors that can affect the feasibility of laparoscopic resection are shown in Table 1. Patient characteristics or underlying disease issue may preclude safety of the laparoscopic approach or greatly increase the operative difficulty and time and these factors should be considered when making the decision to proceed with laparoscopy and during operative planning.
- Obesity poses unique challenges during laparoscopic hemicolectomy. The ease of finding the correct plane and the central vascular anatomy is greatly diminished in obese patients. Patient positioning may also be impacted by obesity as obese patients may not tolerate extreme Trendelenburg, reverse Trendelenburg, or side to side positioning. In addition, obesity has been associated with a higher risk for conversion to open surgery. Despite these challenges, patients who are obese have increased risk for morbidity such as wound infection when compared to nonobese patients and thus may derive significant benefit from laparoscopic surgery.
- Patients with decreased cardiac output may not tolerate increased intraabdominal pressures resulting in decreased venous return secondary to pneumoperitoneum.
- Intraabdominal adhesions caused by prior surgery may preclude laparoscopy. Laparoscopic lysis of adhesions may be

Table 1: Patient Factors that Can Affect the Feasibility of Laparoscopic Resection

Obesity
Prior abdominal surgery
Cardiac dysfunction
Pulmonary dysfunction
Large tumor burden
Potential local involvement of adjacent vital organs
Abnormal intraabdominal anatomy

performed, although surgeon experience and the extent of adhesions should be considered.

- Patients with nutritional deficiencies and impaired healing, such as those on high-dose steroids, recent immunomodulators, or systemic chemotherapy, are at higher risk for anastomotic failure. In those patients with ongoing life-threatening illnesses, ileocolonic anastomosis should be deferred in favor of end ileostomy. An ileocolostomy should not be performed in patients with hemodynamic instability.

DIAGNOSTIC STUDIES

- Colonoscopy: All tumors should be localized, biopsied, and tattooed prior to embarking on laparoscopic surgery. Tattooing allows for intraoperative localization of the tumor, although it may be faint when localized to the mesenteric border (**FIG 1**). The tattoo can also be on the retroperitoneal surface and not seen (**FIG 2**). Synchronous tumors (present in 3% to 5% of patients with colon cancer) and unresected polyps should be noted and considered in the treatment plan.[7] Colonoscopy may not be possible in patients with a complete obstruction. In these patients, intraoperative palpation of the entire colon should be performed to assess for secondary lesions. After recovery from surgery, a short interval completion colonoscopy should be performed.
- CT colonography/enterography: Can be useful in patients not amenable to colonoscopy. Use of CT enterography provides additional information of the small intestines in patients with Crohn's disease that may alter surgical strategy.
- CT scan of the abdomen and pelvis: In inflammatory bowel disease patients, CT scan provides information pertaining to the extent is of colitis, presence of a fistula, and/or abscess. In patients with malignancy, CT scans of the chest, abdomen, and pelvis should be performed to assess for pulmonary, hepatic, and lymphatic metastasis as well as infiltration of the primary tumor into adjacent structures.[8]

SURGICAL MANAGEMENT

Preoperative Planning

- Appropriate preoperative antibiotic coverage before incision has been shown to decrease the risk of surgical site infections, but courses of antibiotics greater than 24 hours are actually associated with worse outcomes.[9]
- The need for a pre-operative mechanical bowel preparation in patients undergoing right hemicolectomy is controversial.[10,11]

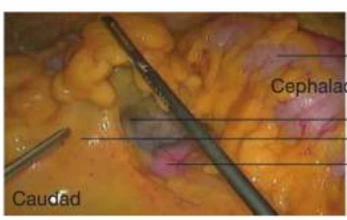

FIG 1 ● Tattooing the target. Tattoos placed within the colonic mesentery may not be visible upon initial inspection. As shown in this operative photograph, the distal ascending colon at the hepatic flexure has been anteriorly reflected to reveal the location of a previously placed intramesenteric tattoo.

FIG 2 ● Tattooing the target. In some instances, a tattoo placed within the mesentery is not visible until dissection into the retroperitoneum. Here, the dissection of Toldt's fascia (anterior) has been performed and the retroperitoneum exposed, revealing the location of the tattoo within the retroperitoneum of the ascending colon.

We use mechanical bowel preparation because it lightens the colon, thus facilitating laparoscopic manipulation of the colon.

Patient Positioning

- The patient is positioned supine and secured with Trendelenburg straps on the ankles (**FIG 3**). If an extended right hemicolectomy will be performed, the patient may be placed in a lithotomy position to facilitate the mobilization of the splenic flexure, if necessary.
- Gravity is the single greatest facilitator of exposure during colectomy. During the course of the case, the patient may be placed in steep Trendelenburg, reverse Trendelenburg and rotated right side up. For this reason, the patient must be secured to be operating table and a variety of devices have been used to secure the patient. We prefer to use ankle and chest straps, but commercially available foam pads placed under the patient to prevent slippage may also be used. We avoid using pads of beanbags placed above the shoulder that can cause brachial plexus injuries.
- Both arms should be padded and tucked at the patient's side. If the patient is too wide for the table, the right arm may

FIG 3 ● Securing the patient to the table. Velcro straps are secured to the patient's ankles, then attached to the operating room table to protect the patient's legs from sliding laterally off the table's sides with extreme left-right positioning and to assist in keeping the patient from slipping toward the head of the table when in placed in steep Trendelenburg position.

be left out so that the operative team standing together on the patient's left side still has sufficient working space. The patient's hands should be turned such that their palms face medially with the thumbs anterior and fingers should be positioned so that they are in a neutral position.

- Ensure that intravenous (IV) lines are working after positioning and prior to the start of the case. A second IV is recommended because the patient's arms will be inaccessible during the operation, thus making the establishment of another IV difficult.

PORT PLACEMENT

- A variety of methods may be employed for the entry into the abdomen during laparoscopic surgery. Two commonly used options are the use of a Veress needle or the authors' preferred technique of a direct fascial cutdown (Hassan technique). Pneumoperitoneum is established with carbon dioxide to 15 mmHg as tolerated.
- Standard port placement includes a 10- to 12-mm umbilical port (camera port), 5-mm working ports in the left upper quadrant, and either a 5-mm or 10- to 12-mm port in the left lower quadrant. A fourth port is used in either the suprapubic or right lower quadrant positions. An optional 5-mm port is placed in the patient's right upper quadrant to assist with the distal transverse colon or splenic flexure mobilization as needed for an extended right hemicolectomy (**FIG 4**).

FIG 4 ● Port placement. This diagram shows the standard and additional laparoscopic port sites for a laparoscopic right hemicolectomy. Standard placement includes a 10- to 12-mm umbilical port *(1)*, 5-mm left upper quadrant port *(2)*, and either a 5-mm or 10- to12-mm left lower quadrant port. A fourth port is used in the optional locations *(o)*, either suprapubic or right lower quadrant positions. An optional 5-mm port is placed in the patient's right upper quadrant to assist with the distal transverse colon or splenic flexure as needed for an extended right hemicolectomy.

VASCULAR TRANSECTION AND MEDIAL TO LATERAL MOBILIZATION OF THE ILEOCOLIC MESENTERY

- The abdomen should be thoroughly inspected to rule out metastatic sites or synchronous pathology with evaluation of the peritoneum, liver, retroperitoneum, and adnexal structures in women.
- The patient is positioned with the left side down and in slight Trendelenburg.
- The omentum is retracted cephalad over the transverse colon into the upper abdomen. In an obese patient with a bulky omentum, an assistant can hold retraction of the omentum through the left upper quadrant port.
- The small intestine is swept to the left lower quadrant, allowing for complete visualization of the mesenteric attachments to the right colon and the superior mesenteric artery (SMA). The ileocolic vessels (ICV) can be identified as they cross over the third portion of the duodenum. The fold of Treves is grasped and retracted laterally to demonstrate the course of the ICV and to identify their origin from the SMA and the confluence of the ileocolic vein into the superior mesenteric vein (SMV) (**FIG 5**).
- The peritoneal surface is scored on the dorsal surface of the ICV near the SMA (**FIG 6**). While ensuring that the lymph node-bearing tissue is dissected into the ileocolic mesentery (specimen side), the retroperitoneal attachments to the colonic mesentery are divided.

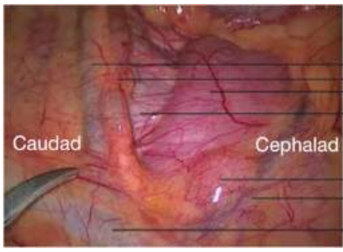

FIG 5 ● Exposure of the ileocolic pedicle. After the small bowel has been placed in the patient's left hemiabdomen exposing the right colon mesentery, the ileocolic pedicle is often seen pulsating within its mesentery. The duodenum is often seen through a thin layer of colon mesentery; the ICV can be identified as they cross the third portion of the duodenum. In this image, the SMV, inferior vena cava, and right colic artery and vein are seen. IVC, inferior vena cava; SMV, superior mesenteric vein.

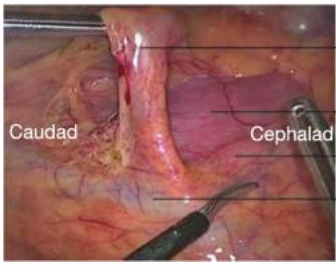

FIG 6 ● Dissection of the ICV. Scoring of the peritoneum along the inferior sulcus of the ICV allows for a posterior dissection to the ICV. Gentle lifting of the pedicle will allow for dissection of the tissue to the origin of the ICV at the SMA and SMV. ICV, ileocolic vessels; SMV, superior mesenteric vein.

- The correct, avascular plane can be developed with a combination of sharp and blunt dissection. The small retroperitoneal vessels can act as a guide and should be dissected downward, away from the colonic mesentery. If these are bluntly torn, minimal, yet bothersome bleeding can ensue. This careful medial to lateral dissection of the ileocolic mesentery is carried cephalad to the origin of the ICV, with care taken not to inadvertently injure the duodenum, and laterally releasing the colonic mesentery from retroperitoneal attachments without injury to the ureter or gonadal vessels. The dissection plane should be anterior to the duodenum and pancreatic head, taking care to avoid inadvertent duodenal mobilization or dissection between the duodenum and pancreas (**FIG 7**).
- The ICV can then be divided at the origin from the SMA/SMV with either an endoscopic GIA stapler with a vascular load (our preference; see **FIG 8**), with an energy device, or between endoclips. Node-bearing tissue should be kept with the specimen.
- Next the dissection is taken up along the SMA to identify the right colic artery and vein (when present) (**FIG 9**) as well as the middle colic vessels (MCV) and their bifurcation (**FIG 10**). This step is facilitated by anterior and cephalad traction on the transverse colon to tent the mesentery.
- By following the SMA from the point of ICV ligation, the variably present right colic artery is identified to arise from the SMA between the ICV and the MCV where it should be divided at its origin with an energy-sealing device.
- The venous drainage of the right colon is also highly variable and the right colic vein is missing in up to 50% of patients. It can be found joining the right gastroepiploic and superior pancreaticoduodenal veins at the gastrocolic trunk of Henle.
- In cases of more distal ascending colon or hepatic flexure tumors, transaction of either the right branch or the entire trunk of the middle colic artery (MCA) should be performed after exposing the origin of these vessels from the SMA. Tearing the vein at this level will result in rapid bleeding; therefore, it is important to carefully and completely identify the vascular anatomy of the right colon prior to dividing the mesentery.

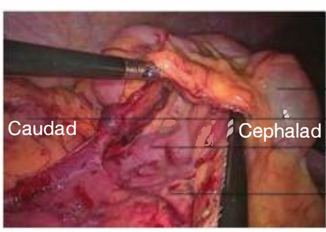

FIG 7 ● Medial to lateral dissection. The medial to lateral dissection of the ileocolic mesentery is continued both laterally and superiorly anterior to the duodenum and head of pancreas along the course of the SMA and SMV to the origin on the middle colic vessels.

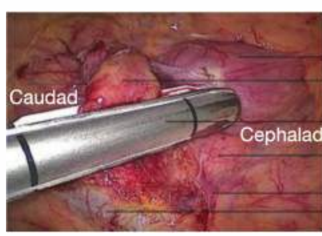

FIG 8 ● Transection of the ICV. Once the ileocolic artery and vein have been cleared of their surrounding fat and lymphatic tissue, they can be transected at their origins off the SMA and SMV. This can be performed with a 30mm stapler (as shown) or with an energy device as appropriate. The vessels can be separated and ligated either separately or together, as per surgeon preference.

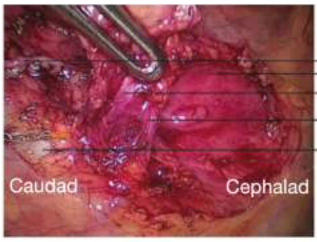

FIG 9 ● Transection of the right colic vessels. A right colic artery and vein are shown originating from the superior mesenteric artery and vein. This is often discovered only after transection of the ileocolic artery and vein has been completed. These vessels are typically smaller than the ileocolic artery and vein and may be ligated with staples, endoclips or an energy device. SMV, superior mesenteric vein.

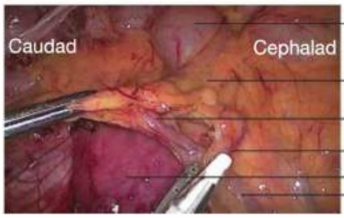

FIG 10 ● Exposure of the middle colic vessels. The colon mesentery is incised along the border of the superior mesenteric vessels to the bifurcation of the right and left branches of the middle colic artery and vein as shown here, ensuring that all lymphatic tissue within the distribution of the right and proximal transverse colon is removed with the specimen. This dissection is performed anteriorly to the duodenum and head of pancreas. The right branch of the middle colic artery and vein are typically small enough to transect with a sealing energy device.

LATERAL COLON MOBILIZATION

- Placing the patient in Trendelenburg position and retracting the small bowel out of the pelvis into the upper abdomen facilitates this step.
- The ascending colon is mobilized in an inferior to superior fashion by lifting the cecum away from the retroperitoneum and scoring the base of the cecal and terminal ileal mesenteries until the medial to lateral dissection is met (**FIG 11**). Care should be taken to avoid inadvertent dissection and injury of the ureter and gonadal vein.
- The lateral attachments along Toldt's fascia are then incised up to the level of the hepatic flexure. We prefer an inferior to superior approach as this minimizes the risk for kidney mobilization or duodenal Kocherization during bowel mobilization (**FIG 12**).
- After the ascending colon has been mobilized, the mobilization of the transverse colon and hepatic flexure is performed. With the patient in reverse Trendelenburg position, the lesser sac is opened by releasing the omentum from the transverse colon. At this level the omentum is frequently fused to the transverse mesocolon so care should be taken to avoid inadvertent mesenteric vascular injury.
- The proximal transverse colonic attachments along the hepatocolic ligament can then be divided with an energy device to meet the plane over the duodenum previously established during the medial to lateral dissection (**FIG 13**). The previous exposure of the duodenum minimizes the risk of inadvertent Kocherization and/or injury to the duodenum at this stage.

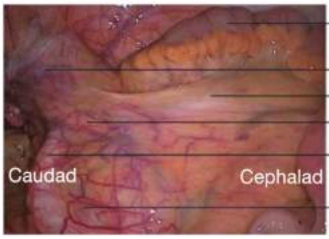

FIG 11 ● Exposure of the right pelvic inlet. With the patient positioned in steep Trendelenburg and the small intestine removed from the pelvis, the proximal lateral pelvic and abdominal attachments of the terminal ileum and cecum are identified. Important anatomy is appreciated in this photo: right common iliac artery and vein and the right ureter. These peritoneal attachments must be incised and freed to allow complete mobility of the small intestine.

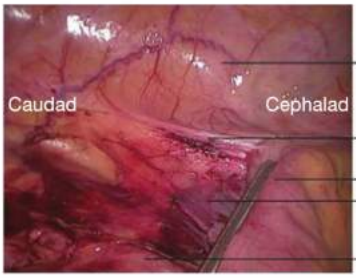

FIG 12 ● Lateral mobilization of the ascending colon. Once the lateral pelvic and initial abdominal attachments are incised, gentle traction on the cecum and ascending colon toward the patient's left upper quadrant will assist in the dissection of Toldt's fascia. The dark purple-appearing tissue toward the bottom of this operative photo reveals the retroperitoneum previously dissected during the initial medial to lateral dissection. The ureter maintains a close approximation to the dissection planes.

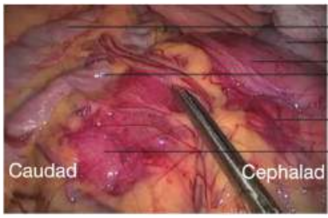

FIG 13 ● Mobilization of the hepatic flexure. With the patient in reverse Trendelenburg position and the transverse colon with its omentum reflected inferiorly, the superior portion of the previous medial to lateral dissection is easily visualized and is seen here in the middle of the photo. Incision into this thin tissue connects with the previous dissection plane and the dissection continues laterally to incise and release the hepatocolic ligaments completing the mobilization of the right colon. After this has been completed, the right colon should be able to be medialized across the midline of the abdomen.

ENTEROCOLONIC ANASTOMOSIS

- Ileocolonic anastomosis may be performed either intracorporeally or extracorporeally.
- We prefer an extracorporeal anastomosis through a periumbilical extraction site, incorporating the supra-umbilical port site. An advantage of this approach is that the anastomosis may be performed according to standard open technique.
- In cancer patients, the extraction site must be sufficiently large to allow for the passage of the tumor-bearing segment. A wound protector is placed into the incision to reduce infection.
- If the terminal ileal or colon mesenteries have not been completely mobilized, or the mesenteries have not been properly ligated, bowel exteriorization may be difficult and associated with a risk for avulsion injury to the mesenteric vessels.
- During bowel exteriorization, it is helpful to initially maintain the reverse Trendelenburg position with the table slightly rotated left-side down to keep the small bowel from falling over the colon and entrapping it.

EXTRACORPOREAL TRANSECTION AND ENTEROCOLONIC ANASTOMOSIS

- Once the right colon and terminal ileum have been delivered through the wound protector, attention is turned to the bowel resection. Investigation of the vascular supply to the planned resection sites prior to division and anastomosis is paramount.
- The mesentery should be carefully inspected and the terminal vessels should be visually assessed for pulsations or pulsatile blood flow should be confirmed by Doppler interrogation. If no pulsations are present, then another site for resection and anastomosis is chosen.
- The terminal ileum and the transverse colon (typically to the right side of the MCV) are transected with a linear stapler. The intervening mesentery is transected with an energy device.
- There are multiple methods to create an anastomosis. We suggest that surgeons use the method with which they are most comfortable. Our preferred approach is to perform a side-to-side, antimesenteric, functional end-to-end, stapled anastomosis in continuity to avoid potential for twisting of the bowel.
- This is done with a colotomy and an enterotomy on the anti-mesenteric side of the specimen about 1 cm or 2 cm away proximal to the planned transection sites. A linear stapler is placed into the enterotomy and colotomy and approximated at their antimesenteric sides. After ensuring that the ileal and colonic mesenteries are free from the closed stapler, it is fired creating the side-to-side enterocolostomy anastomosis (**FIG 14**).
- The common enterocolostomy is closed by using an 85- to 100-mm linear stapler (reload), avoiding narrowing the anastomosis (**FIG 15**).

FIG 14 ● Creation of an extracorporeal side-to-side stapled ileocolonic anastomosis with a linear stapler.

FIG 15 ● Closure of the common enterocolostomy anastomosis opening with a liner stapler.

- The anastomosis is inspected for gross defects or bleeding, both of which can be oversewn. The corners and intersections of the staple lines may be imbricated or reinforced with Lembert sutures.
- An alternative technique includes bowel division and intracorporeal anastomosis with a variety of options for specimen extraction. One advantage of this approach is the ability to avoid a periumbilical incision with its associated risk for hernia in favor of a Pfannenstiel incision.

CLOSURE

- The abdomen should be inspected for hemostasis and to ensure that there has been no inadvertent avulsion injury to the mesentery or twisting of the mesentery. The mesenteric defect will be large after colectomy with proximal vascular ligation; therefore there is neither the need to close the mesentery, nor is it generally possible to do so.
- Any 12 mm port sites are closed and the extraction site can be closed with interrupted suture or according to the surgeon's preference.

PEARLS AND PITFALLS

Patient selection	■ Patients who meet criteria for hereditary nonpolyposis colorectal cancer (HNPCC) or Lynch syndrome should be considered for a subtotal colectomy. ■ Patient should be assessed to ensure they will tolerate pneumoperitoneum and changes in positioning during surgery.
Preoperative planning	■ Ensure a complete colonoscopy was performed. As many as 1 in 20 patients will have synchronous primary cancers. ■ Localize the tumor with CT imaging for larger lesions and colonoscopic tattoo or metallic clip for smaller ones. ■ Careful review preoperative CT imaging identifies locally advanced disease, distant metastases, or aberrant vascular anatomy.
Patient positioning and portplacement	■ Securing the patient to the bed with chest and leg straps is key and allows for extremes in patient positioning. ■ Placing ports in either the midline or contralateral to the target facilitates orientation and maximizes instrument range of motion.
Procedure	■ Completing the medial to lateral dissection from the right branch of the middle colic artery down to the cecum is key to the dissection allowing easier dissection of the lateral ascending colon off of Toldt's fascia. ■ Careful attention to the duodenum and pancreatic head should be maintained while freeing the transverse mesocolon. The duodenum also serves as a landmark for proximal ligation of the ICV. ■ Anticipate variations in the vascular anatomy of the hepatic flexure. The course of the right colic vein in particular is highly variable and it is therefore at risk for avulsion injury especially at the trunk of Henle. ■ Mobilization along the base of the terminal ileal mesentery over the inferior vena cava and toward the ligament of Treitz ensures adequate mobilization for bowel exteriorization and tension-free anastomosis. ■ Sweeping the ascending colon and terminal ileum to the left side of the patient's abdomen is a good test to ensure complete mobilization of the entire right and transverse colon. ■ Ensure an appropriate oncologic resection is performed during all steps of the procedure not leaving behind ileocolic and middle colic lymph nodes.
Orientation	■ Prior to closure, inspect the orientation of the small bowel and its mesentery to ensure that no twists in the bowel were introduced. ■ Closure of the mesenteric defect to prevent internal hernias is not necessary if the defect is large.

POSTOPERATIVE CARE

- Following the procedure, principles of early mobilization and oral intake are observed.
- Early ambulation is encouraged to assist in return of bowel function and any invasive lines or catheters are also removed within 48 hours.
- Diet is initiated with clear liquids on the day of surgery and advanced as tolerated.
- Discharge criteria include (1) ability to maintain oral hydration, (2) adequate pain control without the need for IV narcotics, (3) signs of bowel function (flatus), and (4) afebrile for at least 24 hours. A narcotic minimizing regimen improves recovery.

OUTCOMES

- Laparoscopic procedures, when compared to traditional open surgery, have been shown to have quicker return of bowel function, less requirement of IV narcotics, earlier patient ambulation, fewer surgical site infections, and earlier discharge from the hospital.
- Most importantly, randomized control trials comparing laparoscopic and open colectomies, when performed adequately,

provide equivalent oncologic outcomes with no differences in tumor recurrence and patient survival.

COMPLICATIONS

- Surgical site infection (superficial, deep, and organ space)
- Wound dehiscence
- Hemorrhage
- Anastomotic leak/breakdown
- Bowel obstruction

Chapter 11

Right Hemicolectomy: Hand-Assisted Laparoscopic Surgery Technique

Matthew Albert   Harsha Polavarapu

DEFINITION

- Hand-assisted laparoscopic surgery (HALS) is a hybrid technique, which allows the surgeon to insert his or her hand into the abdominal cavity through a relatively small incision while preserving the ability to work under pneumoperitoneum. This approach aids in tactile feedback, retraction, and dissection by hand assistance in turn eliminating the technical challenges of conventional laparoscopy while maintaining nearly all of its benefits.[1,2]

INDICATIONS

- Colon cancer
- Colon polyps not amenable to colonoscopic removal
- Inflammatory bowel disease
- Angiodysplasia
- Recurrent right colonic diverticulitis

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history should be taken, including a detailed past medical history, past surgical history, present medications and allergies, and a personal and family history of colon and rectal cancer.
- A detailed family history to assess the risk of hereditary polyposis syndromes is critical in selecting the optimal procedure for the patient. Suspected patients should be offered genetic counseling and testing.
- A detailed physical examination of the patient should be performed to identify any prior surgical incisions and palpable masses to plan for the operation.
- The location, histopathology, and the clinical stage of the lesion is crucial prior to any planned procedure.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Colonoscopy remains the investigation of choice for localizing the target lesion, for obtaining tissue for histopathology, and for tattooing for intraoperative localization. This is also helpful in identifying synchronous lesions in the remaining colon.
- Computed tomography (CT) scan of the chest/abdomen/pelvis with IV and oral contrast is recommended as the primary staging tool to assess for local organ invasion and for distant metastasis.[3]
- Serum carcinoembryonic antigen (CEA) level is a valuable marker for postoperative surveillance.
- Bone scan and brain imaging should be reserved for symptomatic patients only.

SURGICAL MANAGEMENT

- The goal of surgery is an en bloc resection of the involved segment of bowel and to perform a high ligation of the vascular pedicle permitting adequate removal of associated lymphatics and lymph nodes.
- At least 12 lymph nodes must be harvested to adequately stage the patient and to avoid risk of understaging.[3]

Preoperative Planning

- Routine use of mechanical bowel preparation is not recommended.[4]
- Deep vein thrombosis prophylaxis with sequential compression devices and subcutaneous heparin dosing before induction of anesthesia is administered.
- A Foley catheter is placed prior to the operation.
- Nasogastric/orogastric tube is placed prior to the operation.
- Preoperative antibiotics covering skin and bowel flora are administered prior to induction of anesthesia.

Positioning

- Patient is positioned in a supine position. In order to prevent the patient from sliding during the case, the arms are tucked to the sides, the feet are placed against a padded footboard, and a strap is placed over the thighs (**FIG 1**).
- Alternatively, the patient can be placed in the low lithotomy position to avoid instrument conflict with the lower extremities. The knees should be slightly flexed and the feet firmly planted on the stirrups to prevent undue pressure on the calves and on the lateral peroneal nerves.
- Depending on the location of pathology and body habitus, a 5- to 7-cm incision is made for the hand port in an epigastric, periumbilical, or Pfannenstiel location (**FIG 2**).
- Location of the trocars can be variable based on surgeon's preference. In general, it is best to triangulate all ports to enhance visualization and to prevent instrument conflict inside the abdomen.
- A traditional port placement includes (**FIG 2**)
  - A GelPort hand port through a 6-cm epigastric incision
  - A 5-mm infraumbilical camera port
  - A 5-mm left lower quadrant instrument port
  - A 5-mm left upper quadrant/left anterior flank

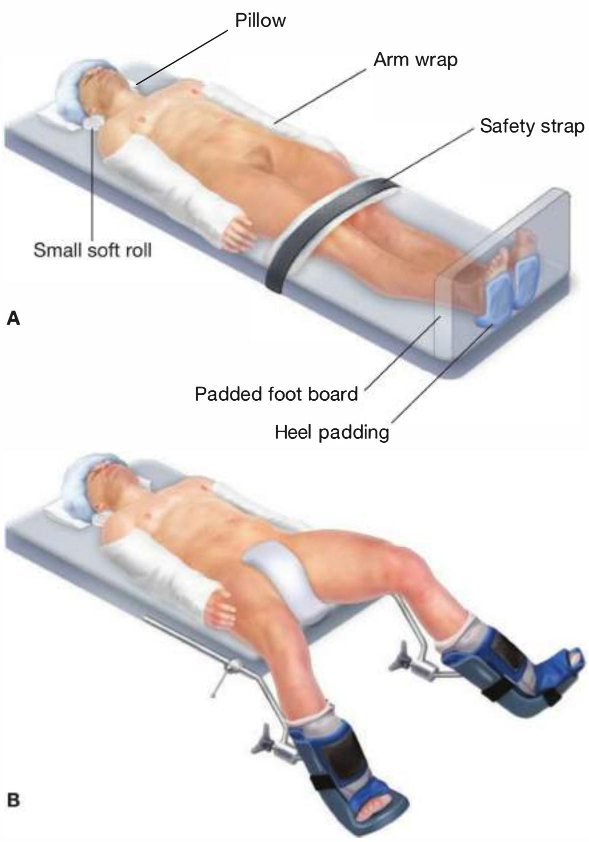

FIG 1 ● Patient positioning. In order to prevent the patient from sliding during the case, the arms are tucked to the sides, the feet are placed against a padded footboard, and a strap is placed over the thighs.

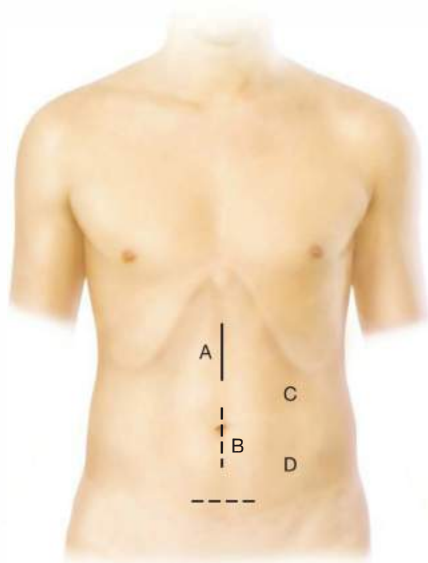

FIG 2 ● Port placement. The hand access port is placed through a 5- to 7-cm epigastric incision *(A)*. Alternatively, it can be placed through a Pfannenstiel or periumbilical incision *(dotted lines)*. A 5-mm camera port is placed infraumbilically *(B)*. Two 5-mm working ports are placed in the left upper *(C)* and left lower *(D)* quadrants.

EXPOSURE

- After placement of the hand port, the abdomen is explored to locate the lesion, to assess the extent of spread, and to palpate the liver and peritoneal cavity for distant metastatic spread.
- In female patients, the ovaries should be examined for metastatic spread or primary neoplasms.
- Pneumoperitoneum is created with carbon dioxide (CO_2) and additional trocars are inserted.
- Patient is placed in a left lateral tilt and slight Trendelenburg position. The small bowel is fanned out along its mesentery to aid in the exposure of the right colon.
- The greater omentum along with the transverse colon is retracted cephalad.
- The cecum is grasped with the hand and retracted toward the anterior abdominal wall using gentle traction to identify the ileocolic vessels.
- The ileocolic pedicle is grasped and retracted toward the anterior abdominal wall (**FIG 3**).

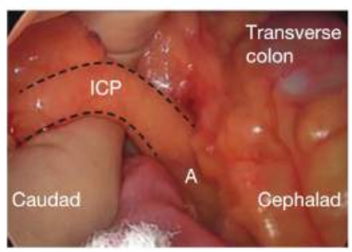

FIG 3 ● The ileocolic pedicle (ICP), identified at its origin off the inferior mesenteric vessels at the root of the mesentery **(A)**, is grasped and retracted toward the anterior abdominal wall.

DIVISION OF ILEOCOLIC PEDICLE

- With the ileocolic pedicle on stretch, a parallel incision is made on the peritoneal layer underneath the pedicle (**FIG 4**) extending to the root of the mesentery and the superior mesenteric vein, using monopolar electrocautery.
- A window is created under the ileocolic pedicle in the avascular plane that separates the pedicle from the retroperitoneum (**FIG 5**).
- The ileocolic pedicle is isolated and divided close to its origin off the superior mesenteric vessels using an energy device, a linear vascular stapler, or surgical clips based on surgeon's preference (**FIG 6**).

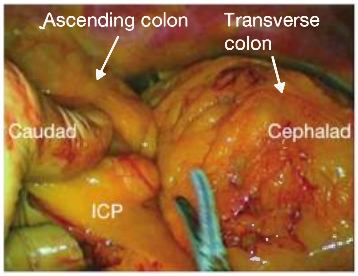

FIG 4 ● With the ileocolic pedicle (ICP) on stretch, a parallel incision has been made on the peritoneal layer underneath the ICP extending to the root of the mesentery. The surgeon, with the left hand now holding the ICP anteriorly, is now ready to open a window through the mesocolon lateral to the ICP.

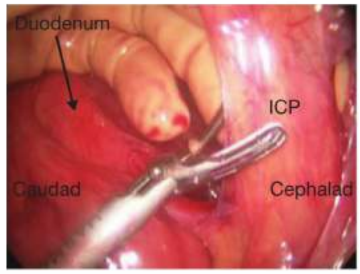

FIG 5 ● The ileocolic pedicle (ICP) has now been completely encircled and is now ready for transection. Notice that the pedicle has been completely separated from the duodenum and other retroperitoneal structures.

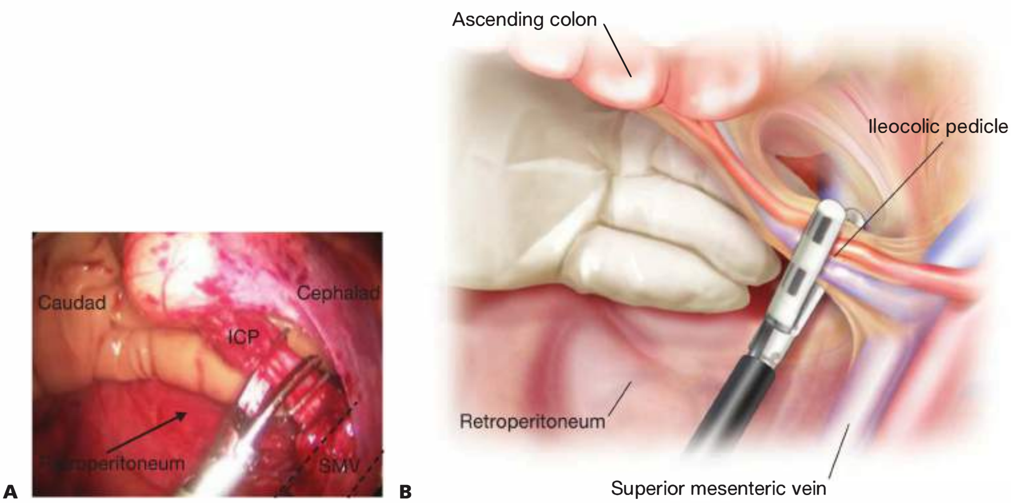

FIG 6 ● **A.** The ileocolic pedicle (ICP) is isolated and divided in between vascular clips with a 5-mm energy device close to its origin off the superior mesenteric vessels (SMV). **B.** Illustration of this step.

MOBILIZATION OF RIGHT MESOCOLON

- Using blunt dissection with a 5-mm energy device, the ascending mesocolon is mobilized off the retroperitoneum (duodenum and Gerota's fascia) using a medial to lateral dissection approach.
- To facilitate exposure, the surgeon's left hand should be pronated and placed underneath the mesocolon, giving upward traction for the retroperitoneal dissection (**FIG 7**).
- Mobilization of the right mesocolon is carried out laterally to the abdominal wall (**FIG 8A**), superiorly to the hepatorenal recess (**FIG 8B**), and medially exposing the third portion of the duodenum (**FIG 8C**).
- At this point, critical structures including the right ureter, the right gonadal vein, and the duodenum are identified and preserved intact in the retroperitoneum (**FIG 9**).

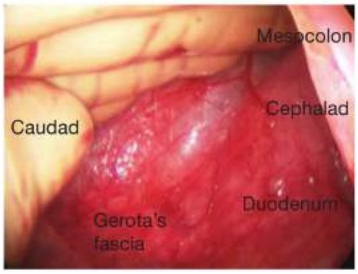

FIG 7 ● The ascending mesocolon is mobilized off the retroperitoneum (duodenum and Gerota's fascia), using a medial to lateral dissection approach. To facilitate exposure, the surgeon's left hand should be pronated and placed underneath the mesocolon, giving upward traction for the retroperitoneal dissection.

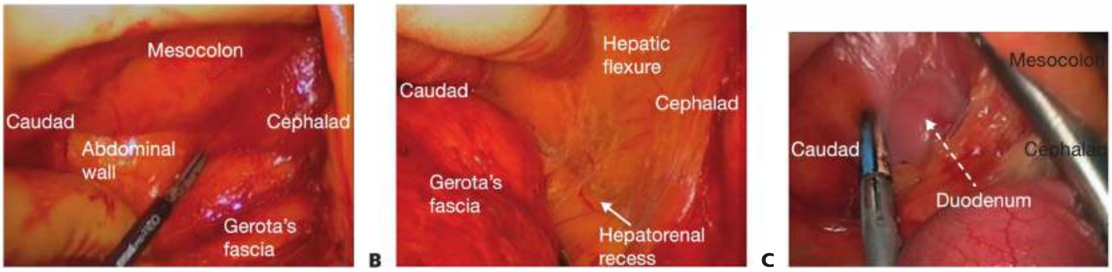

FIG 8 ● **A.** The medial to lateral dissection, performed bluntly with a 5-mm energy device, separates the ascending mesocolon from the retroperitoneal structures (Gerota's fascia and duodenum) until reaching the lateral abdominal wall. **B.** The dissection is carried superiorly until the hepatorenal recess. **C.** The third portion of the duodenum is exposed medially.

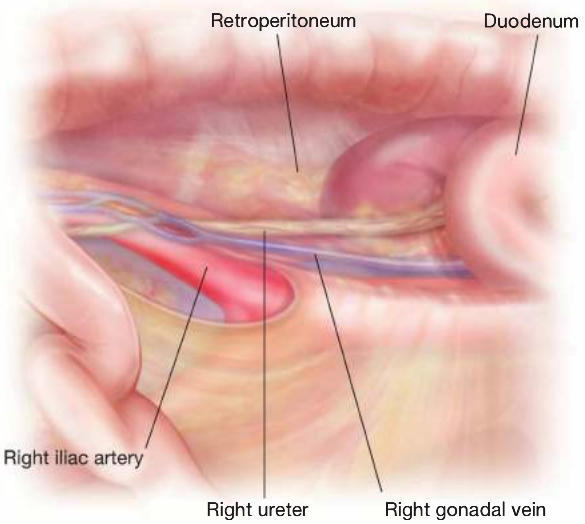

FIG 9 ● After completion of the medial to lateral mobilization of the ascending mesocolon, critical structures including the right ureter, the right gonadal vein, and the duodenum are identified and preserved intact in the retroperitoneum.

LATERAL MOBILIZATION OF THE ASCENDING COLON

- With the patient in a steep Trendelenburg position, the small bowel is retracted out of pelvis, and the base of cecum is grasped and retracted anteriorly toward the abdominal wall.
- With the ileum on stretch, a peritoneal incision is created from the cecum medially along the root of the ileal mesentery (**FIG 10**) to communicate with the retrocolic space previously created by the medial to lateral mobilization of the ascending mesocolon.
- The right ureter and the right gonadal vein are most easily identified at this phase of the operation coursing over the right iliac vessels and into the pelvis (**FIG 11**). Lateral and anterior to the psoas muscle, the lateral femoral cutaneous nerve is also frequently identified.
- The white line of Toldt is incised (**FIG 12**), dividing the only remaining attachments of the ascending colon if the medial to lateral dissection was carried out adequately during the previous step.

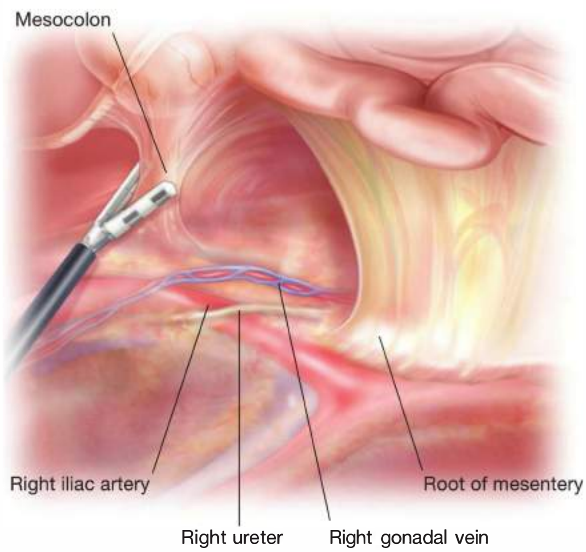

FIG 11 ● After mobilization of the cecum and terminal ileum, the right gonadal vein and the right ureter are seen in the retroperitoneum crossing over the right iliac artery and into the pelvis.

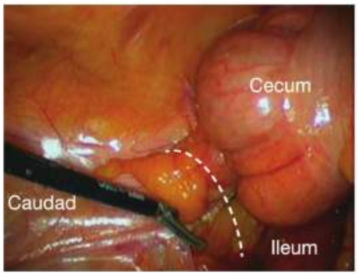

FIG 10 ● With the patient in a steep Trendelenburg position, the small bowel is retracted out of pelvis, and the base of cecum is grasped and retracted anteriorly toward the abdominal wall. With the ileum on stretch, a peritoneal incision is created from the cecum medially along the root of the terminal ileal mesentery.

FIG 12 ● With the surgeon retracting the colon medially, the lateral attachments of the ascending colon (white line of Toldt) are transected with an energy device in a cephalad direction.

MOBILIZATION OF THE HEPATIC FLEXURE AND THE PROXIMAL TRANSVERSE COLON

- The patient is positioned in reverse Trendelenburg position and the hepatic flexure can easily be exposed by grasping the colon in your palm and pulling it downward and medially, as one would do during open surgery.
- The hepatocolic ligament is transected with a 5-mm energy device. The surgeon can facilitate this step by hooking his index finger under the hepatocolic ligament (**FIG 13**).

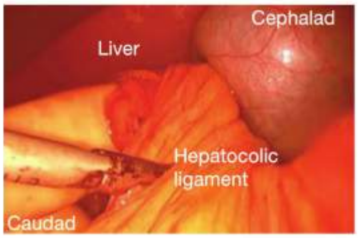

FIG 13 ● Transection of the hepatocolic ligament. The hepatocolic ligament is transected with a 5-mm energy device. The surgeon can facilitate this step by hooking his index finger under the hepatocolic ligament as shown.

- By pulling the transverse colon now downward, the gastrocolic ligament is readily exposed.
- The gastrocolic ligament is transected up to the midtransverse colon with a 5-mm energy device, and the lesser sac entered.
- The extent of mobilization is dictated by the location of the pathology, body habitus, and extraction site.
- With the hepatic flexure and the ascending colon now fully mobilized, we are now ready for the extracorporeal mobilization of the specimen.

BOWEL RESECTION AND ANASTOMOSIS

- Once the colon is completely mobilized, the pneumoperitoneum is desufflated, and the right colon and terminal ileum are exteriorized through the hand port site with the wound protector in place to prevent oncologic and infectious contamination of the wound (**FIG 14**).
- The extracorporeal mobilization of the right colon and terminal ileum should be feasible without any tension. Should there be any tension during the extracorporeal delivery of the specimen, reintroduce it into the abdomen, reinsufflate the pneumoperitoneum, and mobilize the right colon further to avoid potentially troublesome mesenteric tears that could lead to significant bleeding.
- The remaining mesentery of the small bowel and the large bowel is divided followed by the division of the terminal ileum and midtransverse colon with a linear stapler device (**FIG 15**).
- The resected right colon is opened on a side table to confirm complete resection of the target lesion and the specimen is sent for final pathology.
- A side-to-side ileocolic anastomosis is performed (**FIG 16A**). The completed anastomosis is introduced back into the abdominal cavity (**FIG 16B**). Surgeons may choose from either a stapled or a hand-sewn technique for the ileocolic anastomosis.
- The abdomen is reinsufflated to assure that there is good hemostasis as well as a correct bowel orientation.

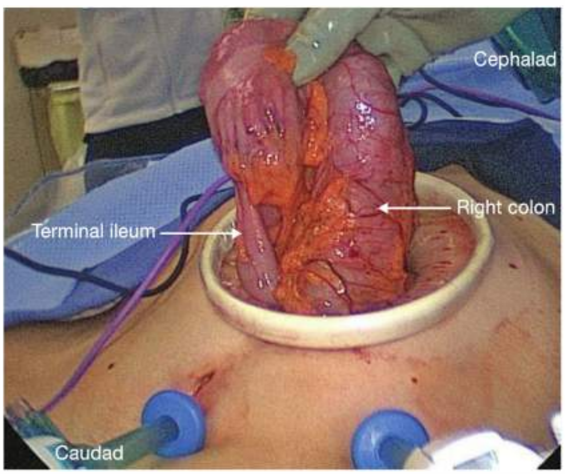

FIG 14 ● Extracorporeal mobilization. The right colon and the terminal ileum are exteriorized through the hand port site with the wound protector in place.

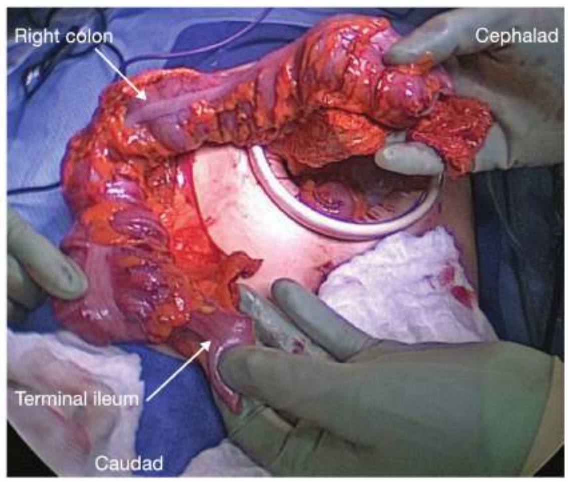

FIG 15 ● Extracorporeal transection. The terminal ileum and the transverse colon have been transected with a linear stapler.

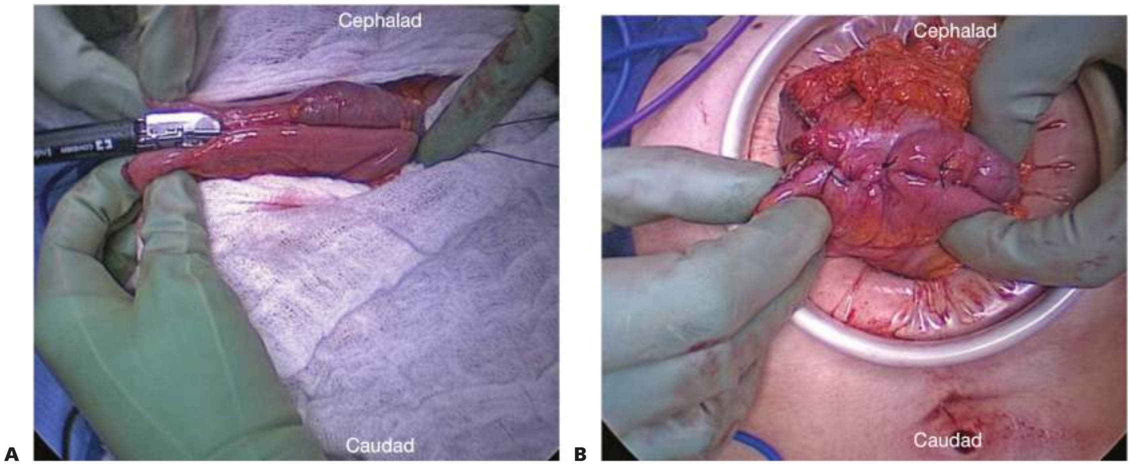

FIG 16 ● Extracorporeal anastomosis. **A.** A stapled side-to-side ileotransverse colon anastomosis technique is shown. **B.** The completed anastomosis will be introduced back into the abdomen.

CLOSURE

- The ports, the hand-assist device, and the wound protector are removed under direct vision.
- Surgical gloves are changed to minimize the chance of a wound infection.
- The hand-port fascial incision is closed with a running absorbable monofilament suture (no. 1 polydioxanone [PDS]).
- All wounds are irrigated and closed with subcuticular 4-0 PDS sutures.

PEARLS AND PITFALLS

Preoperative localization	■ Preoperative localization of the lesion with a tattoo is crucial, especially for polyps, as these can be difficult to identify even with tactile feedback.
Identification of the ileocolic pedicle	■ The ileocecal junction should be elevated to identify the ileocolic vessels as the superior mesenteric vessels can easily be mistaken for the ileocolic vessels.
Avoid the superior mesenteric vein	■ When dissecting high on the ileocolic vessels, care should be taken to avoid the superior mesenteric vein.
Identifying the right ureter	■ The right ureter should be identified and preserved as it can be easily injured if you are in the wrong plane. Stay in the loose areolar plane located between the ascending mesocolon anteriorly and the retroperitoneum posteriorly.
Small bowel orientation	■ Before performing an ileocolic anastomosis, the orientation of the small bowel should be checked, as the small bowel can easily get twisted on itself during the extracorporeal mobilization.

POSTOPERATIVE CARE

- Patients are monitored on a surgical floor bed.
- Start a clear liquid diet on postoperative day 1 and advance diet as tolerated.
- Foley catheter is removed on postoperative day 1.
- Most of the patients are discharged home on postoperative days 2 and 3.

OUTCOMES

- Hand-assisted colectomy has been shown to decrease the total operative time and conversion rate compared to conventional laparoscopy.[2,5]
- The long-term survival of patients with colon cancer correlates with the American Joint Committee on Cancer (AJCC) stage published guidelines.

COMPLICATIONS

- Surgical site infection
- Anastomotic leak
- Postoperative bleeding
- Postoperative ileus
- Intraabdominal infection
- Incisional hernia

Chapter 12

Right Hemicolectomy: Single-Incision Laparoscopic Technique

Theodoros Voloyiannis

DEFINITION

- Single-incision laparoscopic right hemicolectomy is a refined technique of conventional laparoscopy where a single multichannel laparoscopic port is used via a 2.5- to 5-cm total incision length.
- The goal is to keep the procedure simple, safe, and cost-effective with comparable outcomes to hand-assisted or multiport laparoscopic technique.
- Although single-incision laparoscopy differs from the conventional laparoscopy, it follows the same steps and oncologic principles. It can be completed without difficulty with an extracorporeal anastomosis. An intracorporeal anastomosis can be performed as well; however, it requires advanced laparoscopic skills and the addition of laparoscopic Endo GIA staplers.

DIFFERENTIAL DIAGNOSIS

- The procedure can be performed for benign or neoplastic diseases or condition, including the following:
  - Appendectomy
  - Ileocecectomy
  - Formal right colectomy
  - Extended right colectomy

PATIENT HISTORY AND PHYSICAL FINDINGS

- A detailed history and physical exam is essential preoperatively to determine if the patient is suitable for laparoscopic single-incision right hemicolectomy. Potential contraindications to laparoscopic single-incision right hemicolectomy are summarized in Table 1.
- In case of underlying neoplasia, the size of the tumor determines if it can be extracted without tension via the single-port wound protector. In general, tumors up to 7 cm can be extracted via a 5-cm maximum length single incision. The procedure can still be performed with elongation of the incision for extraction of larger tumors. In that case, the benefit of the single port is eliminated, with the exception of the avoidance of use of multiple laparoscopic ports.
- A large palpable tumor preoperatively with fixation to the abdominal wall or other organs may be a contraindication to single-incision laparoscopy, although excision en bloc with soft tissue abdominal wall is still possible via a single incision in some cases.
- Signs and symptoms of obstructing neoplastic lesion with proximal distended right colon with or without competent ileocecal valve and small intestinal dilation may also suggest contraindication to laparoscopic approach due to difficulty establishing a safe working space with pneumoperitoneum. Anastomosis may be contraindicated in this case.
- It is important to define the underlying pathology—benign versus malignant disease and the location of the lesion preoperatively. Ileocecectomy or right hemicolectomy for neoplasia may require formal lymphadenectomy with en bloc resection of the ileocolic vascular pedicle. Hepatic flexure or proximal transverse colon lesions may require additional resection of the right colic vein or right branch or the middle colic artery and vein and further mobilization of the proximal transverse colon.
- Involvement of other organs or structures, such as right ovary, small intestine, abdominal wall, right ureter, right kidney, duodenum, small intestine, omentum, liver, and gallbladder, may require a hand-assisted laparoscopy or open laparotomy. Potential intraoperative consultation to other subspecialties may be required in these cases. It is the primary surgeons' responsibility to communicate with the consulting service that a single-incision laparoscopic approach is planned.
- Failure to identify the tumor extent preoperatively may lead to longer operative time if a single-port technique is used. Conversion to hand-assisted or open approach is prudent in these cases.
- Presence of preoperative umbilical or other incisional hernia does not preclude a single-incision approach; however, it may require lengthier operative time, extension of the incision, and possibly placement of a xenograft.
- Previous abdominal surgeries with extensive abdominal or pelvic adhesions may increase the operative time. A single incision may actually facilitate a faster abdominal adhesiolysis as it can partially be performed open via the port's wound protector with assistance of a retractor.
- Crohn's terminal ileitis or right colitis with a large phlegmon or perforation with complex fistulae or abscess may preclude a single-incision laparoscopic approach.
- Previous appendectomy is not a contraindication to single-incision laparoscopic right hemicolectomy, as adhesions may be the only intraoperative finding with minimal increase to operative time.

Table 1: Absolute Contraindications to Single-Incision Laparoscopic Right Colectomy

– Complex terminal ileal or right colonic inflammatory bowel disease
– Abscess, fistula, obstruction, perforation
– Colon tumor size of more than 7 cm
– Colon obstruction with proximal massive intestinal distention
– Preoperative decision for complex en bloc resection
– Midline incisional hernia longer than the maximum single incision—5 cm

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Preoperative colonoscopy with India ink tattoo injection is of paramount importance for smaller nonpalpable benign or malignant lesions or polyps, which are not resectable endoscopically. The surgeon must clearly identify the site of the tattoo at 5 cm distal to the lesion preoperatively in the absence of other anatomic landmarks, such as the ileocecal valve or the appendiceal orifice and the cecum itself.
- India ink tattoo by different gastroenterologists has been reported to be placed proximally around the lesion, distal to the lesion, or both proximal and distal to the lesion, leading occasionally to a false distal colonic resection margin.
- Inadvertent extracolonic India ink injection may lead to inflammatory—diverticulitis type—reaction of the surrounding mesentery and omentum, thus making the single-incision laparoscopic colonic mobilization challenging.
- Absence of preoperative tattoo for smaller or nonpalpable lesions distal to the ileocecal valve may lead to failure to localize the lesion intraoperatively, lengthy procedure and possible need for intraoperative colonoscopy, and conversion to laparotomy. This may lead to significant air insufflation of the colon and small intestine unless a carbon dioxide (CO_2) colonoscopic insufflation is available. Compressing the terminal ileum with a laparoscopic grasper during the intraoperative colonoscopy may prevent small intestinal distension.
- Computed tomography of the abdomen and pelvis with oral and intravenous (IV) contrast helps determine the feasibility of a single-incision laparoscopic approach and identifies the exact location of larger right colonic neoplastic lesions, involvement of adjacent organs or structures, mesenteric adenopathy and possible metastatic lesions, hernia, and other abdominal nonrelated pathology. Inflammatory disease of the terminal ileum or right colon is suspected by the presence of phlegmon, abscess, fistula, or obstruction.
- Magnetic resonance imaging (MRI) of the abdomen may assist with the identification of indeterminate liver lesions and with the assessment of metastatic lesions preoperatively.
- Positron emission tomography (PET) computed tomography is not generally needed preoperatively.
- Preoperative barium enema or small bowel follow-through contrast study has generally been replaced by colonoscopy.
- Ultrasound (US) of the abdomen has limited usefulness for the identification of colonic pathology.
- A carcinoembryonic antigen is obtained as baseline tumor marker for surveillance.

SURGICAL MANAGEMENT

Preoperative Planning

- Full bowel preparation is administered the day prior to surgery. Right colectomy without bowel preparation is equally safe but it may increase the weight and volume of the right colon and impair the laparoscopic handling of the colon. Furthermore, extraction of the specimen via a small 3.5-cm single incision may become challenging.
- Preoperative medical or pulmonary cardiac clearance as necessary.
- Correction of preoperative anemia as needed.
- IV antibiotics, venous thromboembolism (VTE) prophylaxis, μu-receptor antagonist (alvimopan) immediately preoperatively, correction of electrolyte abnormalities.

Instrumentation

- A bariatric length, 10-mm 30-degree camera is used. Use a right-angle adaptor for fiberoptic attachment to the camera, if needed, to avoid conflict of the fiberoptic cord with other laparoscopic instruments. Use a preheated camera or other devices for camera lens cleansing. Repeated camera cleansing requires frequent removal via the single port, which adds time to the procedure.
- Two bariatric length laparoscopic bowel graspers are used.
- Bariatric length laparoscopic energy device such as 43-cm LigaSure, 5 mm with monopolar tip, Enseal, or similar is used. Energy devices that produce excessive moisture/fog may impair the visibility as most single-incision laparoscopic ports have a side port for smoke evacuation at the same level with the channel for air insufflation.
- Bariatric length laparoscopic 5-mm suction irrigation
- Laparoscopic smoke evacuator channel
- Laparoscopic scissors
- Laparoscopic 5-mm or 10-mm clip applier (optional)
- Laparoscopic Endoloop polydioxanone (PDS) for the ileocolic vascular pedicle
- Staplers: linear gastrointestinal anastomosis (GIA) 75-mm, double, or preferably triple line, blue staple cartridges
- Second set of instruments for extracorporeal anastomosis

Patient, Team, and Operating Room Setup

- The patient is placed over a foam pad on supine position with the arms and legs tucked to the side and secured to the table with a Velcro safety strap or broad tape across the chest and lower extremities (**FIG 1**).
- Sequential compression devices (SCDs) are applied to the lower extremities.
- A laparoscopic operating room (OR) table with steep tilting is used. Test maximum tilting prior to draping to assess patients' secure positioning on the table.

FIG 1 • Patient positioning. The patient is placed over a foam pad on supine position with the arms and legs tucked to the side and secured to the table with a Velcro safety strap or broad tape across the chest and lower extremities.

- A Foley catheter is inserted and taped over the right thigh in order to avoid urethral trauma during patient positioning changes throughout the operation.
- A bear hugger or other thermal device is applied to the chest and legs.
- Protecting foam pad is placed over the head to protect from injury with laparoscopic instruments.
- The laparoscopic tower and energy devices are placed to the right of the patient's head.
- The surgeon stands to the patient's left side with the assistant standing to his right side (**FIG 2**). The scrub nurse stands by the patient's right leg. One or two high-definition monitors are placed to the patient's right side at eye level in front of the surgeon.

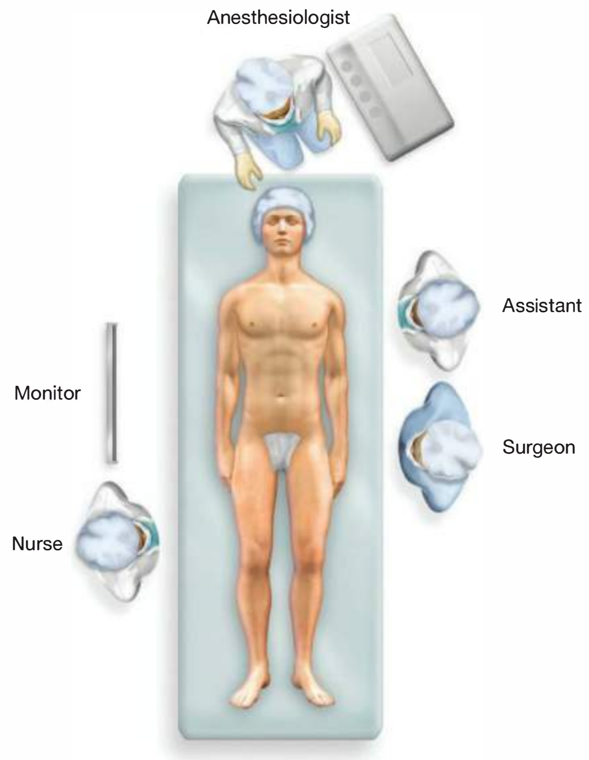

FIG 2 ● Team positioning. The surgeon stands to the patient's left side with the assistant standing to his right side. The scrub nurse stands by the patient's right leg. One or two high-definition monitors are placed to the patient's right side at eye level, in front of the surgeon.

DIAGNOSTIC LAPAROSCOPY—SINGLE MULTICHANNEL PORT TECHNIQUE

- After positioning and securing the patient, the abdominal field is prepped and draped. We recommend laparoscopic draping with side plastic bags/pockets to allow for bariatric instrument placement. All laparoscopic cords are brought via the patient's upper chest side and secured with the drape's Velcro.
- A 3.5-cm vertical midline incision is performed with no. 11 scalpel through the umbilicus (**FIG 3A,B**).
- Assemble all channels of the single port on the back table to avoid losing parts outside the sterile field. Place the laparoscopic multichannel single port (for neoplasia, a single port with a wound protector is required) (**FIG 4A,B**). Insufflate CO_2 pneumoperitoneum to 15 mmHg.
- Perform a diagnostic laparoscopy. The surgical assistant/camera holder and the surgeon stand by the patient's left side, with the assistant to the surgeon's right side. Tilt the OR table to a steep Trendelenburg position and airplane it to the left for maximum exposure of the ileocolic pedicle and the medial mobilization of the small intestine. There is no need for placement of sponges or Ray-Tecs in the abdomen for retraction.
- Minimize excursion/cluster effect around hands and camera between the surgical assistant and the operating

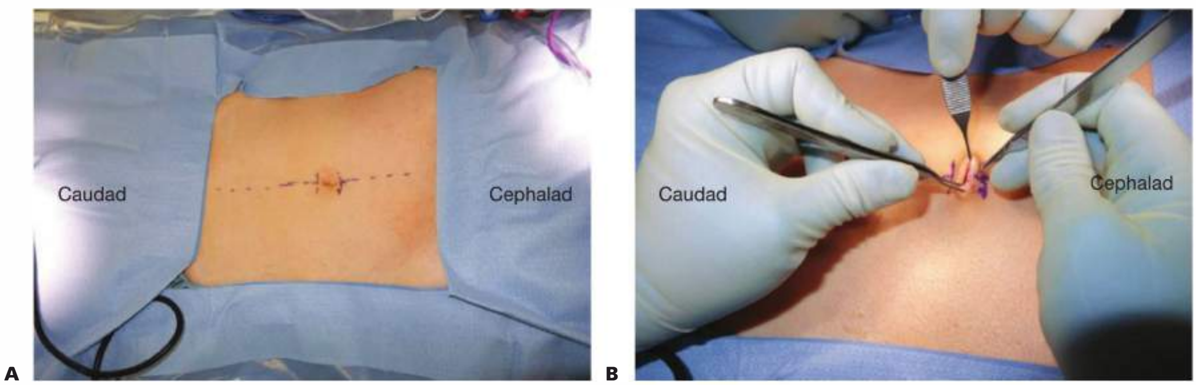

FIG 3 ● Single-incision laparoscopic surgery (SILS) port placement. **A.** Skin markings. **B.** Skin incision.

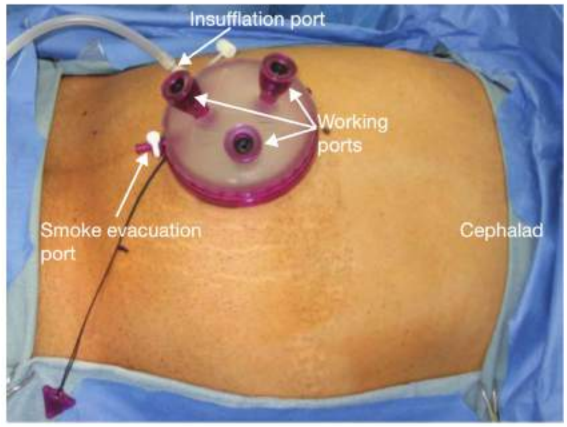
A



B

FIG 4 ● Single-incision laparoscopic surgery (SILS) port placement and configuration. **A.** A wound protector is used. **B.** A multiport channel with three working ports and insufflation port and a smoke evacuator port is used. The port is assembled on a side table prior to insertion in the patient.

surgeon. Adhere to the principle that the surgeon should position his assisting (nondominant hand) instrument distal tip (for grasping, retracting, or suctioning) as close as possible to his dominant operating instrument tip (i.e., energy device at the dissecting surgical plane). This distance should be about 3 to 4 cm between the two instruments' tips. For example, hold the ileocolic vascular pedicle just above the site of the division site rather than holding the cecum itself which is far more distant from the pedicle. This technique allows achieving a wide angle between the two instruments outside the abdomen as they exit and cross via the single port, thus leading to no instrument cluster effect between the surgeon's hands.

- The assistant camera holder will avoid clustering with the surgeon's instruments outside the abdomen if he or she abducts the camera as far as possible from the surgeons' hands and uses the camera's 30-degree angulation for side view as well as the zoom-in option.
- Minimize the need for frequent instrument exchange via the single port, such as for camera lens cleaning or exchange of graspers with monopolar laparoscopic scissors. Instead, consider using energy devices that provide both dissection and sealing-cutting effect, thus allowing constant progress in the operating field and significant time saving.
- The surgeon and the assistant can either switch sides (caudal and cephalad to the patient's left side) during the various steps of the procedure or just rotate the single port clockwise or counterclockwise while the instruments stay in the abdomen under direct visualization with the camera, thus achieving different angles with the camera, better exposure, and visualization.
- If the surgeon's hands are crossing, then rotating the port or switching positions with the assistant (caudal–cephalad) will improve exposure.
- The OR table is also tilted accordingly during the various steps of the procedure to increase exposure and prevent instrument clustering.

DIVISION OF THE ILEOCOLIC VASCULAR PEDICLE AND MEDIAL TO LATERAL MOBILIZATION OF THE ASCENDING MESOCOLON

- The patient is positioned in a steep Trendelenburg position with the table tilted maximally toward the patient's left side. The surgeon stands on the patient's lower left side, using a grasper in the nondominant hand and an energy device on the dominant hand. The assistant stands up the surgeon's right side holding the camera.
- If the omentum is adherent medially to the right colon, we start the procedure with the dissection of the omentum off the colon or perform an omentectomy to allow for maximum exposure of the ileocolic pedicle and the ascending colon mesentery.
- Dissect the terminal ileal retroperitoneal attachments and mobilize it medially toward the midline.
- Identify the ileocolic vessels as they cross over the third portion of the duodenum (**FIG 5**).
- Perform a medial to lateral mobilization of the ascending mesocolon (**FIG 6**). Dissect under (dorsal) the ileocolic vessels, entering the plane between the ascending mesocolon and the retroperitoneal structures (duodenum and Gerota's fascia). The transition between the fat planes of the ascending mesocolon and Gerota's fascia can be easily identified and aids to stay in the proper dissection plane.
- Using an energy device, we divide the ileocolic vascular pedicle at its origin as it crosses the third portion of the

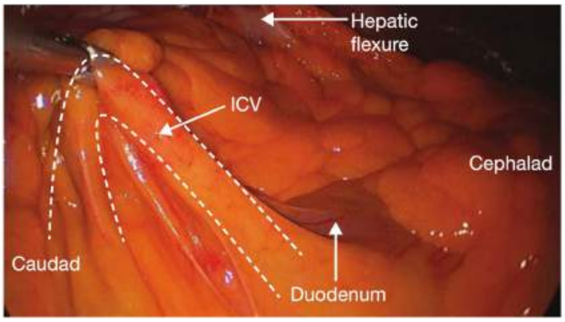


FIG 5 ● Identification the ileocolic vessels (ICV) as they cross over the third portion of the duodenum.

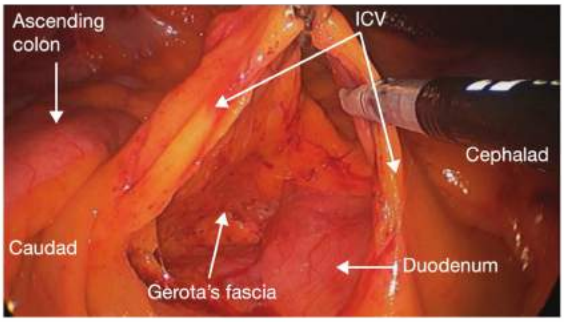

FIG 7 ● Transection of the ileocolic vessels (ICV). Using an energy device, we divide the ileocolic vascular pedicle at its origin as it crosses the third portion of the duodenum.

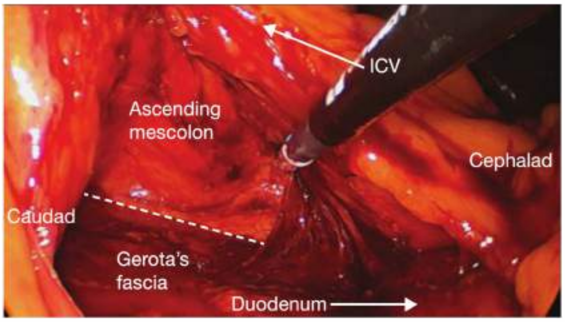

FIG 6 ● Medial to lateral dissection of the ascending mesocolon. Dissect under (dorsal) the ileocolic vessels, entering the plane between the ascending mesocolon and the retroperitoneal structures (duodenum and Gerota's fascia). The transition between the two fat planes (mesocolon and Gerota's fascia) can be easily visualized *(dotted line)*.

duodenum (**FIG 7**) while holding the vessel stump with a grasper to avoid retraction or residual bleeding.

- Place hemostatic clips or Endoloop PDS at the divided stump to secure the hemostasis.
- There is no need for laparoscopic stapled pedicle division unless severe atherosclerosis or vessels larger than 7 mm in size are present, which preclude usage of a laparoscopic energy device. In that case, we may use an Endo GIA stapler with a vascular load.
- Complete the medial to lateral dissection of the ascending colon mesentery, off the retroperitoneal attachments without entering Gerota's fascia, identifying and protecting the right gonadal vessels and the right ureter.
- Continue the medial to lateral dissection of the ascending colon mesentery in a cephalad direction, separating it from the second and third portion of the duodenum and the head of the pancreas in an atraumatic fashion. This will allow for an easier mobilization of the hepatic flexure later during the case.

MOBILIZATION OF TERMINAL ILEUM, ASCENDING COLON, HEPATIC FLEXURE, AND PROXIMAL TRANSVERSE COLON

- Divide the terminal ileal mesentery with energy device flush to the ileocolic vascular pedicle up to the mesenteric border of the terminal ileum at the selected site of proximal intestinal division (**FIG 8**).
- In addition, the terminal ileum is mobilized off the retroperitoneal attachments toward the midline. This will allow for a tension-free extraction via the single port site for the extracorporeal division without tension or risk for avulsing the mesentery. Morbidly obese patients require generous terminal ileum medial mobilization to allow for a tension-free specimen extraction via the single port.

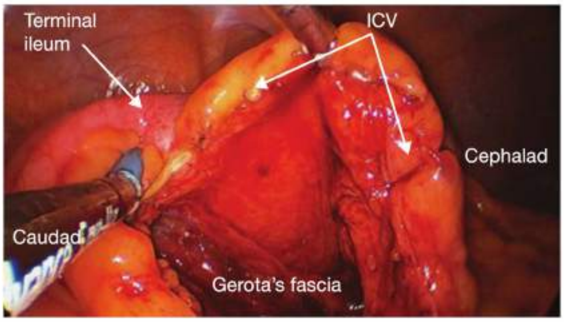

FIG 8 ● Division of terminal ileum mesentery. Transect the terminal ileum mesentery down to the bowel wall with the energy device, keeping the ileocolic vessels (ICV) in the specimen side.

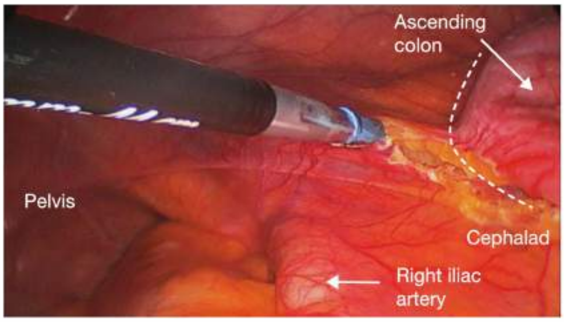

FIG 9 ● Lateral mobilization of the ascending mesocolon. Transect the white line of Toldt *(dotted line)* with the energy device.

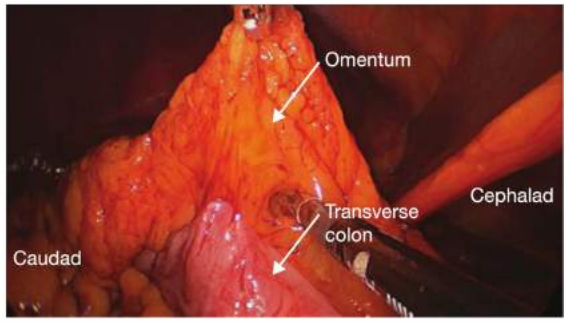

FIG 10 ● Entrance to the lesser sac. Enter the lesser sac via the antimesenteric border of the proximal transverse colon and perform a formal hepatic flexure mobilization using the energy device.

- Mobilize the ascending colon medially by transecting its lateral peritoneal attachments (the white line of Toldt) (**FIG 9**).
- Place the patient on a reverse Trendelenburg position and keep the OR table tilted to the left. The surgeon is positioned now cephalad and the assistant/camera holder is positioned to his or her left side.
- Enter the lesser sac via the antimesenteric border of the proximal transverse colon (**FIG 10**) and perform a formal hepatic flexure mobilization using the energy device.
- Elect the point of distal division of the right colon and divide the corresponding mesentery up to the site of the distal resection margin and to the right of the middle colic vessels (**FIG 11**).
- A more generous distal mobilization of the colon is required compared to hand-assisted laparoscopy, by approximately another 5 cm, to allow for a tension-free extraction of the specimen and to avoid mesenteric avulsion during specimen extraction.

FIG 11 ● Division of the midtransverse colon mesentery. Elect the point of distal division of the right colon and divide the corresponding mesentery up to the site of the distal resection margin and to the right of the middle colic vessels.

EXTRACORPOREAL MOBILIZATION AND TRANSECTION OF THE SPECIMEN

- Grasp the terminal ileum at the proximal resection site securely before evacuating the pneumoperitoneum.
- Place wet lap sponges around the wound protector and use a second towel for the instruments used for creation of the anastomosis in order to avoid fecal contamination to the laparoscopic surgical drapes.
- Extract the terminal ileum first and divide it with a GIA linear 75-mm, double or triple, blue staple load (**FIG 12**). Use a grasper to hold into the terminal ileum stapled stump line and reintroduce into the abdomen.
- Extract the right colon and divide it at the distal site with a GIA linear 75-mm, double or triple, blue staple load (**FIG 13**).
- If the colon with the attached mesentery is too thick or in case of neoplasia the tumor is larger than the incision, then elongate the incision superiorly using an army navy

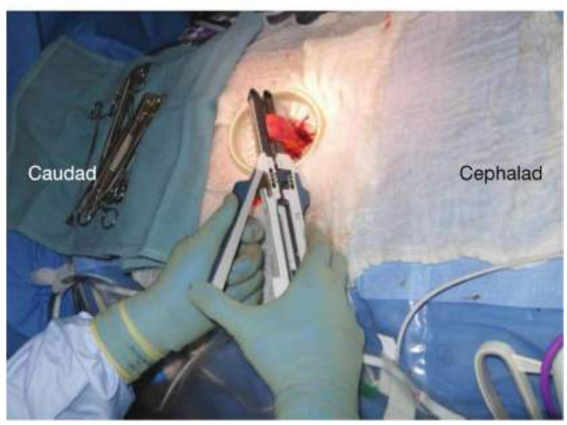

FIG 12 ● Extracorporeal transection of the terminal ileum. Extract the terminal ileum first and divide it with a GIA linear 75-mm double or triple blue staple load.

retractor to "hook" under the fascia and protect the wound protector from perforation. Use a no. 11 scalpel in a sawing motion or electrocautery to elongate the incision as necessary and extract the specimen.

- Divide the remaining mesentery and pass the specimen to pathology, or open the specimen at the back table to confirm adequate margins in case of neoplasia.

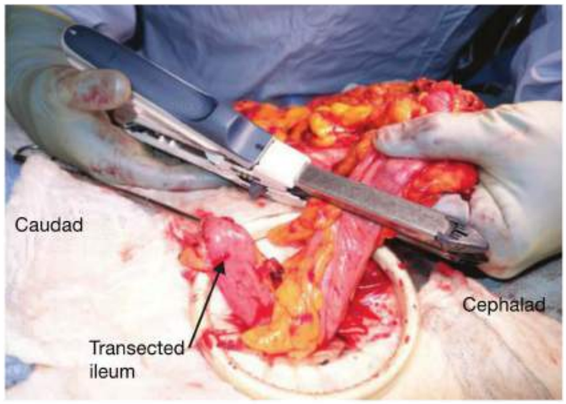

FIG 13 ● Extracorporeal transection of the midtransverse colon. Extract the right colon and divide it at the distal site with a GIA linear 75-mm, double or triple, blue staple load.

EXTRACORPOREAL ANASTOMOSIS

- Perform an extracorporeal side-to-side, functional end-to-end, ileotransverse anastomosis with a GIA linear 75-mm, double or triple, blue staple load (**FIG 14A,B**).
- Inspect the ileal and colonic segments to rule out torsion prior to firing the stapler. The surgeon can palpate with a finger along the mesenteric margin of the terminal ileum mesentery and the distal colon mesentery toward the base at the retroperitoneum and ensure that there is no intestinal torsion.
- Inspect for bleeding from the anastomotic line.
- Approximate the anastomotic stump defect with another GIA linear 75-mm, double or triple, blue staple load. Sometimes, a second load is required, thus eliminating the need for a thoracoabdominal (TA) double staple line, although its use remains on the surgeon's preference.
- Introduce the anastomosis into the abdomen; inspect for bleeding and fecal spillage. Cover the anastomosis with the rest of the omentum or small intestine and ensure there is no torsion of the anastomosis. When in doubt, proceed again with laparoscopic inspection.

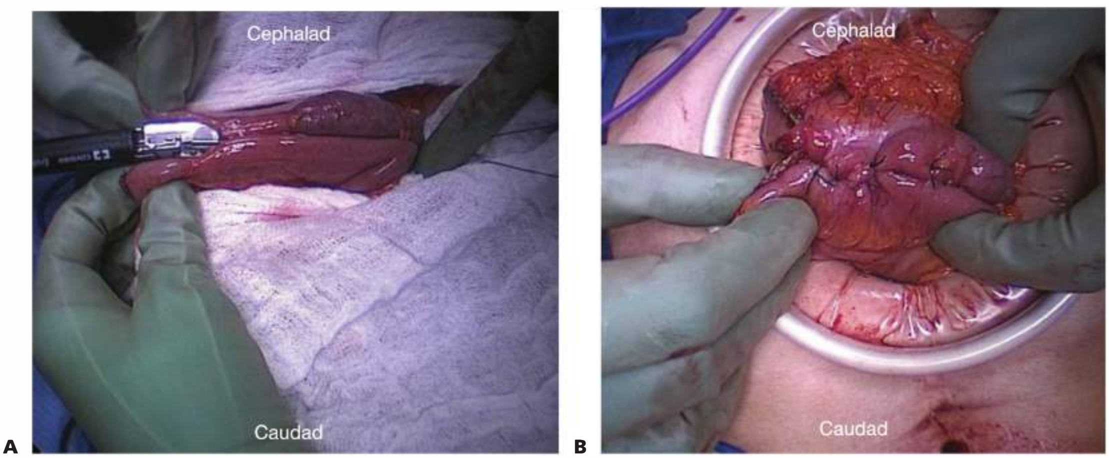

FIG 14 ● Extracorporeal anastomosis. **A.** An anatomic side-to-side, functional end-to-end stapled ileocolonic anastomosis is constructed. **B.** The anastomosis is tension-free and has excellent blood supply.

WOUND CLOSURE

- It is advised to place an antiadhesive sheet posterior to the midline fascia edges while avoiding contact with the anastomotic staple lines. Remove the wound protector and close the fascial incision with no. 1 PDS suture.
- Irrigate the wound copiously with normal saline; obtain wound hemostasis.
- Approximate the skin edges with staples while leaving the umbilical skin edges opened and tucked with a Vaseline gauze with a cotton ball.
- The procedure is a clean contaminated one and leaving the umbilicus skin edges open may protect it from wound infection.

PEARLS AND PITFALLS

Preoperative workup	■ Correct identification of the underlying pathology and extent of the tumor in relation to other organs allows for careful selection of the laparoscopic single-incision technique.
Lesion localization	■ India ink tattoo placement when indicated for preoperative localization of the lesion and the distal resection margin is of paramount importance.
Patient positioning, laparoscopic instruments	■ Securing the patient's position, use of OR table tilting, single port rotation, and usage of bariatric length instruments and camera are necessary for laparoscopic single-incision surgery.
Surgeon and assistant position	■ The surgeon should change his or her position in relation to the assistant several times during the procedure in order to achieve adequate exposure and visualization.
Laparoscopic instrument and tissue handling	■ The tip of the assisting and dominant laparoscopic instruments are positioned as close as possible to each other in the surgical field in order to avoid hand clustering outside the abdomen.

POSTOPERATIVE CARE

- A fast-track postoperative laparoscopic course is initiated.
- The orogastric tube is discontinued in the OR upon completion of the procedure.
- IV acetaminophen, alvimopan, and opioid patient-controlled anesthesia (PCA) or abdominal wall nerve block-"tap" is used as per surgeon's preference the day of surgery. Discontinue the PCA within 36 hours and add IV or oral nonsteroidal antiinflammatory drugs (NSAIDs) such as ketorolac to transition to oral analgesics.
- Ice chips/water sips is introduced the day of surgery with the goal to advance to clear liquids within 24 hours and to a regular high-fiber diet within 48 hours postoperatively.
- The Foley catheter is discontinued within 24 hours.
- Perioperative antibiotics, VTE protocol—mechanical and pharmacologic—as well as early ambulation is initiated within 24 hours of surgery.
- Incentive spirometer is initiated as per standard hospital policy.
- Wound care need is minimal: Remove the umbilical dressing 2 to 3 days postoperatively.
- The patient usually can be safely discharged home within 72 hours when passage of flatus is documented and regular diet is tolerated by at least two consecutive meals, and there are no other adverse postoperative findings such as signs of infection.
- There is no need to wait until the patient has a bowel movement prior to discharge.
- No weight lifting more than 20 lb is recommended for 4 to 6 weeks postoperatively in order to avoid incisional hernia.

OUTCOMES

- Single-port laparoscopic hemicolectomy is considered to be an equally safe and cost-effective technique with better cosmesis, similar morbidity and operative time, possible less postoperative pain and faster return to full activities, possible shorter hospital stay, and comparable oncologic outcomes when performed for neoplastic diseases to conventional hand-assisted or multiport laparoscopic approach.
- It is achieved with equipment that the hospital already has available, with the exception of the single port which is not reusable, and requires no additional training for the operative room personnel while it is reproducible by surgeons who perform advanced laparoscopy.
- It does require one assistant to the surgeon who has advanced laparoscopic skills.
- The laparoscopic single-incision right colectomy technique may contribute to decreased total hospital cost.

COMPLICATIONS

- The procedure has similar morbidity and mortality rates and comparable rates for conversion to laparotomy when compared to conventional laparoscopy.
- Anastomotic leak rate is less than 2%.
- The single-incision laparoscopic technique for right hemicolectomy has the option for conversion to multiport or hand-assisted laparoscopy.
- Because a larger sized laparoscopic port is used, there is a slight increase in the incidence of incisional hernia (1% or more) compared to multiport laparoscopy. However, the incisional hernia rates are similar to the ones in hand-assisted laparoscopy.
- Single-incision laparoscopy may require a longer operative time during the early learning curve. This can complicate an already challenging operation especially for hepatic flexure or proximal transverse colon neoplastic lesions.
- It is intrinsically a one-operating surgeon technique with less involvement of the assistant surgeon and with a potential negative impact on resident education during the learning curve period.

Chapter 13

Transverse Colectomy: Open Technique

Y. Nancy You

DEFINITION

- The transverse colon is the segment of the abdominal colon between the hepatic and the splenic flexures. The transverse colon is an intraperitoneal organ of variable length, bound by the two flexures, which are secondarily retroperitoneal areas of the colon typically fixed in position.
- The main blood supply to the transverse colon is the middle colic vessels. The transverse colon, with transverse mesocolon and middle colic vessels, lies in intimate proximity to the lesser sac, which is in turn bound by the quadrate lobe of the liver, the stomach, the pancreas, and the omentum. The operative surgeon must be fully familiar with these anatomic relations in order to avoid injury to these nearby structures.
- Transverse colectomy is a relatively uncommon procedure, as pathology in the proximal transverse colon is often addressed by an extended right hemicolectomy, whereas pathology in the distal transverse colon is often addressed by an extended left hemicolectomy.
- Indications for transverse colectomy may be broadly divided into benign and malignant reasons.
- Benign diseases with pathology focally located within the segment of the transverse colon represent the most natural indication for transverse colectomy. Examples may include focal inflammatory processes, localized trauma, or local perforation.
- Transverse colectomy for primary malignancies of the transverse colon has been controversial.[1] Because of the varying contributions to the lymphatic drainage of the transverse colon cancer from the ileocolic, the right colic, and the left colic blood vessels, extended right or extended left hemicolectomy has been preferred over segmental transverse colectomy for primary tumors of the transverse colon.[2]
- Transverse colectomy may be required as a part of a curative en bloc resection of a noncolonic malignancy arising from a nearby organ due to the close proximity of the transverse colon to other structures around the lesser sac. Surgeons must be cognizant of anatomic relations in order to safely carry out the intended operation.

DIFFERENTIAL DIAGNOSIS

- Endoscopic tissue biopsy is a key step in the diagnostic workup of patients with both benign and malignant diseases involving the transverse colon.
- In patients presenting with a locally advanced tumor mass that obliterates the lesser sac and involves adjacent organs such as the stomach, the pancreas, and the transverse colon, care must be undertaken to differentiate malignancies of the colonic origin versus those that arose from adjacent organs but involves the transverse colon secondarily. Tissue diagnosis by biopsy should be secured in order to execute the optimal treatment regimen according to the primary malignancy.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The goals of preoperative assessment should include determining whether urgent versus elective intervention is needed, facilitating intraoperative planning, and assessing the benefits versus risks toward a sound surgical decision.
- The patient should be examined for fitness to undergo an operation through a detailed assessment of patient's medical history, performance status, medication regimens, other medical needs, and psychosocial competency.
- Symptoms such as abdominal cramping, difficulty with passage of stool or flatus, bleeding, or severe pain should be queried. Conditions that would necessitate urgent/emergent rather than elective surgical intervention must be ruled out. Patients with an obstructing transverse colonic lesion and a competent ileocecal valve can rapidly develop a closed loop obstruction with high risks for ischemic colon and perforation and must be attended to emergently (**FIG 1**).
- Elements of prior surgical history that may present intraoperative difficulties such as previous stomach, pancreas, or colonic operations, and prior antecolic or retrocolic bowel bypass reconstructions, must be elicited. Prior operative reports should be obtained and reviewed.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- All patients should ideally undergo both abdominal–pelvic cross-sectional imaging as well as endoscopic examination with possible biopsies.

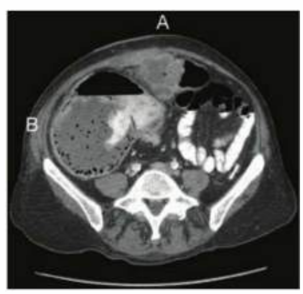

FIG 1 ● CT scan showing an obstructing transverse colonic lesion (*A*) in a patient with a competent ileocecal valve. Closed loop obstruction causes massive dilation of the cecum (*B*). The high risks for ischemia and perforation require emergent surgical intervention.

FIG 2 ● Colonoscopic view of a mass lesion in the transverse colon, which is recognized by the triangular shape of the bowel lumen and the anchoring splenic and hepatic flexures. Histologic diagnosis can be obtained by endoscopic biopsy of the mass.

- Endoscopic examination of the colon should be undertaken preoperatively to confirm the location and the focality of the pathology within the transverse colon (**FIG 2**).
  - Endoscopically, the transverse colon can be recognized by the triangular shape of the bowel lumen as well as by the anchoring landmarks of the splenic and hepatic flexures.
  - If there is any doubt as to whether the lesion will be able to be localized with confidence intraoperatively, then the lesion should be marked with endoscopic tattooing.
  - If there is any concern for involvement of adjacent organs, such as the stomach, an esophagogastroscopy should also be performed.[3]
- Cross-sectional imaging of the abdomen is performed through computed tomography (CT) or magnetic resonance imaging (MRI) scans. Imaging characteristics may supplement histologic data and aid in the differential diagnosis. In addition, percutaneous biopsy may be needed.
  - In cases of malignant disease, imaging will help differentiate between colonic and noncolonic origin of the disease.
  - Presence of distant metastatic disease and evidence of direct local invasion to adjacent organs should be assessed and appropriate intraoperative management plans should be made.
  - Finally, any abnormal-appearing adenopathy along vessels other than the middle colic vascular should be specifically assessed in order to determine whether the particular malignancy would be better managed through an extended right or extended left colectomy rather than a transverse colectomy.

SURGICAL MANAGEMENT

- Thorough preoperative preparation, confirming that the diagnosis is correct, the indication is appropriate, and that possible intraoperative findings have been anticipated and planned for, is the basis for successful intraoperative management and the speedy postoperative recovery.

Preoperative Planning

- The operative surgeon should thoroughly review the patient's history and diagnostic workup to minimize any unexpected and unplanned for intraoperative finding.
- Diagnostic biopsy and histologic results should be verified. A malignant diagnosis should be particularly noted in order to help determine the extent of the bowel resection and lymphadenectomy.
- Documentation from preoperative endoscopy should be reviewed, particularly if the operative surgeon did not perform the procedure. The presence and location of a marking tattoo should be confirmed.
- Preoperative imaging is used to help anticipate any involvement of the adjacent organs and the possible need for en bloc resection intraoperatively. Any need for additional technical assistance from other surgeons should be planned for.
- In cases of perforation and anticipated significant intraperitoneal contamination that may render bowel anastomosis unsafe, plans should be made for ostomy marking and education preoperatively.
- Preoperative bowel preparation, whether antimicrobial and mechanical, mechanical only, or no preparation, is a highly variable practice and is left to the discretion of the practicing surgeon.
- Prophylactic intravenous antibiotics with coverage against gram-positive, gram-negative, and anaerobic flora of the skin and gut are typically administered prior to incision and continued for the first 24 hours.
- Prophylaxis against deep venous thrombosis is typically administered prior to incision and during the hospital stay.

Positioning

- Patients are usually placed in a supine position. If there is any possibility of extending the resection to the left colon or any possible need for intraoperative endoscopy, consideration should be given for placing the patient in lithotomy position.

INCISION AND ABDOMINAL EXPLORATION

- A midline incision extending from the epigastrium to below the umbilicus is made.
- The abdominal cavity is explored for the presence of other pathology not identified by preoperative imaging. In cases of malignant disease, peritoneal lining, omentum, and hepatic and bowel surfaces are inspected and palpated for any evidence of metastatic disease. In women, the pelvic organs, including the ovaries, should be inspected. Any suspicious nodule should be biopsied for pathologic assessment as findings may affect the decision of proceeding to the remaining of the procedure.

OMENTUM DISSECTION AND EXPOSURE OF THE LESSER SAC

- The relationship between the transverse colon pathology and the lesser sac is assessed.
- Exposure to the lesser sac is gained in one of two ways, depending on whether omentectomy is performed or not.
- If disease pathology does not necessitate en bloc omentectomy or if there is desire to preserve as much of the omentum as possible, then greater omentum is retracted cephalad and the transverse colon is retracted caudad. This reveals the avascular plane between the greater omentum and the transverse mesocolon (**FIG 3**). The pale yellow omental fat is distinguished from the fat of the appendices epiploicae of the transverse colon (**FIG 4**). As this plane is dissected, the greater omentum is freed from the transverse colon and mesocolon and entrance into the lesser sac is gained. This can be confirmed by visualization of the posterior wall of the stomach dorsally and of the anterior surfaces of the duodenum, pancreas, and transverse mesocolon ventrally.
- If the disease pathology necessitates en bloc resection of part or all of the omentum, then the gastrocolic ligament should be divided. The gastroepiploic artery arcade is identified along the greater curvature of the stomach. Dissection of the omentum is carried out either proximal (inside of) or distal (outside of) the arcade depending on the extent of the disease, the surgeon preference, and the desire to preserve the gastroepiploic arcade (**FIG 5**). The deeper avascular plane of the lesser sac, deep to the omentum but superficial to the transverse mesocolon, is entered. The omentum is thus isolated and divided between clamps.

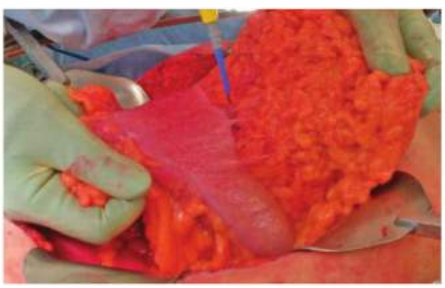

FIG 3 ● Retracting the greater omentum cephalad and the transverse colon caudad helps reveal the avascular plane between the greater omentum and the transverse mesocolon.

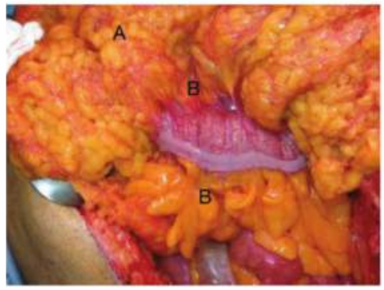

FIG 4 ● The pale yellow cobblestone fat of the omentum (*A*) is distinguished from the bright yellow smooth fat of the appendices epiploicae of the transverse colon (*B*).

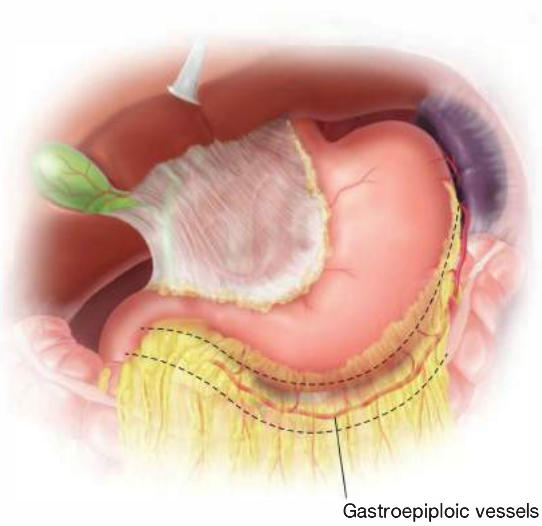

FIG 5 ● Dissection of the omentum is carried out either proximal (inside of) or distal (outside of) the gastroepiploic artery arcade *(dotted lines)* depending on the extent of the disease, surgeon preferences, and the desire to preserve the gastroepiploic arcade.

MOBILIZATION OF THE HEPATIC FLEXURE AND THE SPLENIC FLEXURE

- In order to gain enough mobility of the colon for intraoperative manipulation and to allow for a tension-free anastomosis after resection, it is often necessary to mobilize one or both of the flexures.[4]
- To mobilize the hepatic flexure, attention is turned to the ascending colon. The colon was retracted medially to identify the peritoneal reflection (white line of Toldt). The covering peritoneum of the paracolic gutter is then incised and divided using electrocautery. This avascular tissue plane is followed in a lateral to medial fashion, separating the colonic mesentery from

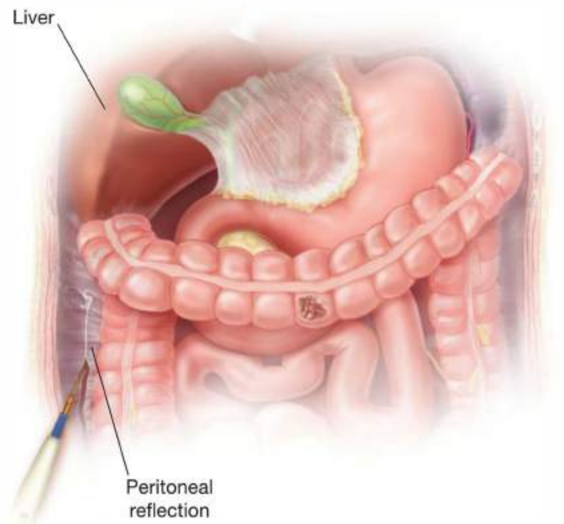

FIG 6 ● Anatomic relations for mobilization of the hepatic flexure: The ascending colon is retracted medially to identify the lateral peritoneal reflection (white line of Toldt); the covering peritoneum is divided to free the hepatic flexure. The hepatic surface, the gallbladder, the duodenum, and the anterior pancreas' surface are in close proximity, and care must be taken to avoid injury to these organs.

the retroperitoneum. This dissection plane is then carried cephalad toward the hepatic flexure, where division of the lateral peritoneal attachments will free the hepatic flexure. As the dissection is carried medially, care must be taken to avoid injury to the retroperitoneal duodenum (**FIG 6**). At this time, this dissection plane should be joined with prior dissection plane of the omentum so that communication to the lesser sac is established.

- To mobilize the splenic flexure, attention is turned to the descending colon. The descending colon is retracted medically to identify the lateral peritoneal attachments in a similar fashion as described in the mobilization of the ascending colon above. The avascular tissue plane is similarly followed and carried cephalad toward the splenic flexure (**FIG 7**). The splenocolic ligament is encountered in this process and divided using electrocautery. As the lower pole of the spleen comes into view, care should be taken to divide any adhesion between the omentum and the capsule as to avoid unintended capsular tears with retraction and dissection. Often, numerous adhesions between the omentum and the appendices epiploicae of the colon are encountered, and care must be taken to separate these either by electrocautery or between clamps to avoid bleeding. Finally, additional avascular ligaments to the stomach and/or the pancreas may be encountered and should be divided. After this, entry into the lesser sac is gained.

FIG 7 ● Mobilization of the splenic flexure. The splenic flexure of the colon (*A*) is retracted medially to identify and release the lateral peritoneal attachments. Care is taken to avoid injury to the spleen (*B*). The renocolic ligament (*C*), the splenocolic ligament (*D*), and the gastrocolic ligament (*E*) are identified and subsequently divided. This allows entry into the lesser sac and frees the distal transverse colon and splenic flexure from posterior retroperitoneal attachments.

The distal transverse colon and splenic flexure are now completely free of posterior retroperitoneal attachments and are fully mobile.

- After completing the dissections outlined in this step, the lesser sac is exposed completely, and the anterior surfaces of the transverse mesocolon should be in full view (**FIG 8**).

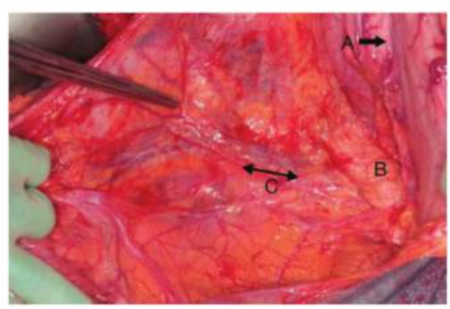

FIG 8 ● After the lesser sac is exposed completely, posterior wall of the stomach (*A*) and anterior surface of the pancreas (*B*) are visualized. The anterior surfaces of the transverse mesocolon with middle colic vessels (*C*) should be in full view.

ISOLATION AND DIVISION OF THE MIDDLE COLIC VESSELS

- The anatomy of the middle colic artery can be highly variable, and often, it does not present as a single vessel.
- The middle colic vessels can usually be identified by visual inspection or palpation along the transverse mesocolon via the lesser sac (**FIG 9**). When proximal ligation is needed, as is in the case for malignant disease, the overlying peritoneum is scored and the vessels should be dissected up to the lower border of the pancreas and ligated at this location (**FIG 9**). Care should be taken to avoid avulsion injury to the smaller collateral venous branches from the pancreaticoduodenal arcade and to avoid clamp injury to the pancreatic parenchyma. When the root of the middle colic vessels is identified, the surrounding nodal-bearing mesenteric tissue should be swept toward the specimen side. The vessels can then be isolated and controlled with suture ligature.
- If the middle colic vessels and the lesser sac are involved by the disease pathology and/or obliterated, then the middle colic vessels can be approached from the root of the small bowel mesentery. After the transverse mesocolon is retracted cephalad, the root of the mesentery is exposed. The overlying peritoneum is scored and dissected away to expose the anterior surface of the superior mesenteric artery.[5] The superior mesenteric artery is followed cephalad until the middle colic branches off, and the origin of the middle colic vessels can be isolated at this location (**FIG 10**). Extreme care must be undertaken to prevent injury to the underlying superior mesenteric vessels.

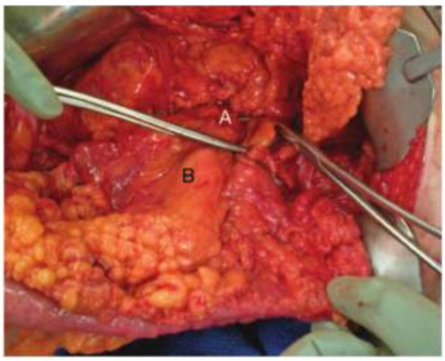

FIG 9 ● The middle colic vessels (*A*) are identified in the transverse mesocolon (*B*) and then dissected and taken between clamps. When proximal ligation of the middle colic vessel is required, the vessels are transected at the inferior border of the pancreas.

FIG 10 ● At the root of the small bowel mesentery, superior mesenteric artery (*A*) is followed cephalad until the middle colic branches off (*B*).

BOWEL RESECTION AND ANASTOMOSIS

- After division of the middle colic vessels, the blood supply to the transverse colon is maintained by the marginal artery, which can be found along the entire colon.
- The length of the bowel resection is determined by the extent of disease pathology and by the extent of the vascular supply. In cases of benign inflammatory disease, a margin of normal, healthy colon should be present for reanastomosis. In cases of primary malignancy of the transverse colon, a minimum gross negative margin of 5 cm proximal and distal to the tumor should be present.
- Once the points of proximal and distal bowel resection are identified, the presence of pulsatile blood supply to the cut ends via the marginal artery should be verified. If adequate blood supply cannot be confirmed, the length of the resection must be extended to points where blood supply is present.
- In most cases, bowel continuity is immediately reestablished. However, in cases of gross peritoneal contamination, gross inflammation, grave systemic illness, and others, the safety of a bowel anastomosis may be questioned, and creation of an end colostomy with either a mucous fistula or a long distal blind limb may be wise. A second-stage procedure can be performed for delayed reanastomosis.
- Once the decision for immediate bowel anastomosis is made, the mesenteric orientation is checked to ensure that there is no twisting.
- The bowel anastomosis can be performed in a variety of ways, depending on the surgeon's preference. The most common methods include a hand-sewn end-to-end technique or a stapled side-to-side (functional end-to-end) technique.
  - Using the hand-sewn technique, the divided ends of the colon are aligned end-to-end. The anastomosis is created in two layers, with an outer layer

of interrupted sutures placed into the seromuscular layer of the bowel wall and an inner layer of running suture placed full thickness, incorporating the bowel mucosa (**FIG 11**).

- In the stapled technique, the ends of the bowel are divided with a linear stapler. These divided ends of the colon are then aligned side-to-side. Small enterotomies are made typically by excising a corner off each staple line, allowing the jaws of the linear stapler to be inserted and the stapler to be fired (**FIG 12**). The area of the enterotomy through which the stapler has been inserted is then closed either by sutures or by a second firing of the stapler. Staple lines are inspected for hemostasis. Areas of crossing staple lines may be imbricated with interrupted suture in a Lambert fashion.
- If there is well-vascularized omentum nearby, it may be patched over the anastomosis to help future contain any anastomotic leakage postoperatively.

- The size of the mesenteric defect between the right and left colon should be assessed. Small- and moderate-sized defects should be closed to prevent internal hernia and any mesenteric twisting. Typically, if the middle colic vessels had been ligated at their origins, the defect is large and closure is not necessary.

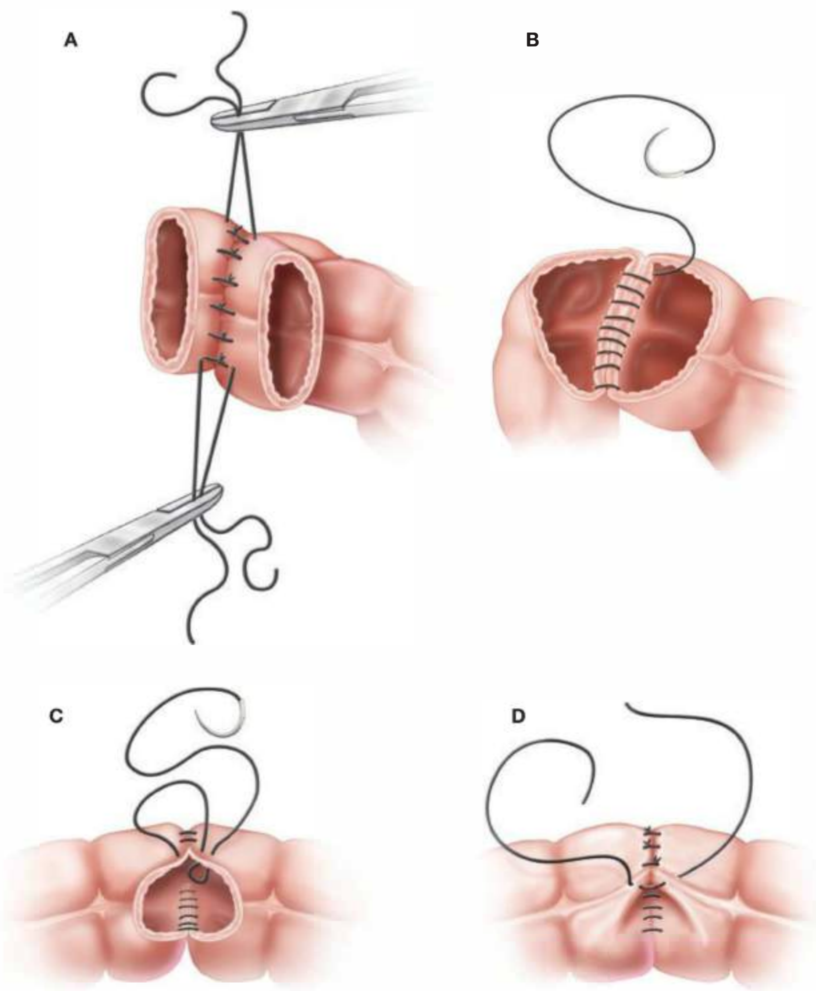

FIG 11 ● In a hand-sewn end-to-end colocolonic anastomosis, the divided ends of the colon are aligned **(A)**; the anastomosis is typically created in two layers, with an outer layer of interrupted sutures and an inner layer of running suture **(B–D)**.

FIG 12 ● In a stapled side-to-side (functional end-to-end) colocolonic anastomosis, the ends of the bowel are aligned side-to-side. Small enterotomies are made by excising a corner off each staple line, allowing the jaws of the linear stapler to be inserted into each lumen. The stapler is fired.

ABDOMINAL CLOSURE

- The abdominal fascia is closed after placing any remaining omentum between the bowel loops and the incision if possible. The skin incision is closed using absorbable subcuticular suture or staples. Abdominal drain is not placed.

PEARLS AND PITFALLS

Diagnostic and preoperative assessments	■ Any pathology outside of the transverse colon, transverse mesocolon, and middle colic vessels should be assessed on preoperative imaging, and an extended right or an extended left hemicolectomy should be performed if necessary. ■ In patients presenting with a large tumor mass, anatomic relations to the pancreas, duodenum, stomach, and mesenteric vessels should be carefully accessed. ■ Endoscopic and/or percutaneous tissue biopsy should be obtained to help differentiate malignancies of colonic versus noncolonic origin to allow for optimal treatment planning. ■ Patients presenting with an obstructing transverse colonic lesion and a competent ileocecal valve require emergent surgical attention to avoid perforation secondary to a closed loop large bowel obstruction. ■ The potential need for an ostomy in cases where bowel anastomosis may not be safe should be anticipated to allow for preoperative ostomy marking and education.
Omental dissection and exposure of the lesser sac	■ Exposure to the lesser sac can be gained with or without an omentectomy. ■ The pale granular yellow of the omental fat can be distinguished from the bright, smooth yellow of the fat of the colonic appendices epiploicae to help identify the avascular dissection plane.
Mobilization of the hepatic and/or splenic flexure	■ The surgeon should not hesitate to mobilize either or both of the flexures, as it often greatly facilitates intraoperative manipulation and facilitates a tension-free bowel anastomosis.
Isolation and ligation of the middle colic vessels	■ When the root of the middle colic vessels is approached through the lesser sac, injury to the small veins at the inferior border of the pancreas should be avoided. ■ When the root of the middle colic vessels is approached from the root of the small bowel mesentery, injury to the superior mesenteric vessels should be avoided.
Bowel resection and anastomosis	■ A transverse colectomy can be easily converted to an extended right or an extended left hemicolectomy if needed by intraoperative findings. ■ In some cases, immediate bowel anastomosis may not be safe, and an end colostomy can be made with either a mucous fistula or a long distal blind limb for delayed reanastomosis.

POSTOPERATIVE CARE

- Patients should receive routine postoperative care including adequate analgesia, aggressive pulmonary toilet, and early ambulation.
- Patients are typically kept on no more than a clear liquid diet the night of the operation in case there is a need for any emergency intervention and then advanced to a soft diet by the time of discharge.
- An occasional patient may experience diarrhea, which requires initiation of medicinal fiber and/or Imodium for symptom control.

OUTCOMES

- Patients generally tolerate a transverse colectomy well. The risk of anastomotic complications requiring reoperation is less than 5%, and a colostomy is not routinely required.
- Leakage from the colocolonic anastomosis may manifest as peritonitis, colocutaneous fistula, or localized intraperitoneal abscess.
  - Patients with clinical signs of sepsis and peritonitis should be managed by prompt return to the operation for reexploration, washout, resection of the prior anastomosis, and creation of end colostomy and mucous fistula.
  - Localized abscesses may collect in the subhepatic, subphrenic, and lesser sac spaces. The diagnosis can be made by CT of the abdomen, and clinically stable patients may be managed by percutaneous drainage.
- Superficial wound infection occurs in 10% to 15% of the cases and should be managed by incision and drainage of any subcutaneous abscess.
- Transverse colectomy is not expected to significantly alter bowel function postoperatively.[6] Although some patients may experience more frequent and looser stools during the immediate postoperative period, most patients reported an average of 1 to 2 stools per day and adapt to a normal bowel regimen over 6 to 12 months.

COMPLICATIONS

- Bleeding
- Wound infection
- Anastomotic leak
- Intraabdominal abscess
- Poor bowel function

Chapter 14

Laparoscopic Transverse Colectomy

Govind Nandakumar   Sang W. Lee

DEFINITION

- Transverse colectomy refers to removal of the portion of the colon between the hepatic flexure and the splenic flexure—the transverse colon. This portion of the colon derives its blood supply from the right and left branch of the middle colic vessels in addition to collateral flow from the ileocolic, right colic, and left colic vessels. Transverse colectomy is commonly performed for tumors and/or polyps of this region. An alternative approach to these tumors is to perform an extended right or extended left colectomy. This chapter focuses on laparoscopic transverse colectomy.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A complete history and physical focusing on the underlying pathology is essential. For patients with colon cancer and/or polyps, a detailed surgical history, personal cancer history, and family history is essential.
- Preoperative genetic counseling and testing may be indicated based on age and family history.
- Presence of an inherited cancer syndrome such as familial adenomatous polyposis or hereditary nonpolyposis colon cancer syndrome may require a total colectomy rather than a transverse colectomy.
- Prior abdominal surgery, distension, and obstruction are important to elicit in the history and physical examination prior to making a decision regarding open versus laparoscopic approach.
- History or physical examination suggestive of focal abdominal pain and tenderness are suggestive of abdominal wall invasion and more extensive or open surgical approach may be needed.
- History and physical examination should also evaluate the cardiovascular and respiratory systems to assess the ability to tolerate pneumoperitoneum.
- Nutritional status and recent history of major weight loss should be considered in performing primary anastomosis.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- All patients with colon cancer and/or a polyp should have a complete extent of disease workup including carcinoembryonic antigen (CEA), computed tomography (CT) of the abdomen and pelvic, chest X-ray, colonoscopy, and routine preoperative testing.
- The CT should be reviewed carefully to assess adjacent organ involvement, metastatic disease, and obstructive disease.
- Laparoscopic approach may not be feasible in the presence of massive distension and obstruction.
- Large bulky tumors with a tethered mesentery or adjacent organ involvement may also preclude laparoscopy.
- Colonoscopy and evaluation of the entire colon is important to ensure there are no synchronous lesions proximal or distal to the area of resection.
- For small nonobstructing lesions, endoscopic tattoo marking should be performed prior to surgery.
- Endoscopic tattooing should be performed just distal to the tumor and in three quadrants.
- In general, tumors that are identified on CT scan can be readily identified laparoscopically and do not require a tattoo.

SURGICAL MANAGEMENT

Preoperative Planning

- The patient receives a mechanical bowel preparation to facilitate handling of the colon and to facilitate intraoperative colonoscopy if required. The need for bowel preparation is controversial. The consequences of a leak may be more significant without preparation. Laparoscopic handling of the colon is easier after mechanical bowel preparation.
- The patient is seen and evaluated by the surgical and anesthesia teams in the preoperative area on the day of surgery.
- Most patients are offered and elect to have an epidural or intravenous catheter for patient-controlled anesthesia.
- A second- or third-generation cephalosporin or ertapenem is used for antibiotic prophylaxis within 1 hour of skin incision and redosed as needed. No antibiotics are administered postoperatively.
- Venodyne boots and 5,000 units of subcutaneous heparin are used for deep vein thrombosis prophylaxis.

Positioning

- The patient is positioned in a modified lithotomy position with both arms tucked to the sides. It is essential to ensure that all pressure points, fingers, and calves are padded adequately.
- Use of a beanbag and cloth tape allows extreme positioning with decrease in possibility of patient sliding.
- Alternatively, use of gel pads commonly available in the operating room (OR) makes routine taping of patient not necessary.
- Use of shoulder braces should be avoided as they can cause brachial plexus injury.
- Prior to draping, the patient is placed in steep Trendelenburg and the table is rotated to ensure that the patient is secured well.
- It is essential to ensure that both knees are in line with the torso in order to avoid collision of instruments to patient's thighs when working in the upper quadrants of the abdomen. The abdomen is prepped from the nipples to the midthigh.
- Access to the anus is always maintained for possible intraoperative colonoscopy.
- **FIG 1** (laparoscopic setup) shows the OR setup for this procedure. Monitors are placed over the shoulders of the patient so that the surgeon, pathology, and monitors are situated in line.

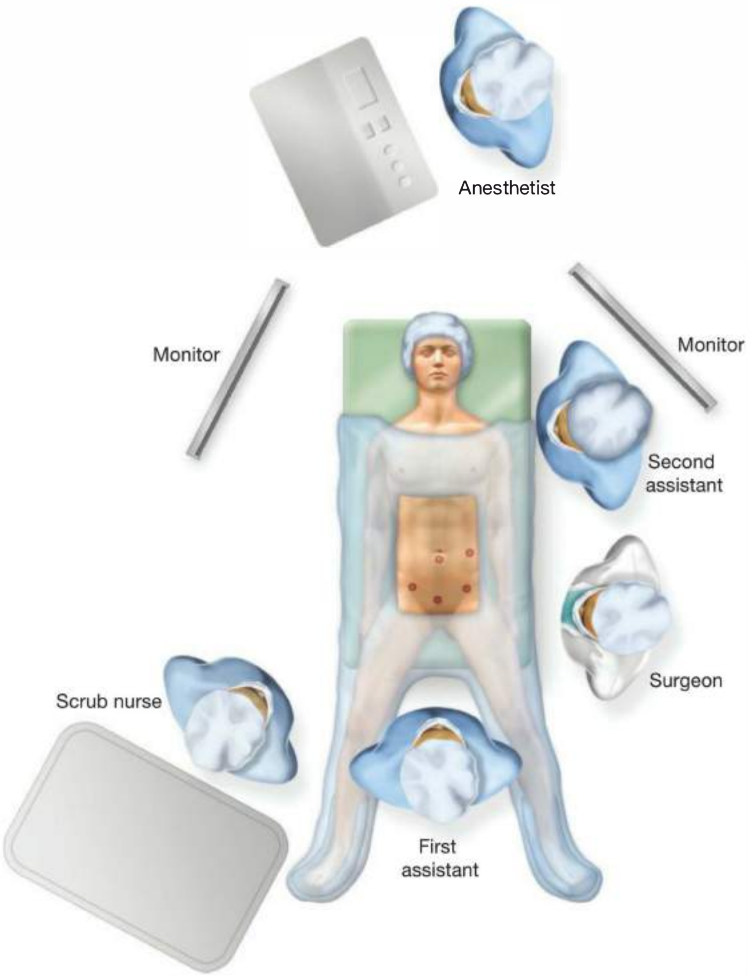

FIG 1 ● Illustrates the patient setup. A modified lithotomy position allows the surgeon or assistant to stand between the legs and to have access to the anus for intraoperative colonoscopy.

SKIN INCISIONS

- A Hasson technique is used to achieve access to the abdomen at the umbilicus.
- Four 5-mm trocars are placed—two on either side of the abdomen lateral to the rectus with one hand breadth between the trocars. An optional fifth trocar can be placed in the suprapubic area if required for retraction. **FIG 2** (trocars) shows the typical trocar placement.

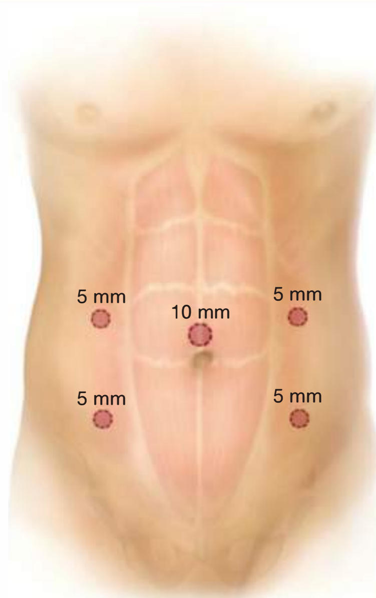

FIG 2 ● We use this standard configuration of trocar placement for the majority of laparoscopic colon and rectal operations.

LAPAROSCOPIC EXPLORATION

- The abdomen is systematically explored in all four quadrants to look for metastatic disease and/or unexpected pathology.
- Knowledge of the mesenteric anatomy is essential for a successful laparoscopic approach.
- **FIG 3** (colon anatomy) shows the colon with its major vascular pedicles. Also depicted is the gastrocolic trunk of Henle that can be a source of bleeding if not recognized during the dissection.
- The right colic vessels commonly originate from the ileocolics (85%).
- The middle colic arteries commonly have more than two branches (55%).

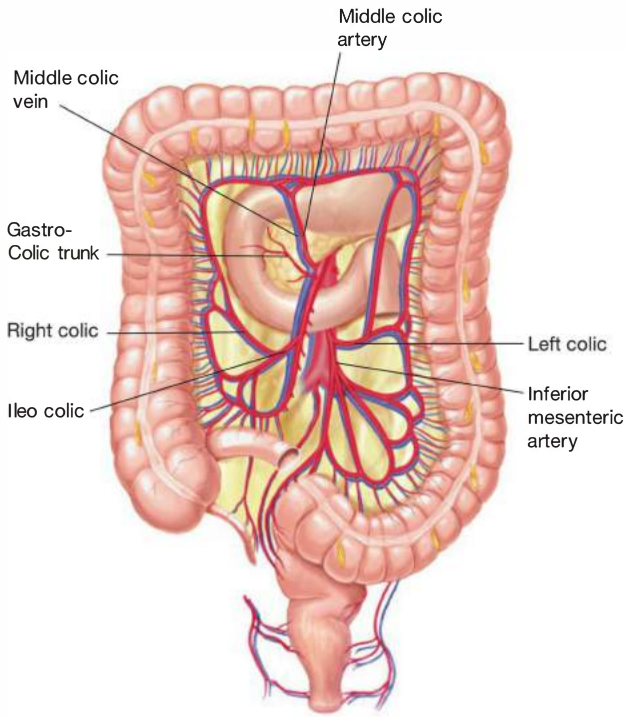

FIG 3 ● Shows the major vascular pedicles to the colon and the marginal artery that maintains collateral circulation.

PEDICLE LIGATION

- The ileocolic, middle colic, and left colic vessels are first identified (**FIG 4**). Identification of the vascular pedicles is facilitated by traction on the colon to tent the mesentery. Adequate exposure is achieved by grasping each flexure and retracting superiorly and laterally (**FIG 5**).
- A window is created in the colon mesentery between the ileocolic and middle colic vessels. With appropriate traction and countertraction, the retromesenteric dissection is continued superiorly, medially, and laterally into the lesser sac (**FIG 6**).
- Care is taken to protect the duodenum, head of the pancreas, and the superior mesenteric artery (SMA) and vein during the dissection.
- The middle colic vessels can be divided at the common trunk or divided individually after bifurcation (**FIG 7**). There is significant variation in the anatomy of the middle colic trunk.
- Our practice is to use a bipolar vessel-sealing device to divide the pedicles, but clips and staplers are also options to divide the pedicles. It is important to ensure that the SMA and vein are protected and that sufficient cuff of the vascular pedicle is retained to control bleeding should the vessel sealers fail.
- Strong anterior traction on the transverse colon mesentery optimizes middle colic dissection and decreases the likelihood of inadvertent injury to SMA.

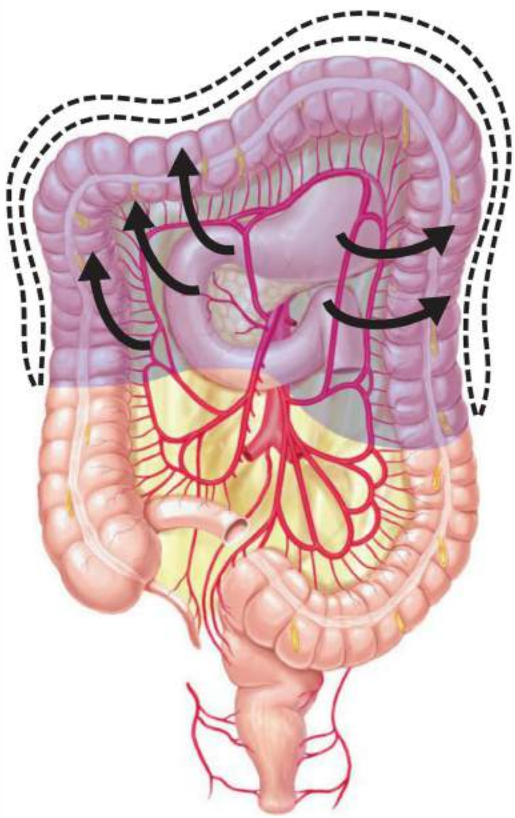

FIG 4 ● Appropriate traction on the colon in the direction of the *arrows* exposes the mesentery and allows for identification of the major vascular pedicles.

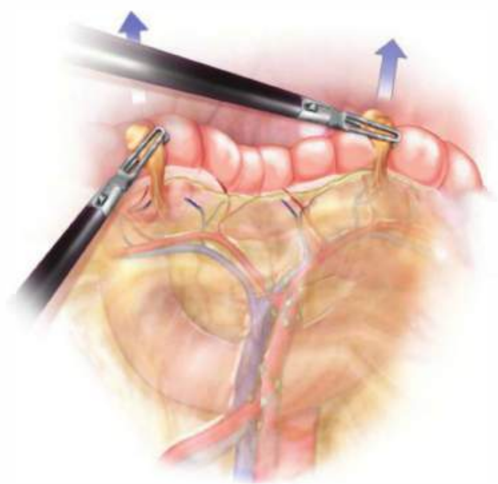

FIG 5 ● Cephalad and lateral traction is used to visualize the middle colic vessels.

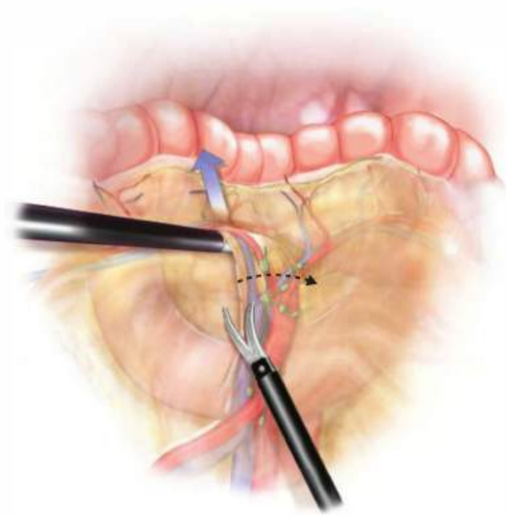

FIG 6 ● A window is created to the right of the middle colic vessels.

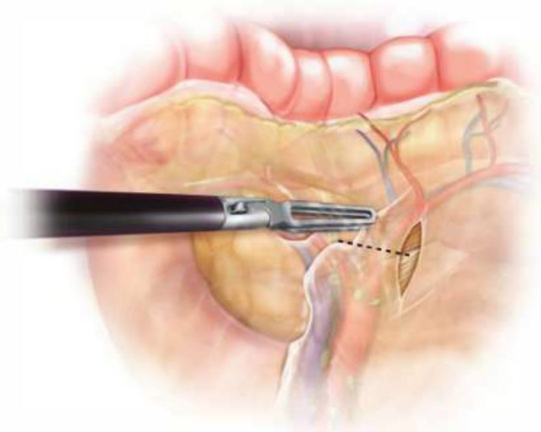

FIG 7 ● After adequate mobilization and protecting the duodenum and pancreas, the middle colic vessels are divided.

RETROMESENTERIC DISSECTION

- Right retromesenteric dissection
  - Laterally, the dissection is carried to the white line of Toldt and the hepatic flexure (**FIG 8**).
  - Medially, the dissection is carried to the root of the middle colic vessels and anterior to the head of the

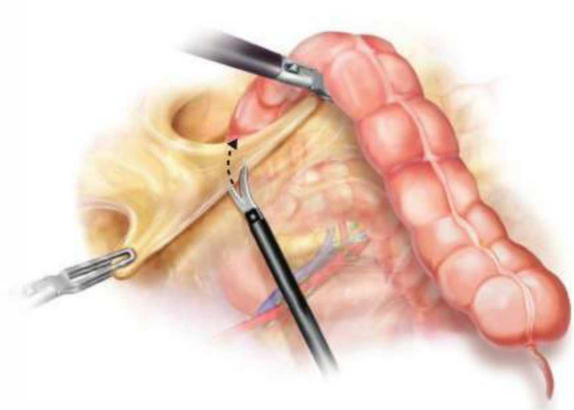

FIG 8 ● The lateral attachments of the colon are taken down, ensuring there is no thermal injury to the bowel.

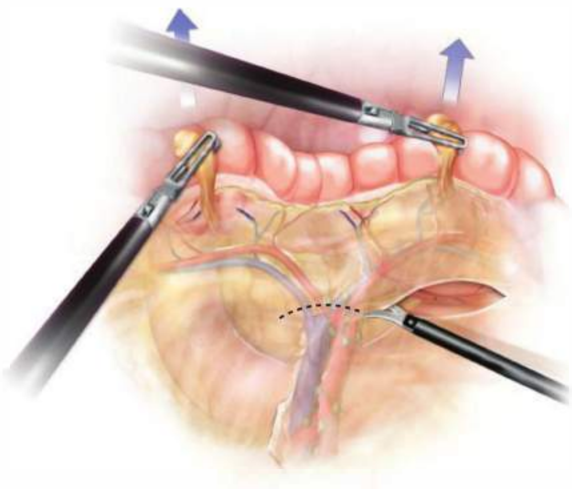

FIG 9 ● Dissection of the middle colic vessels.

pancreas and the duodenum (**FIG 9**). The gastrocolic venous trunk is often encountered during this dissection and can be a source of bleeding if not recognized and controlled (**FIG 10**).

- Superiorly, the dissection is carried cephalad to the transverse colon wall.
- The remaining attachments to the liver are taken down (**FIG 11**).

- Left retromesenteric dissection
  - A similar dissection is carried out on the left side, creating a window between the left colic and middle colic vessels (**FIG 7**).

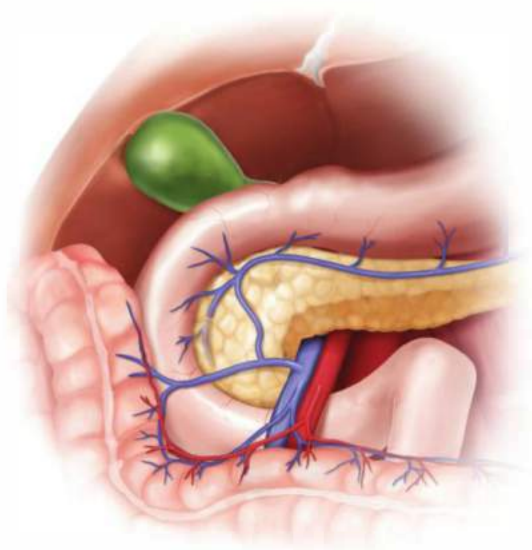

FIG 10 ● Early identification and control of the gastrocolic trunk prevents bleeding and injury to the superior mesenteric vein.

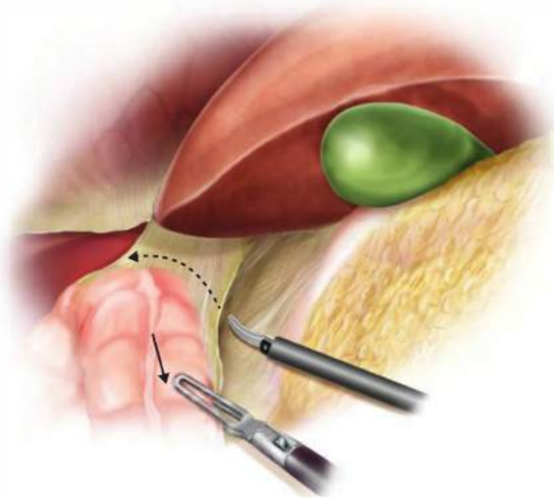

FIG 11 ● Remaining attachments of the hepatic flexure of the colon to the liver are taken down. The dissection is facilitated by working close to the colon.

  - Laterally, the dissection is carried to the white line of Toldt and the splenic flexure of the colon (**FIG 12**).
  - Medially, the dissection is carried to the root of the middle colic vessels.
- Superiorly, the dissection is carried to the inferior border of the pancreas and continued along the avascular plain between the left colon mesentery and the tail of the pancreas (**FIG 13**).
- At this point, the colon mesentery should be completely mobilized. The transverse colon is only held by the lateral attachments, the omentum, and the pedicles.

FIG 12 ● Splenic flexure mobilization requires takedown of the splenocolic ligament.

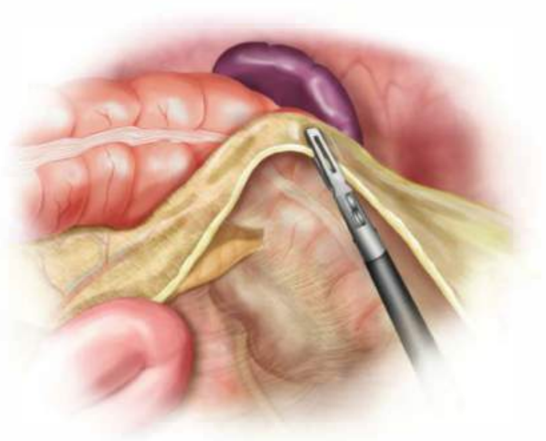

FIG 13 ● To achieve adequate mobilization, the posterior attachments along the inferior border of the pancreas need to be dissected with entry into the lesser sac.

RELEASE OF LATERAL ATTACHMENTS AND THE OMENTUM

- The omentum is next taken off the transverse colon (FIG 14). The lateral attachments are taken down on both sides. The dissection should be started in the midtransverse colon where the two leaves of the greater omentum are fused together. Visualization of the posterior wall of the stomach ensures that the surgical dissection is in the proper plane into the lesser sac. It is important to protect the colon from thermal injury during this portion of the dissection.

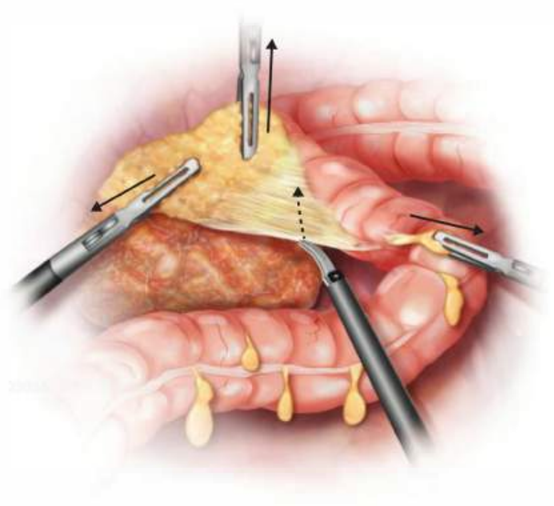

FIG 14 ● The omentum is dissected off the transverse colon. The omentum is left on the colon around the tumor to ensure an en bloc resection. Early entry into the lesser sac and identification of the posterior wall of the stomach facilitates an efficient dissection.

- In addition to mobilizing the transverse colon, the right colon, with the hepatic flexure, and the left colon, with the splenic flexure, need to be fully mobilized. This will allow for specimen extraction and the creation of a tension-free anastomosis (FIG 15).

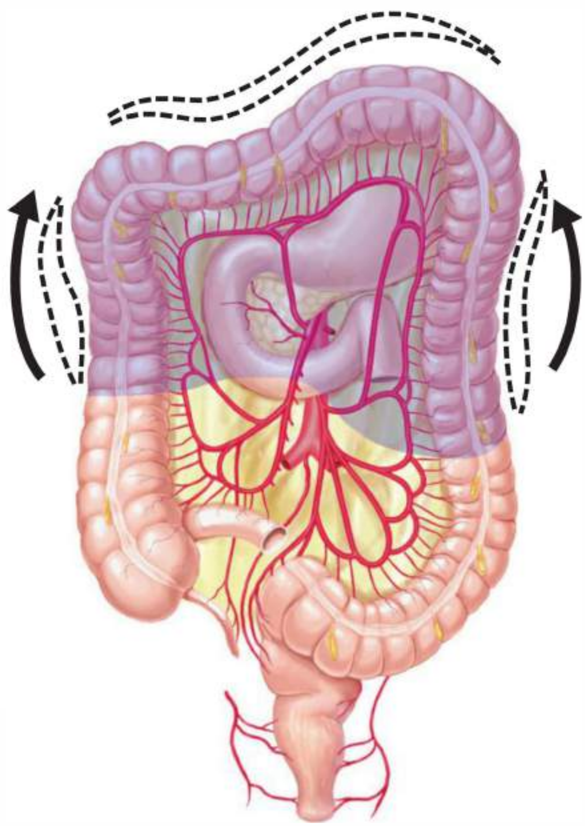

FIG 15 ● Complete mobilization of the hepatic and splenic flexures allows for safe specimen extraction and tension-free anastomosis.

SPECIMEN EXTERIORIZATION AND ANASTOMOSIS

- The periumbilical incision is commonly extended as an extraction site and a wound protector is placed (**FIG 16**).
- The mobilized transverse colon is exteriorized. Any remaining mesentery is divided.
- A linear stapler is used to divide the colon proximal to the hepatic flexure and distal to the splenic flexure as shown (**FIG 16**).
- The specimen is either sent for gross examination or opened in the OR to ensure that adequate margins (5 cm for cancer) were obtained.
- If the lesion is located laterally, additional pedicles can be taken as needed.
- A side-to-side functional end-to-end stapled anastomosis or a hand-sewn anastomosis can be fashioned based on the preference of the surgeon (**FIG 17**).
- The colon is replaced in the peritoneal cavity, and the operative area is examined for hemostasis.
- If there is concern for bleeding, the pneumoperitoneum can be reestablished prior to closure.
- Routine closure of the colonic mesenteric defect is not necessary as complications are minimal.[1]
- The extraction site fascia is closed, the trocars are removed under direct visualization, and the skin is closed.

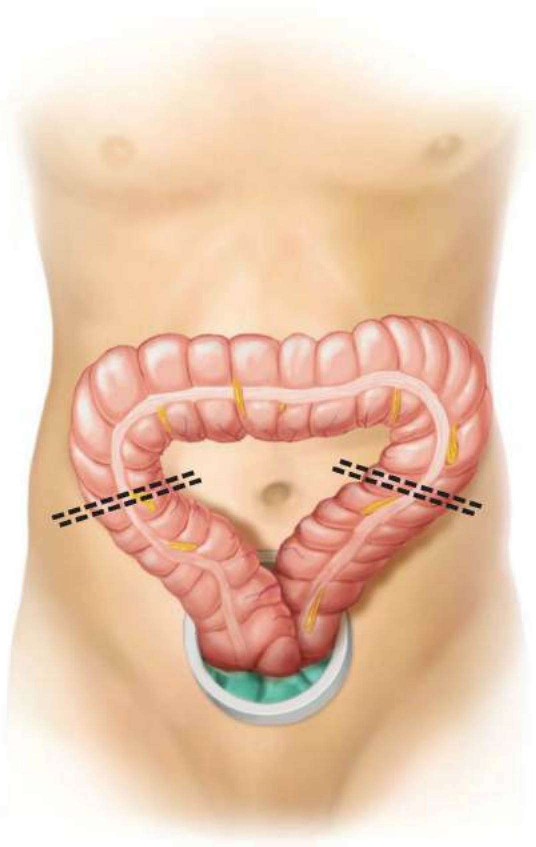

FIG 16 ● Periumbilical incision with wound protector to extract specimen.

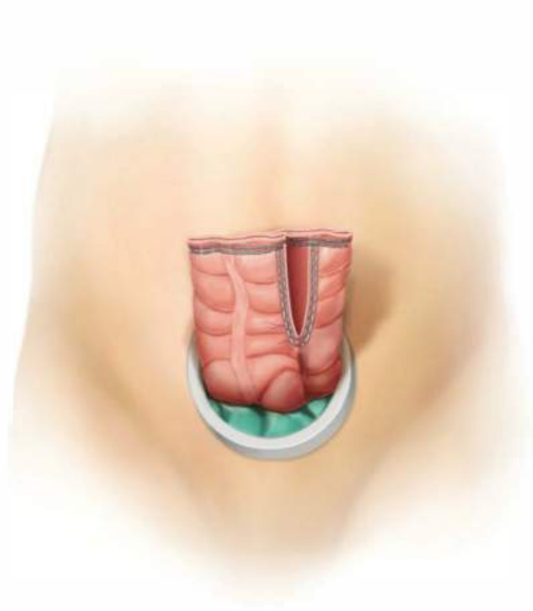

FIG 17 ● Side-to-side functional end-to-end stapled anastomosis through a wound protector is illustrated.

PEARLS AND PITFALLS

Indications	■ Extended right or left colectomies may be more appropriate for tumors located closer to the flexures. ■ Laparoscopy may not be feasible in obstructing tumors with massive bowel distension or tumors with extensive local invasion. History of prior surgeries is not a contraindication to laparoscopy.
Placement of incisions (trocars)	■ Lateral to the rectus and at least 7–8 cm between each trocar to avoid clashing of instruments. ■ The extraction incision is usually at or superior to the umbilicus.
Positioning	■ Thighs should be parallel to the floor and knees in line with the torso to prevent collision of the instruments with the knees.

Laparoscopic retraction, manipulation, and dissection	▪ Care should be taken when dissecting over the pancreas to avoid causing bleeding from the gastrocolic venous trunk of Henle. ▪ The superior mesenteric artery and vein should be protected during vessel ligation. ▪ Bipolar energy devices may not be effective in sealing calcified vessels. Endoloops should be available to control unexpected bleeding. ▪ Vessel-sealing devices can lead to lateral spread of thermal energy, and the colon should be protected during dissection. ▪ Intraoperative colonoscopy is useful if the exact location of the tumor is unclear. ▪ A hand access port can serve as a useful adjunct to complete difficult and challenging dissections.
Anastomosis	▪ Complete mobilization of both flexures is essential for a tension-free anastomosis. ▪ Inadequate mobilization of the splenic flexure can lead to traction injury of the spleen. ▪ In cases where there is tension, an extended right colectomy is safer as the small bowel is freely mobile. ▪ A wound protector is useful in minimizing contamination and limiting the length of the extraction incision.

POSTOPERATIVE CARE

- The patient is sent to the postsurgical unit and is usually given sips after recovery from anesthesia. Diet is advanced on postoperative day 1 to clear liquids and solids after passing flatus.
- The Foley catheter is removed on day 1 and oral pain medications started once the patient tolerates solid food.
- The patient is usually discharged on day 3 or 4 when the patient is on oral pain medications, tolerating a diet, and passing flatus.

OUTCOMES

- Large multicenter randomized trials have validated the oncologic safety and potential short-term benefits of laparoscopic surgery for colon cancer.[2,3] Transverse colon cancers were not included in these major trials.
- Smaller retrospective studies have concluded that the oncologic outcomes for laparoscopic treatment of transverse colon cancer are equivalent to the open approach. They also reported some potential short-term benefits.[4–6]
- There is limited data on laparoscopic transverse colectomy for benign lesions.
- Laparoscopic transverse colectomy is technically challenging and may carry a higher incidence of conversion to open surgery during the procedure.[7]
- This procedure is best performed by surgeons experienced with open resections of the transverse colon and those with significant laparoscopic colorectal experience.

COMPLICATIONS

- Bleeding
  - A medial to lateral dissection approach allows early identification and control of the major vessels and may avoid bleeding.
  - It is important to remain in the avascular plane between the mesentery and retroperitoneum. Significant oozing is a sign that the dissection may be too anterior into the mesentery or too posterior into the retroperitoneum.
  - Clips and endoloops are rarely required with modern energy and vessel-sealing devices but should be easily available to control bleeding, especially in patients with calcified vessels.
  - Postoperative abdominal hemorrhage can be managed with repeat laparoscopic exploration.
  - Postoperative intraluminal hemorrhage is best managed with carbon dioxide colonoscopy and endoluminal control.
- Splenic injury
  - It is safest to dissect toward the spleen rather than to retract the colon away from the spleen and cause a traction injury.
  - Complete mobilization of the splenic flexure will avoid traction injury during the extracorporeal portion of the operation.
  - Splenic injury can usually be managed with pressure and hemostatic agents.
  - Occasionally, with uncontrollable bleeding or with injury to the hilum, splenectomy may be required.
- Anastomotic leak
  - A tension-free anastomosis is facilitated by complete mobilization of both flexures.
  - Pulsatile blood flow is confirmed at the mesenteric transection line.
  - If the proximal margin is devascularized, conversion to an extended right hemicolectomy with an ileocolonic anastomosis may be safer.
  - Small leaks may be managed nonoperatively.
  - Larger leaks with peritonitis or contamination will likely require proximal diversion.
  - In extreme cases, the anastomosis may need to be taken down and converted to an end stoma.
- Serosal or full-thickness injury to the bowel
  - Careful dissection with attention to the possibility of lateral thermal spread is important.
  - The duodenum should be completely dissected off the mesentery and protected prior to pedicle ligation.
  - The small and large bowels are also at risk for puncture or shear injury during insertion of laparoscopic instruments.
- Deep and superficial surgical site infection
- Early and later incisional hernia formation

Chapter 15

Transverse Colectomy: Hand-Assisted Laparoscopic Surgery Technique

Daniel Albo

DEFINITION

- Transverse colectomy refers to removal of the portion of the colon between the hepatic and the splenic flexures. The transverse colon derives its blood supply primarily from the middle colic vessels. In addition, the transverse colon receives collateral blood flow from the left and right marginal arcades (marginal artery of Drummond and arch of Riolan, respectively).
- Hand-assisted laparoscopic surgery (HALS) is a minimally invasive surgical approach that uses conventional laparoscopic-assisted (LA) surgery techniques but with the addition of a hand-assist device that allows for the introduction of one of the surgeon's hands into the surgical field. The hand-assist device is placed at the projected specimen extraction site. HALS in colorectal surgery retains all of the same advantages of conventional LA surgery over open surgery, including less pain, faster recovery, lower incidence of wound complications, and reduction of cardiopulmonary complications, especially in the obese and in the elderly.
- HALS has significant advantages over conventional LA colorectal surgery, including
  - Reintroduces tactile feedback into the field
  - Shorter learning curves; easier to teach
  - Shorter operative times and lower conversion to open rates
  - Allows for insertion of multiple ports through the hand-assist device
  - Allows for the introduction of laparotomy pads into the field (helps keeping the small bowel and omentum out of the way, particularly in the obese)
  - Higher usage rates of minimally invasive surgery

DIFFERENTIAL DIAGNOSIS

- Focal inflammatory processes, localized trauma, or local perforation
- Colon cancer located in the midtransverse colon. Cancers located at the flexures may necessitate extended right or left hemicolectomies in order to ensure adequate lymphadenectomy.
- Other tumors locally extending into the transverse colon (i.e., gastric, pancreatic, adrenal tumors, sarcomas) may necessitate en bloc transverse colectomy when resecting the primary tumor to achieve negative margins.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with colon cancer generally present with occult bleeding and anemia. Patients may also present with high-grade obstructing symptoms (crampy abdominal pain and constipation). More advance tumors may present with a complete large bowel obstruction. If these patients have a competent ileocecal valve, they develop a closed loop large bowel obstruction and present with severe right lower quadrant abdominal pain and abdominal distention secondary to a massive colonic dilation proximal to the obstructing lesion. These patients should be taken to the operating room emergently. Unopposed, this will ultimately cause an ischemic perforation of the cecum leading to a catastrophic fecaloid peritonitis and potential oncologic contamination of the abdominal cavity leading to carcinomatosis.
- A detailed personal and family history of colorectal cancer, polyps, and/or other malignancies should be elicited. Physical examination should include a routine abdominal examination, noting any previous incisions.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- A full colonoscopy with documentation of all polyps should be performed. Lesions that are unresectable endoscopically and/or are suspicious for cancer should be tattooed to facilitate localization during surgery. If there is any concern for involvement of adjacent organs, such as the stomach, an esophagogastroscopy should also be performed.
- A computed tomography (CT) scan of the chest, abdomen, and pelvis evaluates for potential metastases. In patients with a large bowel obstruction, the CT scan shows dilation of the right colon and cecum, collapse of the distal colon, and a paucity of fluid and gas in the small bowel (**FIG 1**).
- A preoperative carcinoembryonic antigen level is obtained.

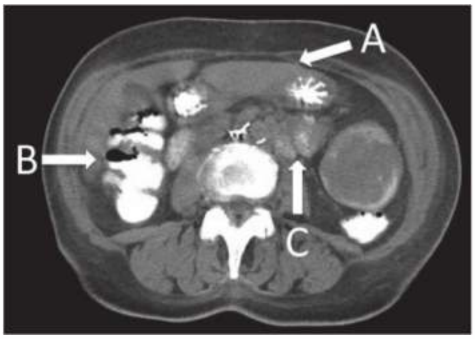

FIG 1 ● CT scan shows a large obstructing colon cancer in the transverse colon (*A*) with dilation of the cecum (*B*) and a paucity of fluid and gas in the small bowel (*C*).

SURGICAL MANAGEMENT

Preoperative Preparation

- Clinical trials have shown no need for mechanical bowel preparation.
- Intravenous cefoxitin is administered within 1 hour of skin incision.
- Use hair clippers if needed and chlorhexidine gluconate skin preparation.
- Preoperative time-out and briefing is performed.

Equipment and Instrumentation

- 5-mm camera with high-resolution monitors
- 5-mm clear ports with balloon tips. They hold ports in the abdomen and minimize their intraabdominal profile during surgery.
- Atraumatic graspers and laparoscopic endoscopic scissors
- A blunt tip, 5-mm energy device
- 60-mm linear reticulating laparoscopic staplers with vascular and tan loads
- We use the GelPort hand-assist device due to its versatility and ease of use. This device allows for the introduction/removal of the hand without losing pneumoperitoneum.

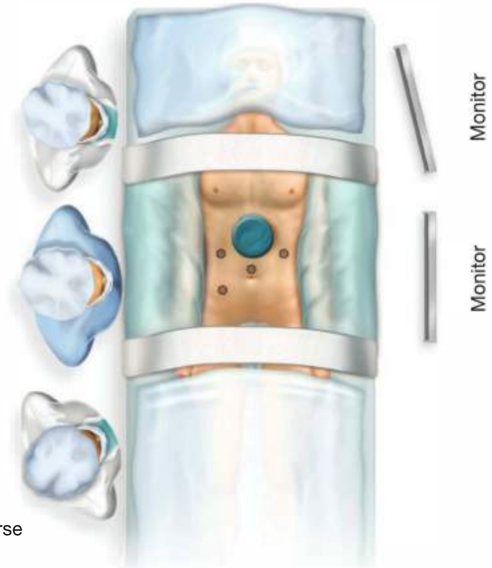

FIG 2 • Patient and team setup.

Patient Positioning and Surgical Team Setup

- This is the single most critical determinant of success in laparoscopic colorectal surgery (**FIG 2**).
- Place the patient on a supine position, with the arms tucked and padded (to avoid nerve/tendon injuries). The patient is taped over a towel across the chest without compromising chest expansion.
- The surgeon starts at the patient's right lower side with the scrub nurse to the surgeon's right side. The assistant stands at the surgeon's left side.
- Align the surgeon, the ports, the targets, and the monitors in straight line. Place monitors in front of the surgeon and at eye level to prevent lower neck stress injuries.
- Avoid unnecessary restrictions to potential team movement around the table. All energy device cables exit by the patient's upper left side. All laparoscopic (gas, light cord, and camera) elements exit by the patient's upper right side.

TECHNIQUES

PORT PLACEMENT AND OPERATIVE FIELD SETUP

- Insert a GelPort through a 5- to 6-cm epigastric incision. This incision will be also used for specimen extraction, transection, and anastomosis. Placement in the epigastric area greatly facilitates dissection of the middle colic vessels through a supramesocolic approach (see step 7).
- Insert three 5-mm working ports in the right upper, right lower, and left upper quadrants. Insert a 5-mm camera port above the umbilicus. Triangulate the ports so the camera port is at the apex of the triangle. This avoids conflict between the instruments and prevents disorientation ("working on a mirror").

OPERATIVE STEPS

- Our HALS transverse colectomy operation is highly standardized and it consists of nine steps:
  - Transection of the inferior mesenteric vein (IMV)
  - Medial to lateral dissection of the descending mesocolon
  - Transection of the left colic artery
  - Mobilization of the sigmoid off the pelvic inlet
  - Mobilization of the descending colon
  - Mobilization of the splenic flexure
  - Mobilization of the right colon
  - Transection of the middle colic vessels (supramesocolic approach)
  - Extracorporeal transection and anastomosis

Step 1. Transection of the Inferior Mesenteric Vein

- This is the critical "point of entry" in this operation. At the level of the ligament of Treitz, the IMV is easy to visualize and is far from critical structures that can be injured during its dissection (no iliac vessels or left

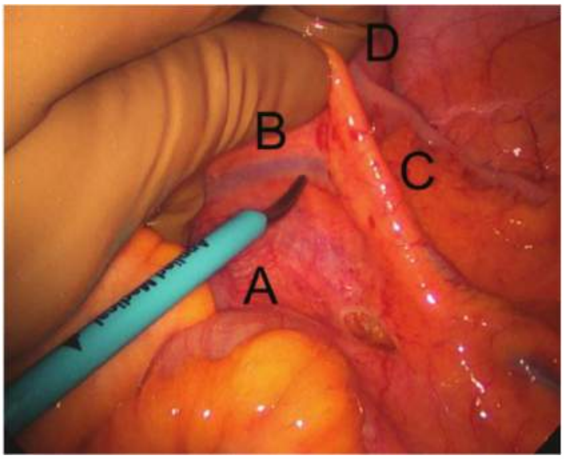

FIG 3 ● Step 1: Key anatomy. Ligament of Treitz *(A)*. IMV *(B)*. Left colic artery *(C)* as it separates from the IMV and goes toward the splenic flexure of the colon *(D)*.

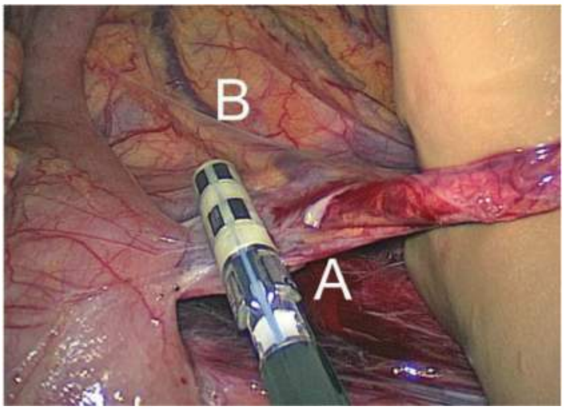

FIG 4 ● Step 1: Transection of the IMV *(A)* cephalad of the left colic artery *(B)*.

ureter nearby). This will be the only time when a true virgin tissue plane is entered. Every step will setup the following ones, opening the tissue planes sequentially.

- The patient is placed on a steep Trendelenburg position with the left side up. Using the right hand, move the small bowel into the right upper quadrant (RUQ) and the transverse colon and omentum into the upper abdomen. If necessary, place a laparotomy pad to hold the bowel out of the field of view especially in obese patients. This pad can also be used to dry up the field and to clean the scope tip intracorporeally. Make sure that the circulating nurse notes the laparotomy pad in the abdomen on the white board.
- Identify the critical anatomy: IMV, ligament of Treitz, and left colic artery (**FIG 3**).
- If there are attachments between the duodenum/root of mesentery and the mesocolon, transect them with laparoscopic scissors. This will allow for adequate exposure of midline structures.
- Pick up the IMV with the left hand. Dissect under the IMV and in front of Gerota's fascia with endoscopic scissors, starting at the level of the ligament of Treitz and proceeding toward the inferior mesenteric artery (IMA). The assistant provides upward traction with a grasper.
- Transect the IMV cephalad of the left colic artery (which moves away from the IMV and toward the splenic flexure of the colon) with the 5-mm energy device (**FIG 4**), thus preserving intact the left-sided marginal arterial arcade and maintaining the blood supply to the descending colon segment.

Step 2. Medial to Lateral Dissection of the Descending Mesocolon

- The surgeon's hand and the assistant's grasper retract the IMV/left colic pedicle at the cut edge of the descending mesocolon upwards towards the enterior abdominal wall. He or she then dissects the plane between the mesocolon and Gerota's fascia (readily identified by the transition between the two fat planes) with a 5-mm energy device (**FIG 5**). We like to dissect this space by gently pushing the retroperitoneum down with the blunt tip of the 5-mm energy device.
- Dissect caudally under the IMV/left colic artery toward the takeoff of the left colic artery off the IMA. Dissect laterally until you reach the lateral abdominal wall. This will greatly facilitate step 5. Dissect superiorly between the splenic flexure and the tail of the pancreas. This will greatly facilitate step 6.

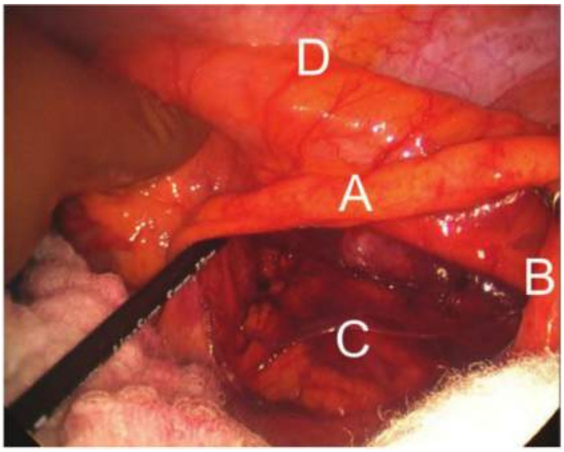

FIG 5 ● Step 2: Medial to lateral dissection of the descending mesocolon. The surgeon is holding the splenic flexure upward. Notice that there is a laparotomy pad on the field holding the small bowel out of the way and helping provide excellent exposure. The left colic artery is located in the medial edge of the descending mesocolon *(A)*. IMA *(B)*. Gerota's fascia *(C)*. Descending colon *(D)*.

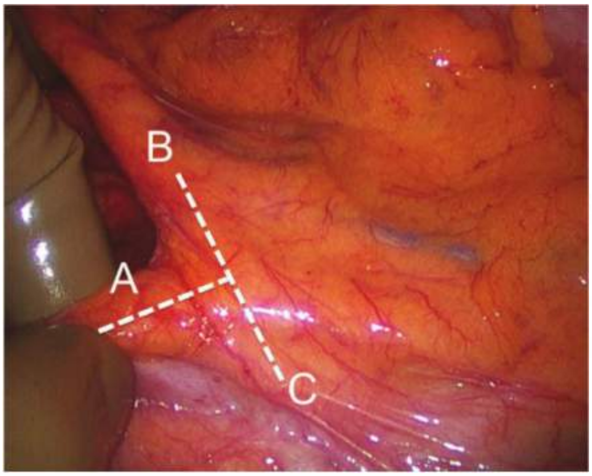

FIG 6 ● Step 3: Critical anatomy. The letter T formed between the IMA *(A)* and it's left colic artery *(B)* and SHA *(C)* terminal branches.

Step 3. Transection of the Left Colic Artery

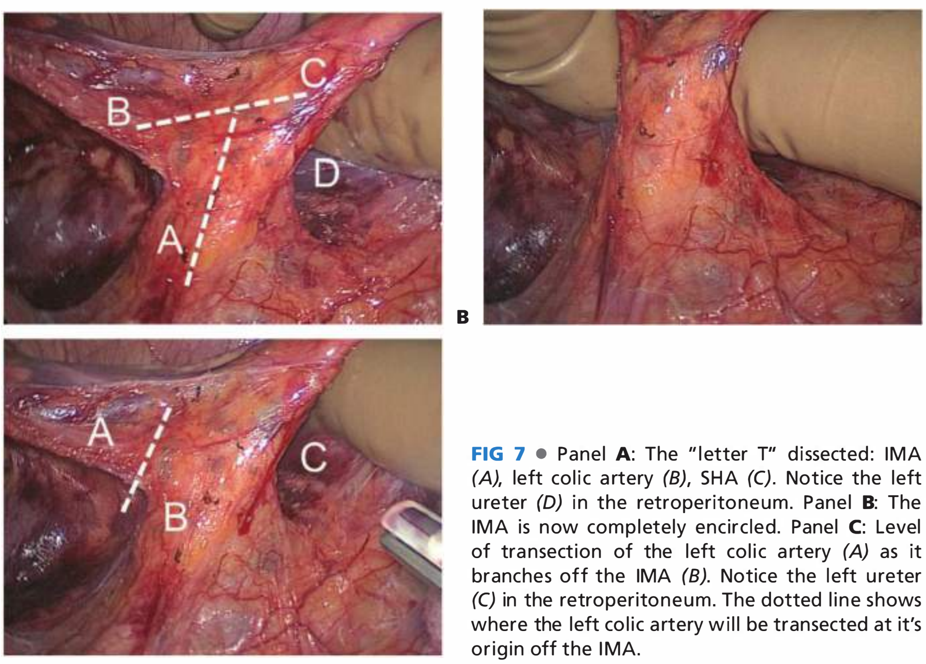
- Identify the critical anatomy: The "letter T" formed between the IMA and its left colic and superior hemorrhoidal artery (SHA) terminal branches (**FIG 6**).
- Holding the SHA up with the left hand, dissect the plane along the palpable groove between the SHA and the left iliac artery using laparoscopic scissors and a 5-mm energy device. Preserve the sympathetic nerve trunk intact in the retroperitoneum. Identify the left ureter in front of the left iliac artery and psoas muscle, and medial to the gonadal vessels before transecting anything (**FIG 7A**).
- Dissect with your thumb and index finger around and behind the IMA (**FIG 7B**)
- Visualize the letter "T" formed between the IMA, the left colic artery, and the SHA (**FIG 7A**). Transect the left colic artery as it takes off the IMA with the energy device (**FIG 7C**). The surgeon can now complete the dissection of the mesocolon off the retroperitoneum in a superior to inferior direction down to the level of the pelvic inlet. This will greatly facilitate steps 4 and 5.

Step 4. Mobilization of the Sigmoid off the Pelvic Inlet

- The surgeon pulls the proximal sigmoid colon medially with the left hand and the assistant pulls the distal sigmoid colon medially with a grasper (**FIG 8A**). Transect the lateral sigmoid colon attachments to the pelvic inlet with laparoscopic scissors in your right hand. Stay medially, close to the sigmoid and mesosigmoid, to avoid injuring the left ureter (**FIG 8B**). You should readily enter the retroperitoneal dissection plane dissected during the previous step.
- Dissect caudally until reaching the left side of the Douglas pouch.

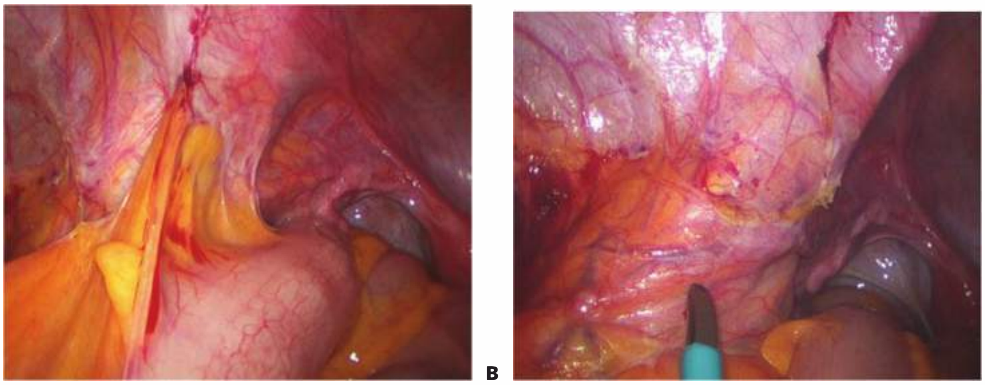
Step 5. Mobilization of the Descending Colon

- Retract the descending colon medially with your left hand. Transect the white line of Toldt up to the splenic flexure using endoscopic scissors or energy device with your right hand through the left-sided port. You should readily enter the retroperitoneal dissection plane dissected during step 2.



A B C

FIG 7 ● Panel **A**: The "letter T" dissected: IMA *(A)*, left colic artery *(B)*, SHA *(C)*. Notice the left ureter *(D)* in the retroperitoneum. Panel **B**: The IMA is now completely encircled. Panel **C**: Level of transection of the left colic artery *(A)* as it branches off the IMA *(B)*. Notice the left ureter *(C)* in the retroperitoneum. The dotted line shows where the left colic artery will be transected at it's origin off the IMA.

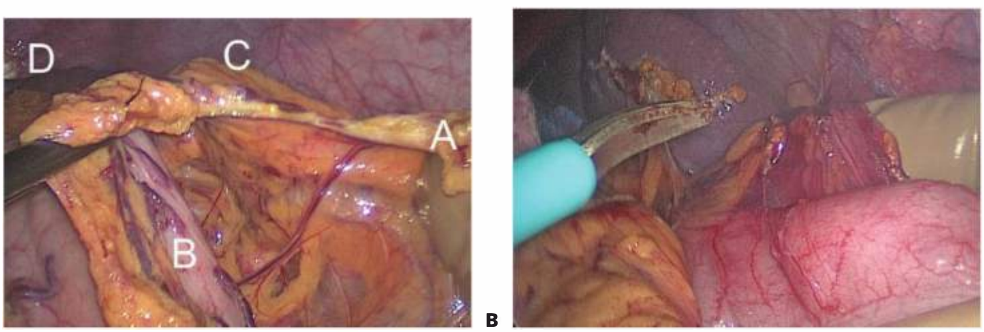


A B

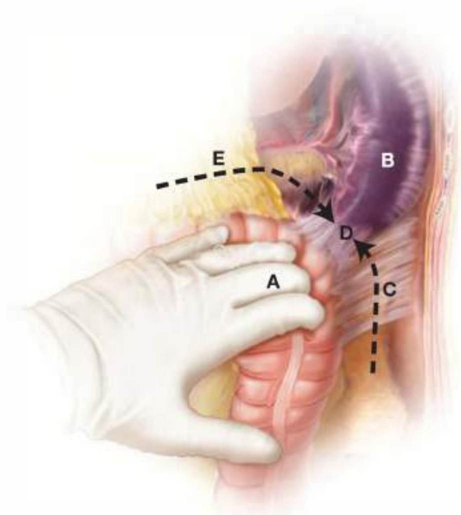
FIG 8 ● Step 4. Panel **A**: Medial traction on the sigmoid exposes its lateral attachments to the pelvic inlet. Panel **B**: After the sigmoid mobilization is completed, the left ureter is visualized as it crosses over the left iliac artery.

Step 6. Mobilization of the Splenic Flexure

- Place the patient on reverse Trendelenburg position with the left side up to help displace the splenic flexure down out of the left upper quadrant.
- With the assistant pulling the transverse colon downward with a grasper, the surgeon lifts the stomach up with his left hand and transects the gastrocolic ligament in between the stomach and transverse colon using a 5-mm energy device through the RUQ port site (**FIG 9A**). This allows for entrance into the lesser sac and provides for an excellent view of the splenic flexure.
- Transect the gastrocolic ligament (from medial to lateral) with the 5-mm energy device, staying close to the transverse colon and avoiding the spleen. Proceed laterally to the splenic flexure.
- Because the dissection performed in step 2 completely separated the splenic flexure of the colon from the



A B



C

FIG 9 ● Mobilization of the splenic flexure. Panel **A**: The partially transected gastrocolic ligament is visible between the transverse colon *(A)* and the stomach *(B)*. Notice the excellent view of the lesser sac laterally toward the splenic flexure of the colon *(C)* and the spleen *(D)*. Panel **B**: The surgeon is "hugging" the splenic flexure with his hand and "hooking" his index finger under the splenocolic ligament allowing for an excellent exposure and transection of this ligament with an energy device. **C**: Splenic flexure mobilization. The surgeon retracts the splenic flexure of the colon *(A)* downwards and medially, exposing the attachments of the splenic flexure to the spleen *(B)*. The phrenocolic *(C)* and splenocolic *(D)* ligaments are transected in an inferior to superior, and lateral to medial direction. The gastrocolic ligament *(E)* is then transected in a medial to lateral direction, until both planes of dissection meet and the splenic flexure is fully mobilized.

retroperitoneum, the surgeon can now slide his or her right hand under the splenic flexure, holding the splenic flexure up with the index finger "hooked" under the splenocolic ligament. This allows for an easy transection of the splenocolic ligament with an energy device (FIGS 9B and C). The left colon should be now fully mobilized to the midline.

Step 7. Mobilization of the Right Colon

- Standing at the left side of the table, the surgeon completes the transection of the gastrocolic ligament until reaching the hepatic flexure of the colon using a 5-mm energy device.
- At this point, the hepatocolic ligament is readily visible. Slide your right index finger under it, hold it upward, and transect it with a 5-mm energy device.
- Proceeding on a superior to inferior dissection, transect to the right white line of Toldt with laparoscopic scissors. Fully mobilize the ascending colon off the retroperitoneum with the 5-mm energy device. This dissection should proceed from a lateral to medial as well as from a superior to inferior direction. Stay in front of the duodenum, the head of the pancreas, and Gerota's fascia.

Step 8. Transection of the Middle Colic Vessels (Supramesocolic Approach)

- Dissection and transection of the middle colic vessels can be one of the most daunting maneuvers in colorectal surgery. Traditionally, these vessels are approached inframesocolically by dissecting the root of the mesotransverse colon at the intersection with the root of the mesentery where the venous anatomy is extremely variable and complex. The superior mesenteric vein (SMV) and its branches, and the gastrocolic venous trunk of Henle and its branches, surround the middle colic vessels. Venous tears tend to travel distally to the next major tributary. In terms of the SMV and the gastrocolic trunk of Henle, this next "tributary" is the portal vein confluence, which lies in a retroperitoneal plane for which you do not have control at this time.
- In order to prevent potentially devastating bleeding complications during the dissection and transection of the middle colic vessels, we have developed a supramesocolic approach to these vessels. The hand-assisted technique greatly facilitates the performance of this technique and makes it very safe.
- The superior aspect of the transverse mesocolon is now readily visible, with the middle colic vessels easily palpable as they cross the third portion of the duodenum in the midtransverse colon (FIG 10). With the assistant pulling down on the transverse colon downward with a grasper, the surgeon "picks up" the middle colic vessels supramesocolically with his or her right thumb and index finger. Using his or her left hand, the surgeon now dissects under the middle colic vessels with the 5-mm energy device, completely encircling the middle colic vessels with the thumb and index finger. With great exposure and control, the surgeon now transects the middle colic vessels with the 5-mm energy device.

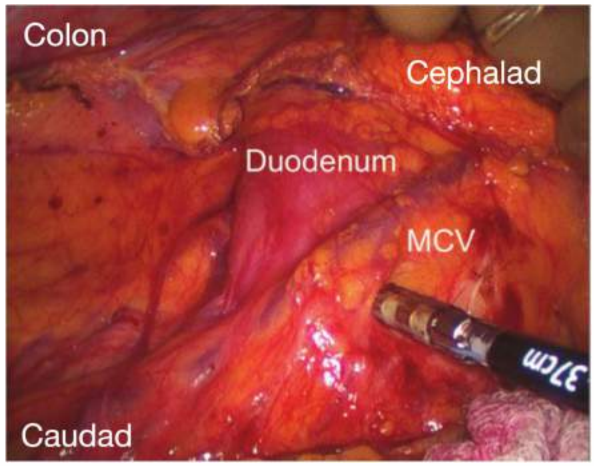


FIG 10 ● Supramesocolic transection of the middle colic vessels (MCV). The MCV are readily visualized at this point through a supramesocolic approach as they cross over the third portion of the duodenum. This allows for a safe dissection and transection with a 5-mm energy device.

- During this approach, the transverse mesocolon separates the SMV and the gastrocolic venous trunk of Henle from the middle colic vessels shielding them and, thus, greatly reducing the potential risk of serious venous injuries. It also allows for a very high transection of the middle colic vessels and, therefore, a great lymphatic nodal capture.
- Prior to the extracorporeal mobilization, we transect the right colic vessels intracorporeally (FIG 11). Hold the transverse colon up with the right hand; while the assistant retracts the right colon anteriorly and laterally,

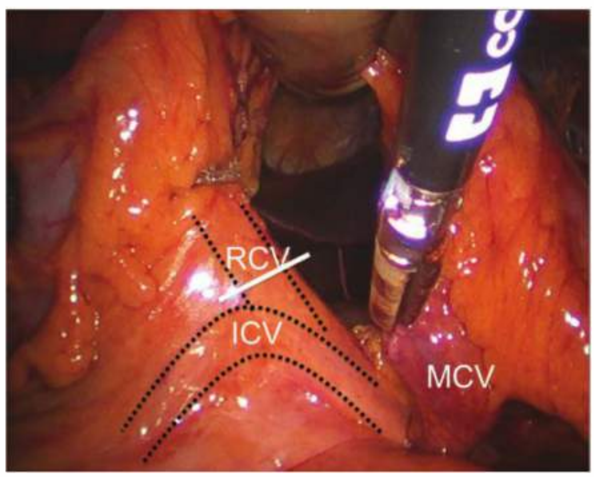

FIG 11 ● Transection of the right colic vessels. The surgeon is holding the transverse colon (with the right-sided vascular arcade along its mesenteric border) up. The *solid white line* shows where to transect the right colic vessels (RCV) as they branch off the ileocolic vessels (ICV). Transected middle colic vessels (MCV).

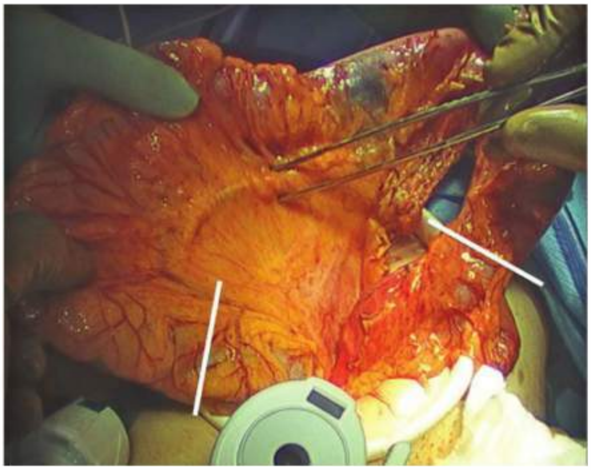

FIG 12 ● Extracorporeal mobilization and transection. The specimen is exteriorized without any tension. The *white solid lines* show where to transect the colon proximal and distal to the hepatic and splenic flexures, respectively. The tattooed target in the midtransverse colon and the vascular arcade (arch of Riolan) are readily visible.

expose the right-sided vascular arcade that connects the right branches of the middle colic vessels with the right colic vessels (the arch of Riolan). You can now safely transect the right colic vessels at its origin from the ileocolic vessels.

Step 9. Extracorporeal Transection and Anastomosis

- Deliver the transverse colon through the epigastric incision with the wound protector in place to minimize the chance of wound infection and oncologic contamination of the wound. Should there be any tension, reintroduce the colon into the abdominal cavity and mobilize the right and/or left colon more laparoscopically. Excessive traction during this step can lead to troublesome vascular injuries on mesenteric structures.
- Transect the colon extracorporeally proximal to the hepatic flexure and distal to the splenic flexure with a linear 60-mm endostapler with tan loads (**FIG 12**). The transverse colon specimen contains the middle, right, and left colic pedicles.
- At this point, we perform an extracorporeal, anatomic side-to-side, colocolonic anastomosis with a 60-mm linear endostapler using a vascular load (**FIG 13**). We avoid using the stapled colonic ends in the anastomosis to prevent potential ischemia at the staple lines intersection. The anastomosis should be tension-free and have an excellent blood supply. We do not close the anastomotic mesenteric gap to prevent potential damage to its blood supply.
- The anastomosis is reintroduced into the abdominal cavity. After changing gloves, all ports are removed. Wounds are closed with absorbable sutures and sealed off with Dermabond. We place a bilateral subcostal nerve block with bupivacaine for postoperative analgesia purposes.

FIG 13 ● Extracorporeal stapled side-to-side colocolonic anastomosis. The anastomosis is tension-free and has excellent blood supply.

PEARLS AND PITFALLS

Setup	■ Proper patient, team, port, and instrumentation setup is critical.
Operative technique	■ Point of entry: IMV at the ligament of Treitz. ■ Complete every step. Each step sets up the next ones sequentially. ■ Vascular dissection to visualize the letter T of the IMA and its SHA and left colic branches; identify left ureter prior to left colic transection. ■ Supramesocolic approach to the middle colic vessels is critical to prevent serious venous injuries.
Pitfall: dissecting anterior to the SHA	■ Solution: Identify "groove" between left common iliac artery and SHA and dissect in between the two vessels.
Pitfall: tension during extraction of the specimen	■ Reintroduce the colon into the abdominal cavity and mobilize the right and/or left colon further. Tension during the extraction phase can lead to serious bleeding problems.

POSTOPERATIVE CARE

- Postoperative care is driven by clinical pathways that includes the following:
  - Pain control: Intravenous acetaminophen for 24 hours (start in the operating room) followed by intravenous ketorolac for 72 hours (if creatinine is normal). The subcostal nerve block greatly reduces the need for narcotics.
  - Deep vein thrombosis (DVT) prophylaxis with enoxaparin starting within 24 hours of surgery
  - No additional antibiotics, judicious use of intravenous fluids
  - No nasogastric tube. Remove Foley catheter on postoperative day 1.
  - Early ambulation, diet ad lib, aggressive pulmonary toilet
  - Targeted discharge: postoperative day 3

OUTCOMES

- HALS leads to improvements in short-term outcomes, including less pain, faster recovery, shorter hospital stay, and lower incidence of cardiac/pulmonary complications when compared to open surgery.
- When compared to conventional laparoscopy, HALS results in higher usage rates of minimally invasive surgery, shorter learning curves, lower conversion rates, shorter operative times, and shorter hospital stays.
- For cancer resection, minimally invasive surgery oncologic outcomes are at least comparable to those of open surgery.

COMPLICATIONS

- Wound infections and hernias are markedly reduced versus open surgery.
- Anastomotic leak rates should be below 5%.
- Ureteral injury: critical to identify the left ureter prior to vascular transection
- DVT: low risk with use of DVT prophylaxis
- Cardiac and pulmonary complications: significantly reduced compared to the open surgery approach

Chapter 16 Left Colectomy for Colon Cancer

Saul J. Rugeles   Luis Jorge Lombana

DEFINITION

- Left colectomy for cancer is defined as the resection of the left colon in which the extension must correspond to the distribution of the lymphovascular drainage of the tumor-compromised segment, having as the result negative borders on histopathologic studies, along with in block extirpation of the lymphovascular tissue that nurtures that zone of the colon with a minimum number of 12 lymph nodes available to be evaluated by a histopathologic study.[1]

DIFFERENTIAL DIAGNOSIS

- Most of patients with left colon tumors must have a cancer histologic diagnosis before being taken to surgery.
- However, there are existing cases in which the biopsies taken by colonoscopy do not identify the presence of a neoplasia. In these cases, it is recommended to take another biopsy set. If a second set is not diagnostic, it is recommended to proceed with the colectomy and obtain the pathologic study from the surgical specimen.
- The differential diagnoses for left colon cancer include complicated diverticular disease with stenosis, intraluminal foreign bodies with an inflammatory reaction, neoplastic invasion from adjacent organs (especially ovaries), and colonic endometriosis.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The patient's medical record must be complete, including a detailed description of signs and symptoms; medical history, with special attention to the evolution of symptoms; food intake and weight changes; and a thorough physical examination, including rectal examination. The abdomen must be carefully palpated, aimed to search for lumps, carcinomatosis, or ascites. The lymphatic nodal basin must be examined as well.
- Family history of cancer is especially important, including two generations, and asking for the presence of colon, gastrointestinal, breast, endometrial, and prostate cancer. This will allow the identification of possible cases of familiar colon cancer.
- The clinical evaluation must include a subjective global assessment of nutritional status to identify the patients who may benefit from perioperative nutritional therapy.[2]
- The physiologic risk of the patient must be evaluated according to his or her age, intercurrent diseases, and type of surgery, following the institutional preoperative evaluation guidelines.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Carcinoembryonic antigen (CEA): The baseline preoperative result and postsurgical control must be obtained as an assessment for complete tumor resection. On the other hand, the absolute presurgical value is an independent variable for survival.[1]
- Abdominal computed tomography is the most sensitive and specific test for detection of intraabdominal metastases.[1]
- Chest computed tomography is the most sensitive and specific test to detect mediastinal and lung metastases.[1]
- Total colonoscopy: Regardless of the primary localization of the tumor, every patient should have a complete colonoscopy study whenever possible, because 2% to 9% of the patients may have synchronous tumors.[1] The colonic enema with double contrast may be used in those patients in whom the colonoscopy is not possible.
- Tumor histologic studies that describe the cell differentiation and the extent of the invasion.

SURGICAL MANAGEMENT

Preoperative Planning

- The extension and type of procedure must be thoroughly discussed with the patient and family. This includes the possibility of a temporary or permanent colostomy.
- Left colectomy is a major surgery that has potential for postoperative morbidity and mortality. It is desirable to discuss with the patient the local statistical rates for morbidity and mortality before obtaining the informed consent.
- There is controversy about the effectiveness and need of mechanical preparation of the bowel before the colectomy.[3–5] I personally use a "mild" preparation with 2 days of liquid diet and polyethylene laxatives the day before the surgery, achieving the evacuation of large fecal residues. I do not demand a crystalline wash before the surgery.
- In the operating room, before initiating the anesthetic act, it is desirable to follow a checklist in which every professional involved in the surgical act must participate. This list should include at least patient identification, type of surgery, type of anesthesia, expected events during the surgery, the need for blood components, prophylactic antibiotic, surgical devices availability, and potential adverse events and their prevention.

Positioning

- The surgery is performed with the patient in a supine position. The arms should ideally be tucked to the sides, allowing freedom of movement for the surgical team. If one extended arm is required, it should be placed at an angle of 90 degrees and the right arm is preferred.
- If a colorectal anastomosis with a circular stapler is assumed, the patient should be in the lithotomy position. In this case, one must ensure that the patient's thighs maintain a horizontal plane with the patient's abdomen, for them not to interfere with the surgeon's arms (**FIG 1**). The lower extremities' position in the brackets must protect them from neuropraxias or vascular compressions.
- The surgical team setup is shown in **FIG 2**.
- The surgical table must allow inclinations in every way, which will be necessary to expose regions with difficult access, such as the splenic flexure of the colon.
- The patient must be secured to the surgical table adequately to prevent body displacements with position changes of the surgical table.

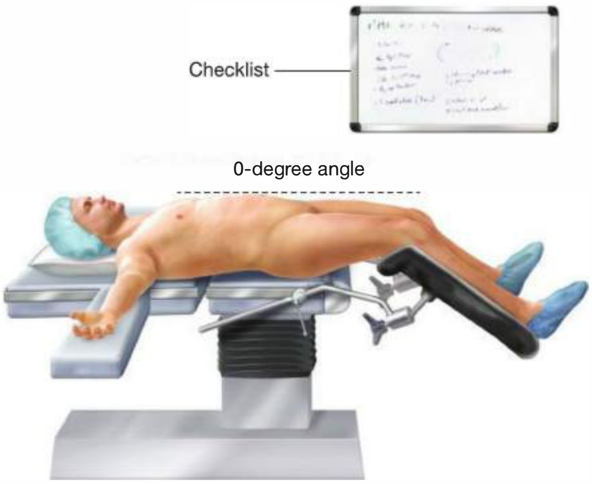

FIG 1 ● Correct position of the patient in the operating table. Note the horizontal position of the thighs to ensure free movement of surgeon's arms and hands.

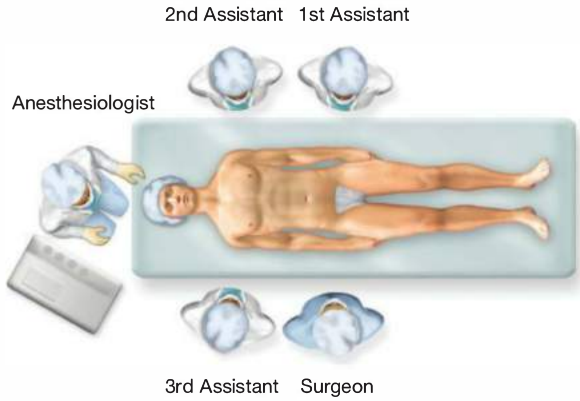

FIG 2 ● Surgical team setup.

LAPAROTOMY, REVISION OF PERITONEAL CAVITY, AND SURGICAL FIELD PREPARATION

- A medial supra- and infraumbilical laparotomy is performed, carrying the incision down to the pubis, which will improve pelvic exposure. Once the abdominal cavity is opened, it is advisable to protect the wound edges from bacterial and cellular contamination by placing an Alexis® wound protector or similar instrument (**FIG 3A,B**).
- Following this, one should explore the abdominal cavity, emphasizing in the search for liver metastases and synchronous colon tumors, especially in patients in which the total colonoscopy was not possible due to an obstructive tumor.
- Next, the small bowel is displaced toward the right upper quadrant of the abdomen and contained using pads and abdominal rolls. I personally prefer not to eviscerate the patient because this increases manipulation of the intestines and therefore increases the possibility of postoperative ileus. In order to achieve good pelvic and distal descending colon exposure, the patient is placed in a Trendelenburg position. A slight inclination of the surgical table toward the right can be helpful. Placement of a Bookwalter retractor facilitates operative exposure.
- The exact location of the left colon tumor is identified and the extent of colonic and lymphovascular pedicle resection is defined (**FIG 4**).

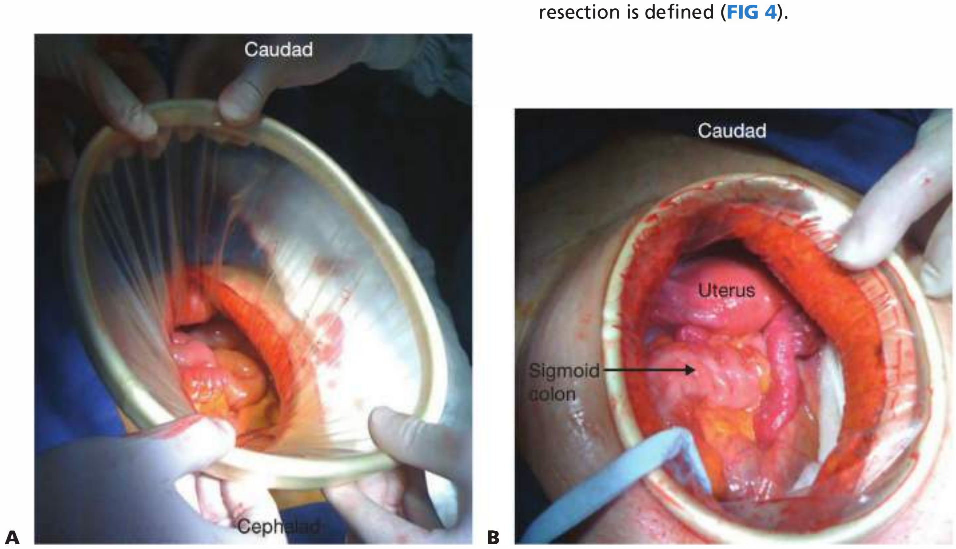

FIG 3 ● **A,B.** The Alexis® retractor has been placed to protect the wound from fecal and tumoral contamination.

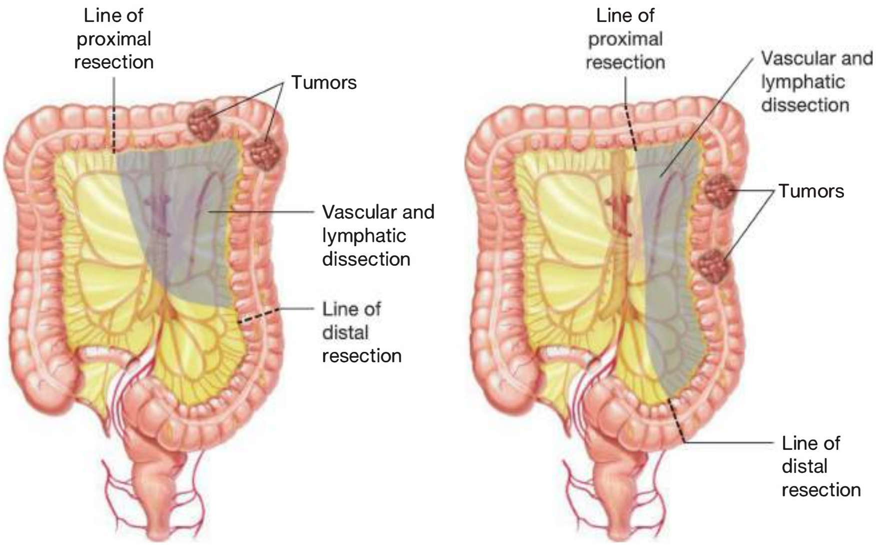

FIG 4 ● Levels of colon and lymphovascular pedicle resection in accordance to tumor localization.

IDENTIFICATION OF THE LEFT URETER AND START OF LEFT COLON MOBILIZATION

- The sigmoid colon is retracted toward the right side, and the lateral peritoneal fold is exposed up to the pelvic ring.
- Peritoneal sectioning is initiated with the monopolar electrocautery in a cephalocaudal direction. The loose retroperitoneal tissue is exposed and it can be separated with a combination of blunt and sharp dissection in order to identify the gonadal vessels, the left ureter, and the left common iliac artery. It is useful to know that the left ureter is always medial to the gonadal vessels, crossing over the common iliac artery prior to its bifurcation. The left ureter is marked with a vessel loop, being careful of including its accompanying longitudinal vascularization (FIG 5).
- At this point, an avascular tissue plane located in between the ureter and the gonadal vessels in the back and the mesentery of the sigmoid and descending colon in the front should be searched for. Using blunt dissection, it is possible to separate these structures in a cephalad direction, staying in front of Gerota's fascia, which should be preserved intact. Meanwhile, the descending colon mesentery is elevated. At the end of this maneuver, the descending colon mesentery will be raised, containing the inferior mesenteric artery (IMA) and its branches and the inferior mesenteric vein and its tributaries (FIG 6).

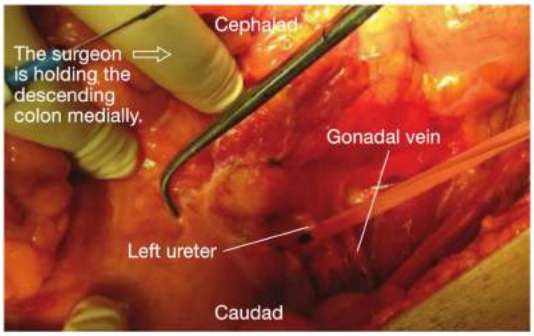

FIG 5 ● The left ureter, located medial to the gonadal vessels, has been identified and marked.

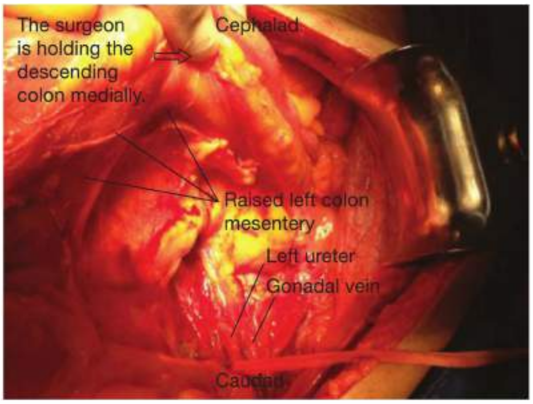

FIG 6 ● The left colon mesentery has been raised. The retroperitoneal structures are exposed.

LATERAL TO MEDIAL DISSECTION AND VASCULAR ISOLATION

- The sigmoid and descending colon are retracted laterally, and the peritoneum is sectioned in a vertical direction from the ligament of Treitz to the pelvic inlet, anterior to the aortic artery pulse. At this time, it is possible to see a slight hematoma behind the root of colonic mesentery, product of the previously described lateral dissection. Sectioning the loose tissue in the mesentery root (under the superior hemorrhoidal vessels) communicates the medial and lateral dissection planes (**FIG 7**).
- Lateral to the fourth portion of the duodenum and below the inferior pancreatic border, it is possible to identify the inferior mesenteric vein. The inferior mesenteric vein is then ligated and divided (**FIG 8**).
- On this anatomic plane, one should continue sectioning the mesentery in a caudal direction, remaining 1 cm ahead the aorta in order to preserve the abdominal sympathetic plexus (hypogastric trunk). In almost every patient, it is possible to observe the hypogastric trunk as it traverses over the promontory. The hypogastric trunk divides into the right and left hypogastric trunk, which can be identified in the right and left posterolateral pelvis, respectively (**FIG 9**). These nerves must be preserved in order to avoid autonomic dysfunction postoperatively.
- The IMA, identified a few centimeters above the aortic bifurcation, is ligated and divided. In proximal tumors, this division can be performed at the origin of left colic artery in order to preserve the IMA, sigmoidal vessels, and superior hemorrhoidal arteries intact. This ensures preservation of a well-vascularized sigmoid colon for the anastomosis, without compromising the oncological extent of the lymphadenectomy (**FIG 4**).

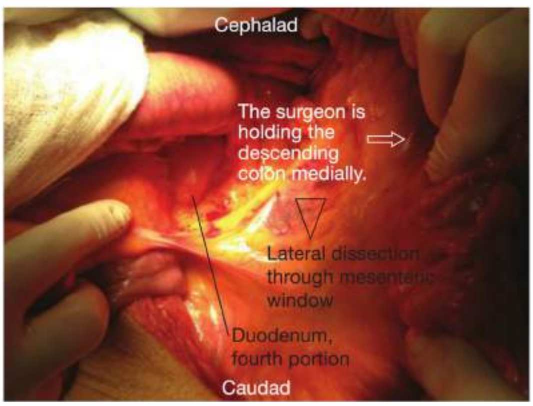

FIG 7 ● Medial view of dissection. The fourth portion of duodenum is seen in the surgeon's left and the assistant is retracting the left colon laterally. Notice the slight hematoma behind the root of the colonic mesentery in the right, indicating the zone of dissection under the superior hemorrhoidal vessels.

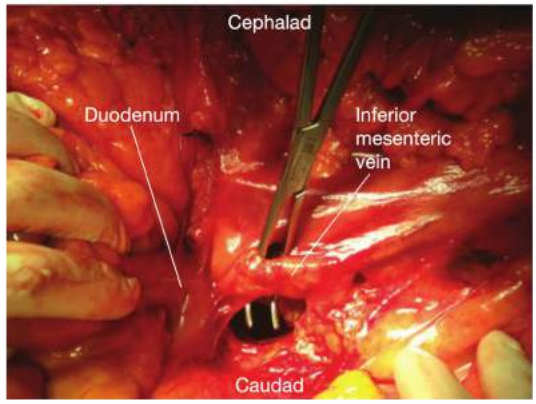

FIG 8 ● The inferior mesenteric vein has been dissected and is ready to be transected.

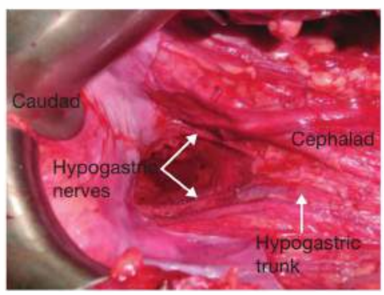

FIG 9 ● View of sympathetic plexus and origin of the left and right hypogastric nerves.

MOBILIZATION OF THE SPLENIC FLEXURE

- At this time, the only remaining step needed for a full mobilization of the left colon is the mobilization of the splenic flexure. This maneuver can be challenging, because the splenic flexure can have a very deep location in the left upper quadrant of the abdomen.
- The lateral peritoneum sectioning is continued from the initial incision in a cephalic direction as far as possible, avoiding excessive traction of the splenic flexure in order to prevent splenic lacerations. This dissection can be done with a monopolar scalpel or with a bipolar vessel-sealing device.
- The final approach to the splenic flexure should be complemented with another point of dissection that is initiated in the transverse colon to the left of the middle colic vessels. At this point, the gastrocolic ligament is transected, entering the lesser sac (**FIG 10**). The gastrocolic ligament is then transected from medial to lateral with a monopolar scalpel or with a bipolar vessel-sealing device, leaving the greater omentum attached to the surgical specimen.
- With a combined traction of the transverse and descending colon, it is now easier to expose the splenocolic ligament, allowing for its transection with a monopolar scalpel or with a bipolar vessel-sealing device (**FIG 11**). The left colon is now fully mobilized all the way to the midline.

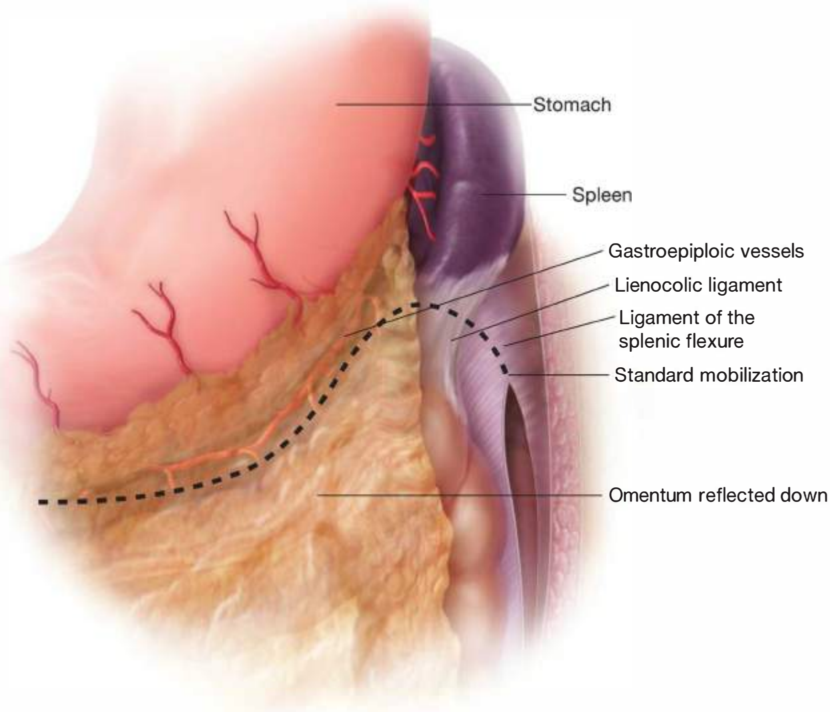

FIG 10 ● The gastrocolic ligament will be transected, starting to the left side of the middle colic vessels and proceeding from medial to lateral and around the splenic flexure of the colon, until the lateral dissection spleen is reached.

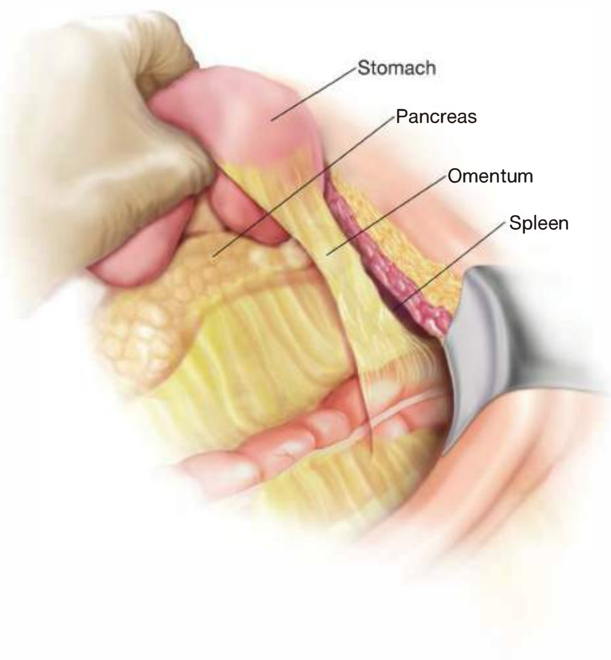
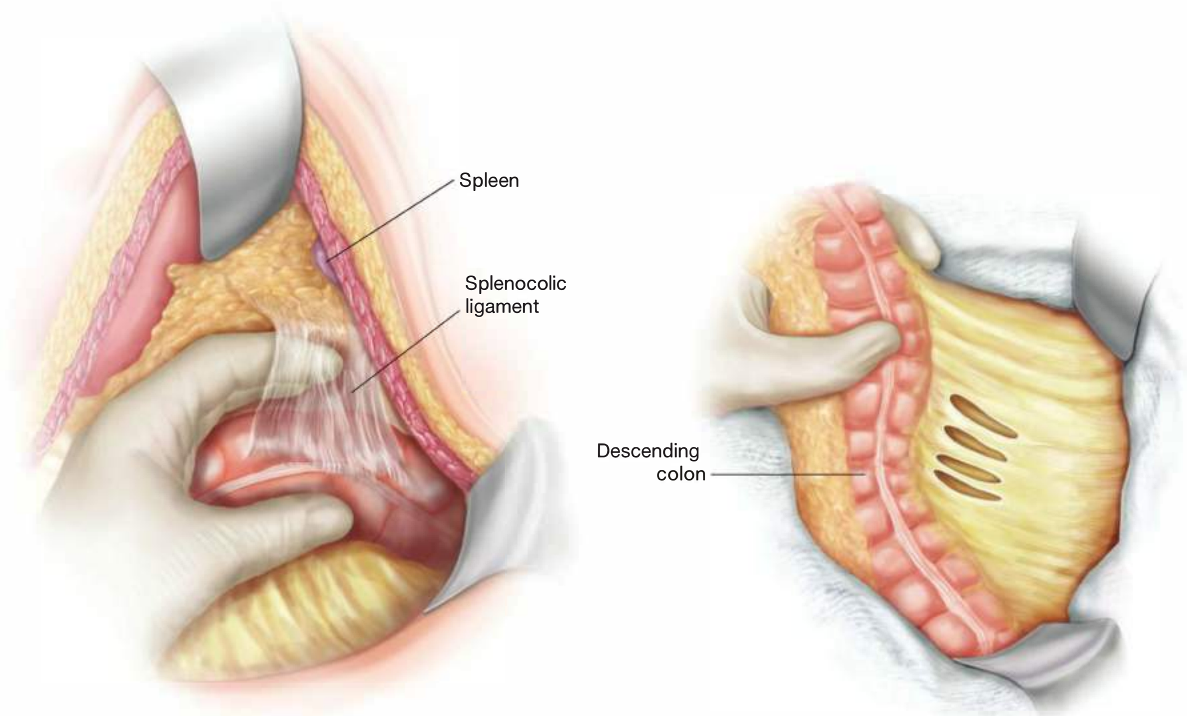


A

FIG 11 ● **A–C.** Exposure of the splenocolic ligament. Once the medial and lateral dissection planes are connected, the splenocolic ligament is easily visualized and is now ready to be transected. *(continued)*



B C

FIG 11 ● *(continued)*

COLON EXTRACTION AND ANASTOMOSIS

- At this time, a colon segment from the distal third of the transverse colon down to the rectosigmoid junction could be taken to the midline and externalized through the laparotomy incision (**FIG 12**). The transection points are chosen based on the oncologic margins needed, ensuring an adequate capture of the appropriate lymphovascular pedicles (**FIG 4**). In thin patients, it is possible to feel the pulse of the marginal artery near the points of transection. In more obese patients, or if the pulse is not palpable, the presence of a normal color in the colon is a good indicator of adequate perfusion on the colonic segments to be used for the anastomosis.
- If the extension of the resection allows preserving the sigmoid colon, a side-to-side transverse colon–sigmoid anastomosis with a mechanical stapler is advisable (**FIG 13A1,A2**). If the sigmoid colon has to be included in the resection specimen, then an end-to-end colorectal anastomosis with circular stapler via a transanal route must be performed (**FIG 13B1,B2**). It is critical that the anastomosis is tension-free; full mobilization of the splenic flexure ensures that this is possible.

FIG 12 ● The left colon is now fully mobilized and is exteriorized through the surgical incision. Full mobilization of the splenic flexure will ensure a tension-free anastomosis.

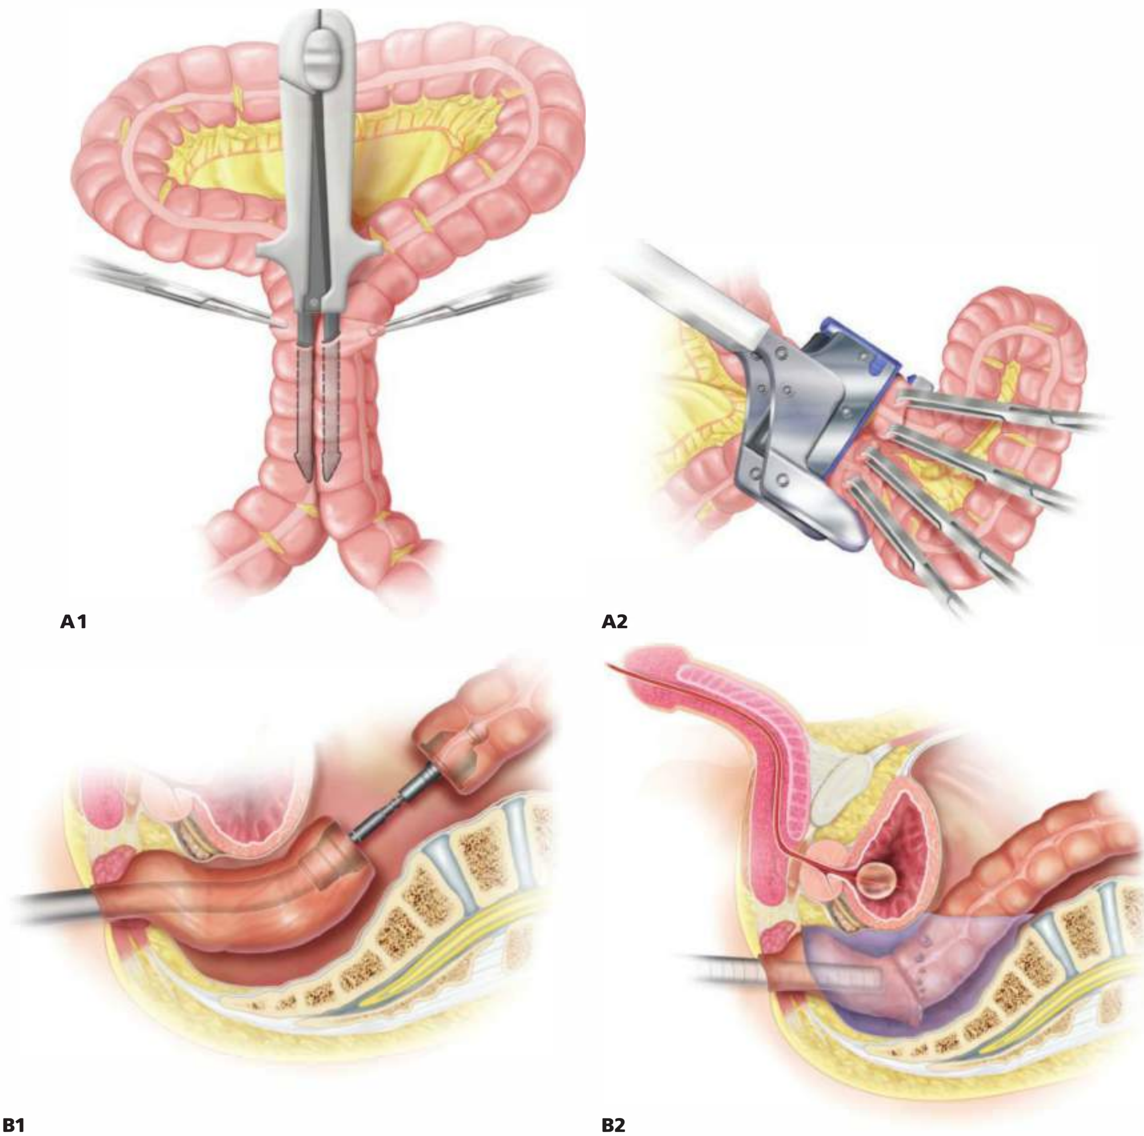


FIG 13 ● Anastomosis: **A1.** Side-to-side stapled transverse colon–sigmoid anastomosis. **A2.** Completion of the anastomosis and resection of the left colon specimen with a thoracoabdominal (TA) stapler. **B1.** End-to-end stapled colorectal anastomosis. **B2.** Completed colorectal anastomosis tested under water. Air bubbles identified during insufflation of the anastomosis indicate an anastomotic leak.

FINAL REVIEW AND CLOSURE OF THE PERITONEAL CAVITY

- Once the anastomosis is completed, the surgical bed must be reviewed to identify and control small bleeding retroperitoneal points, which are frequent. The vessel loop is removed from the left ureter and the anastomosed colon is left in the retroperitoneum. The rest of the abdominal cavity is checked, the surgical pads are counted, and the abdominal cavity is closed in the usual way.

PEARLS AND PITFALLS

Patient position	▪ An improper position with hip flexion will make it difficult to maneuver during the whole procedure. Make sure the patient's thighs are completely horizontal.
Left ureter identification	▪ The left ureter must be identified all the way through and not just at the entrance to the pelvis. At the arterial ligation point, this organ can become medial and be injured. Make sure to identify it during the vascular isolation.
Splenic flexure mobilization	▪ It is usually the most challenging step of this operation. It must be done with patience, good lighting, and using the dual (medial and lateral) approach previously described.
Tension-free anastomosis	▪ Full mobilization of the splenic flexure is critical for a tension-free anastomosis. Anastomotic tension can lead to anastomotic leaks.

POSTOPERATIVE CARE

- Fluid resuscitation with Ringer's lactate to maintain a urinary output of 1 mL/kg/hr without overhydration
- Pain control with patient-controlled analgesia or epidural analgesia
- Early oral intake and patient mobilization
- Early removal of bladder catheter
- Venous thrombosis prophylaxis according to guidelines
- Routine use of nasogastric tube is not recommended.
- No postoperative antibiotics are needed.

OUTCOMES

- The patient's prognosis depends on the tumor staging, which is determined by the histopathologic study of the specimen (pTNM).[6]
- Many patients will require adjuvant chemotherapy according to the tumor stage.[7]

COMPLICATIONS

- Surgical site infection
- Hematomas
- Anastomotic leak
- Peritonitis
- Prolonged postsurgical ileus
- Incisional hernia

Chapter 17 Left Hemicolectomy: Laparoscopic Technique

Erik Askenasy

DEFINITION

- A "left hemicolectomy" can be a nebulous term because three colonic segments lie in the left abdomen: the splenic flexure, the descending colon, and the sigmoid colon. At times, this can lead to consternation during surgical planning or even intraoperatively. Remembering that the location of the pathology guides the extent of colonic resection as well as the associated vascular and regional lymph nodes can provide much needed clarity. Additionally, understanding the vascular anatomy of the left colon and its common variations is essential for a well-vascularized and tension-free anastomosis.
- The left colon develops embryologically from the hindgut and contains three segments: the splenic flexure, the descending colon, and the sigmoid colon. The splenic flexure is located in the left upper quadrant and is supplied by antegrade flow from the left branch of the middle colic as well as retrograde flow from the left colic artery. Griffith's point is typically found in the splenic flexure and refers to the watershed area between these two arteries and represents a circulatory communication between the superior and inferior mesenteric arteries. The descending colon lies in between the sigmoid colon and the splenic flexure and is supplied by the left colic artery. Finally, the sigmoid colon is located in the left lower quadrant and is supplied by the sigmoidal arteries, branches of the inferior mesenteric artery (IMA) after the takeoff of the left colic artery. In this chapter, we will focus on the splenic flexure and the descending colon.
- A surgeon must be ready for "surprises" when entering the abdomen for a lesion in the descending colon, because there can be wide variation between the location of the target lesion as reported during flexible colonoscopy and the actual location found during surgery. The exact type and extent of resection will be dictated by the lymphovascular pedicles associated with the location of the target lesion (**FIG 1**).
- Laparoscopic surgery provides many advantages to the patient, including the following:[1–4]
  - Less pain
  - Faster return to work
  - Quicker return of bowel function
  - Shorter hospital stay

DIFFERENTIAL DIAGNOSIS

- Common indications for laparoscopic left hemicolectomy
  - Cancer of the splenic flexure or descending colon
  - Diverticular disease and its sequelae, including colovesicular or colovaginal fistulas

PATIENT HISTORY AND PHYSICAL FINDINGS

- Most patients with early-stage colon cancer are asymptomatic, with lesions found on colonoscopy performed for screening purposes or secondary to a positive fecal occult blood test.
- Late-stage colon cancer can present with abdominal pain, unexplained weight loss, melena, iron deficiency anemia, or a change in bowel habits. Obstructive symptoms are typically secondary to circumferential tumors.
- Patients with uncomplicated diverticulitis report episodic pain in the left lower quadrant associated with fever, changes in bowel habits, and/or bloating.
- The spectrum of symptomatology for complex diverticulitis can be as benign as those for uncomplicated

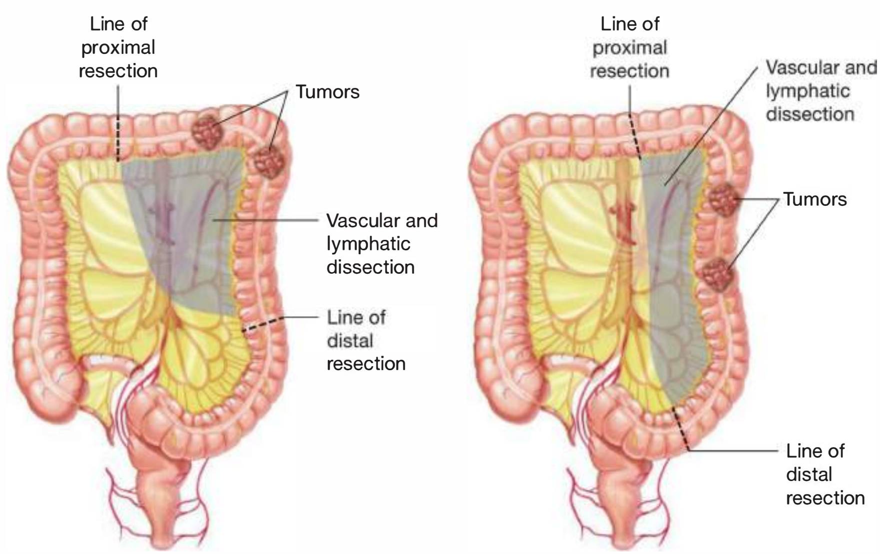

FIG 1 ● Extent of lymphovascular pedicle resection based on location of the primary tumor.

diverticulitis but can progress to localized or even generalized peritonitis.

- Patients with neoplastic or inflammatory erosion into adjacent organs, such as the bladder or vagina, can present with pneumaturia, fecaluria, or fecaloid vaginal discharge.
- A thorough family history of colon or rectal cancer, polyps, and/or other malignancies should be elicited.
- Physical examination should include the following:
  - Abdominal examination, focusing on localized tenderness, masses, and previous scars
  - Digital rectal examination to assess for blood as well as sphincter function

IMAGING AND OTHER DIAGNOSTIC STUDIES

- A full colonoscopy is essential. If a lesion is identified and it is suspicious for malignancy, the area should be tattooed to aid in intraoperative localization.
- In malignancy, a triple-phase computed tomography (CT) chest/abdomen/pelvis scan is performed to evaluate for metastases and locoregional extent of disease as well as to delineate the vascular anatomy. A preoperative carcinoembryonic antigen level should also be obtained.
- In diverticulitis, a routine CT abdomen/pelvis scan with oral and intravenous (IV) contrast is obtained.

SURGICAL MANAGEMENT

Preoperative Preparation

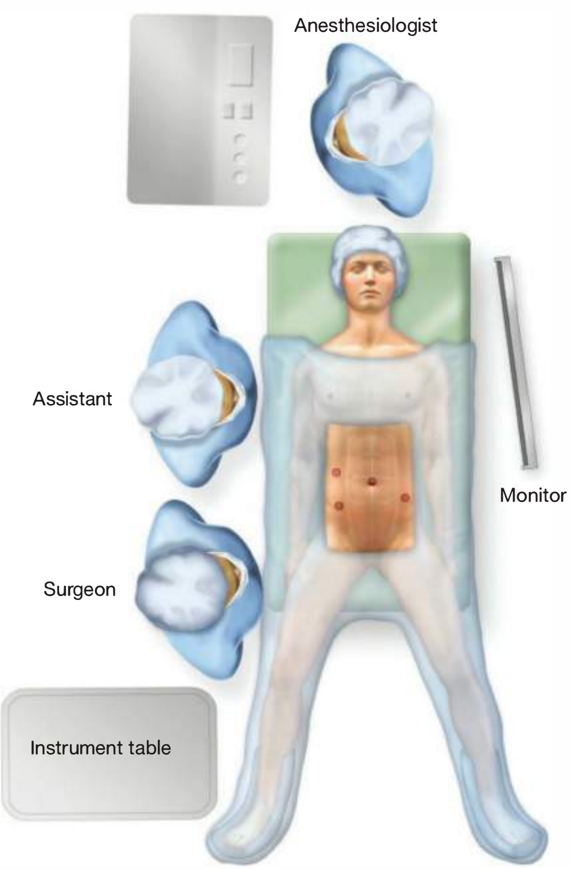
- Although preoperative bowel preparation is controversial, we routinely use it, as it makes the bowel easier to handle.
- Chlorhexidine shower the evening prior to surgery
- Normothermia maintained with Bair Hugger (36°C to 37°C) perioperatively
- Euglycemia maintained perioperatively
- One gram of Rocephin and 500 mg of Flagyl are administered within 1 hour of skin incision.
- Hair clippers are used to clear the field.
- Chlorhexidine is used for skin preparation; Betadine is used for perineal preparation.
- Preoperative time-out and briefing

Equipment and Instrumentation

- One Hasson trochar, one 12-mm port, and two 5-mm ports
- A 10-mm, 45-degree camera (may use 5 mm if quality of camera is acceptable)
- Atraumatic bowel gaspers, laparoscopic endoscissors, and a 5-mm energy device

Patient Positioning and Surgical Team Setup

- For pathology proximal to the mid–descending colon, the patient is placed on a supine position. Otherwise, the patient is placed on a lithotomy position.
- Both arms are tucked and padded. Wide silk tape is applied over two towels across the patient's chest in an "X" figure to secure the patient (**FIG 2B**).



A

B

C

FIG 2 ● **A.** Patient, ports, and team setup. **B.** Wide silk tape is applied over two towels across the patient's chest in an X figure to secure the patient. **C.** The thighs are positioned parallel with the floor to minimize encroachment on the surgeon's right operating arm.

- The patient is positioned such that the anus is easily accessible.
- The legs are placed in Allen stirrups, making sure the heel is flush against the base. Pressure points are padded posteriorly and laterally.
- The thighs are positioned parallel with the floor to minimize encroachment on the surgeon's right operating arm (**FIG 2C**).
- Thighs are wrapped with warm blankets to minimize heat loss during surgery.
- Draping is performed to allow for easy access to the perineum.
- The surgeon starts at the patient's right lower side with the assistant to his or her left. The assistant drives the camera while the surgeon uses both working ports (**FIG 2A**).
- A single monitor is needed and located on the patient's left side, across from the surgeon and at or slightly below eye level.
- All laparoscopic cables should come in from the patient's upper left side. All energy devices, Bovie, and suction should come in from the patient's upper right side. This setup prevents cluttering of the field and facilitates movement of the team around the table.

PORT PLACEMENT AND OPERATIVE FIELD SETUP

- A Hasson trochar is placed at the umbilicus. This serves as the camera port as well as the extraction site. If the pathology is located in the distal descending colon, a 12-mm port is placed in the right lower quadrant and a 5-mm port is placed in the right midquadrant. If the pathology is more proximal, then the two right abdominal ports are shifted cephalad a few centimeters (**FIG 2A**).
- A 5-mm port can be placed in the left lower quadrant to aid with takedown of the white line of Toldt and with the splenic flexure mobilization.

OPERATIVE STEPS

- Although slight adjustments may be necessary based on the exact location of the lesion, laparoscopic surgery for lesions in the splenic flexure or in the descending colon should be standardized to maximize operative efficiency, following these sequential steps:
  - Placement of the omentum above the transverse colon
  - Transection of the superior mesenteric vein (SMV)
  - Transection of the left colic artery or the IMA (depending on pathology location)
  - Medial to lateral dissection of the descending mesocolon
  - Transection of the gastrocolic ligament and entrance into the lesser sac
  - Transection of the white line of Toldt
  - Mobilization of the splenic flexure
  - Extracorporeal resection and anastomosis
  - Closure of abdominal wounds

Step 1. Placement of Omentum above the Transverse Colon

- The patient is placed in a steep Trendelenburg and rotated to the right. Omental attachments to the pelvis are taken down with an energy device. The omentum is then placed over the transverse colon and into the left upper quadrant (**FIG 3**).

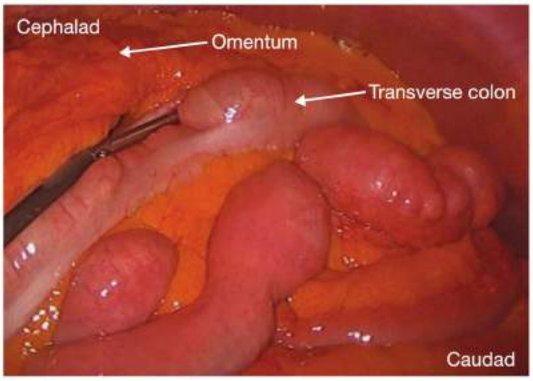


FIG 3 • The omentum is placed over the transverse colon.

Step 2. Transection of the Inferior Mesenteric Vein

- The inferior mesenteric vein (IMV) serves as the gateway to the retroperitoneum. Entering this plane in the correct location will facilitate the rest of the operation. The small bowel is swept to the right and the ligament of Treitz is exposed. If necessary, a Ray-Tec sponge can be placed in to the abdomen through the 12-mm port to assist with exposure.
- The IMV, located lateral to the ligament of Treitz, and the left colic artery are identified (**FIG 4A**).
- Start by picking up the IMV just lateral to the ligament of Treitz and dissect under it with either hot scissors or an energy device.
- Encircle the IMV and transect it with either a stapler or an energy device (**FIG 4B**).
- Lift up on the cut IMV and begin exposure of the retroperitoneal plane (**FIG 4C**).
- There is a "bare area" of mesentery between the left colic artery and the middle colic artery. Using an energy device, take this mesentery 1 cm from the lateral edge of the duodenum as far lateral as it is safe. Care must be taken here to avoid angling up toward the colon and risk injuring the marginal artery (**FIG 4D**).

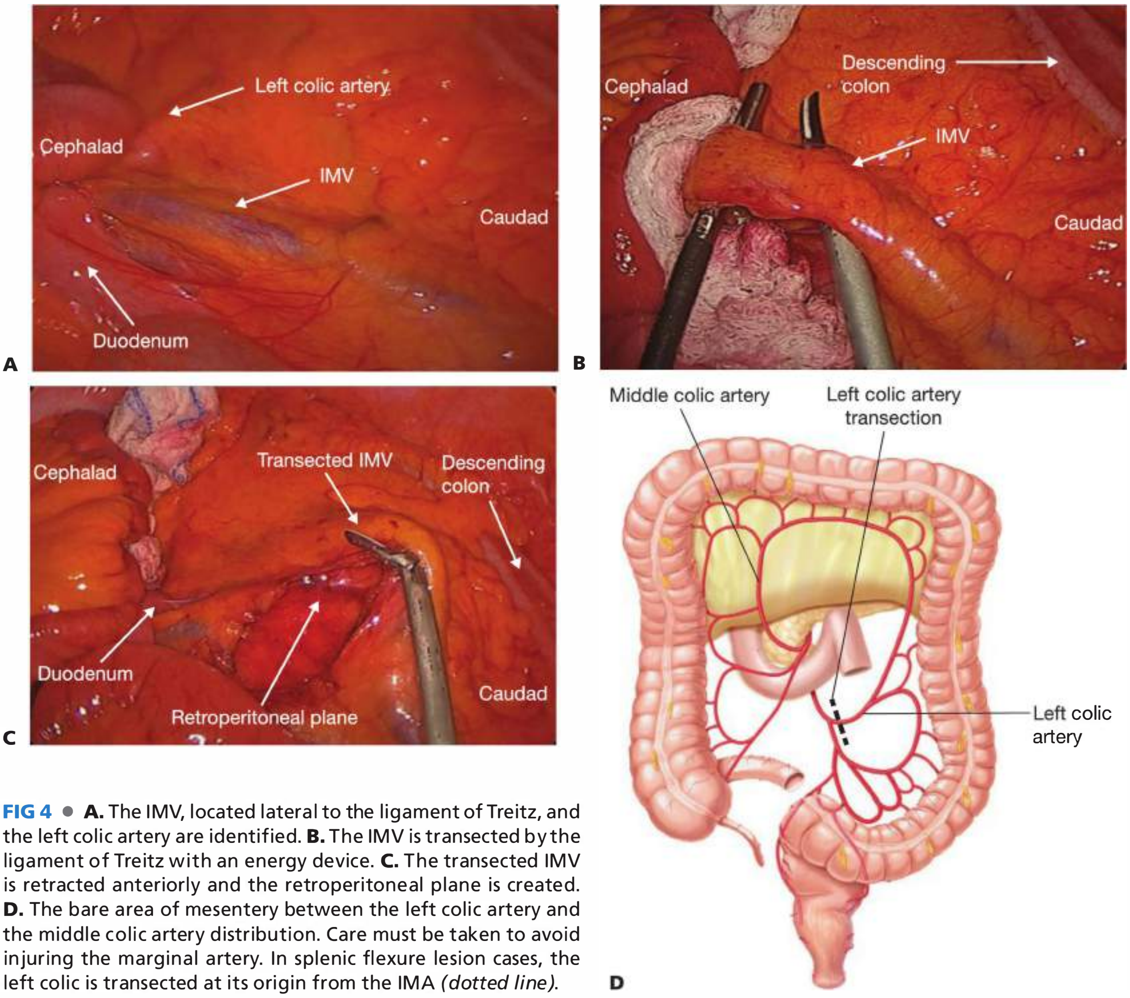

FIG 4 ● **A.** The IMV, located lateral to the ligament of Treitz, and the left colic artery are identified. **B.** The IMV is transected by the ligament of Treitz with an energy device. **C.** The transected IMV is retracted anteriorly and the retroperitoneal plane is created. **D.** The bare area of mesentery between the left colic artery and the middle colic artery distribution. Care must be taken to avoid injuring the marginal artery. In splenic flexure lesion cases, the left colic is transected at its origin from the IMA *(dotted line)*.

Step 3. Transection of the Left Colic Artery or the Inferior Mesenteric Artery

- Proceeding with the dissection caudally, the left colic artery can be readily identified branching off the IMA. For splenic flexure lesions, transection of the left colic artery at its origin of the IMA using an energy device or stapler provides an adequate lymphovascular pedicle (**FIGS 4D** and **5A**).
- Lesions located in descending colon frequently require inclusion of the sigmoid in the specimen, necessitating a high IMA transection to perform an adequate lymphadenectomy.
- In these patients, the mesodescending colon is dissected caudally until the left colic artery is appreciated and the retroperitoneal plane is created.
- The groove in between the superior hemorrhoidal artery (SHA) and the left iliac artery is identified. The surgeon elevates the SHA and incises the peritoneum under it using hot scissors or an energy device.
- The avascular retroperitoneal plane is swept down bluntly and the left ureter and gonadal vessels are identified and pushed posteriorly into the retroperitoneum. This retroperitoneal dissection plane is carried in a cephalad direction until all that remains between the superior and inferior dissections is the IMA.
- Lifting up on the IMA and its terminal branches, the SHA and the left colic artery will form what appears to be a letter "T" (**FIG 5A**). The IMA is then transected at its origin off the aorta with a vascular load stapler (**FIG 5B**).

Step 4. Medial to Lateral Dissection of the Descending Mesocolon

- The retroperitoneal plane, dissection of which was initiated during the IMV transection step, is now easily accessible. The surgeon completes dissection of this space, avascular plane, located between Gerota's fascia posteriorly and the descending mesocolon anteriorly, by holding the mesocolon up with a grasper while

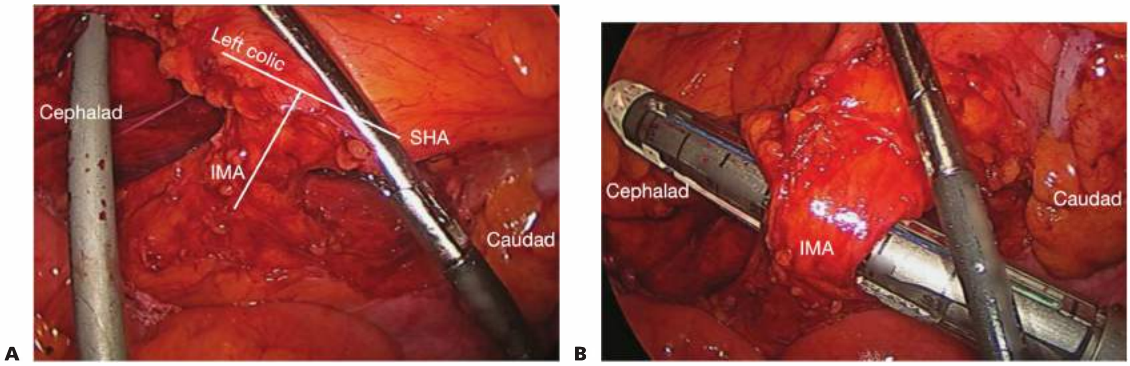

FIG 5 ● **A.** The "letter T." The IMA and its terminal branches, the SHA and the left colic artery, form what looks like a letter T. **B.** High IMA transection with linear vascular load stapler.

pushing the retroperitoneum down bluntly with an energy device (**FIG 6**). If needed, an additional 5-mm port is placed in the right upper quadrant for the assistant to help retract the mesocolon anteriorly.

- The retroperitoneal plane is continued until the abdominal wall is reached laterally and until the splenic flexure reached superiorly. The inferior extent of the retroperitoneal dissection depends on the location of the pathology. For lesions at the splenic flexure where the IMA has been left intact, the retroperitoneal dissection continues distally until further dissection is prohibited by the IMA. For lesions at the distal descending colon, where the IMA has been transected, the dissection continues until the pelvic inlet is reached.

Step 5. Transection of the Gastrocolic Ligament and Entrance to the Lesser Sac

- The transverse colon is retracted downward and the stomach is retracted superiorly, exposing the gastrocolic ligament. The gastrocolic ligament is then transected medially with an energy device until the lesser sac is entered.
- Transection of the gastrocolic ligament then proceeds along the distal transverse colon until the splenic flexure is reached (**FIG 6**). Care must be taken to avoid inadvertent injury to the colon.

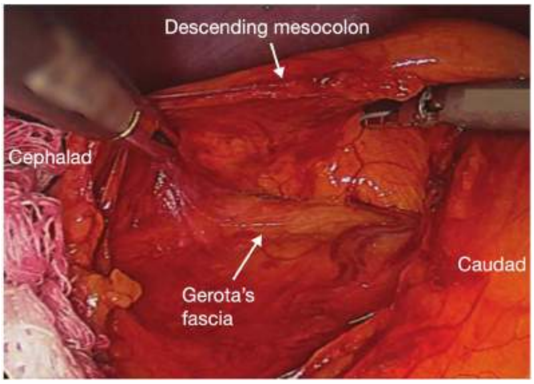

FIG 6 ● Completion of the medial to lateral dissection. The dissection proceeds in the plane located between the descending mesocolon anteriorly and Gerota's fascia posteriorly.

Step 6. Transection of the White Line of Toldt

- The descending colon is now only attached to the lateral abdominal wall by the lateral peritoneal attachments (the white line of Toldt). Medial retraction of the descending colon allows for good exposure of these lateral peritoneal attachments.
- Standing on the right side of the table, the surgeon then takes down the white line of Toldt using hot scissors.
- Alternatively, the surgeon can move in between the patient's legs, place a 5-mm port in the left lower quadrant, and transect the white line of Toldt moving up the left gutter, until reaching the splenic flexure of the colon.

Step 7. Splenic Flexure Mobilization

- The splenic flexure is now encountered. The patient is placed on a reverse Trendelenburg position, helping bring the splenic flexure into view.
- The surgeon and the assistant retract the splenic flexure inferiorly and medially, exposing the splenocolic and phrenocolic ligaments. These ligaments are then transected with a 5-mm energy device (**FIG 7**).
- The splenic flexure and descending colon are now completely free of any attachments and fully mobilized.

Step 8. Extracorporeal Resection and Anastomosis

- The pneumoperitoneum is evacuated and a 4- to 5-cm midline incision is made, centering on the Hasson trochar site at the level of the umbilicus.
- A small Alexis retractor is placed to protect the wound from infection and oncologic contamination. The colon is delivered into the operating field (**FIG 8A**). There should be no tension along mesenteric structures during the delivery of the specimen.
- The mesentery of the proximal and distal colon segment is taken in between clamps to the colonic wall. To ensure a well-vascularized anastomosis, the clamp is briefly taken off the marginal artery on the proximal colon side to ensure pulsatile flow.
- The proximal and distal margins are circumferentially cleared of excess fat and Kocher clamps are placed on the proximal and distal margins of the resection.

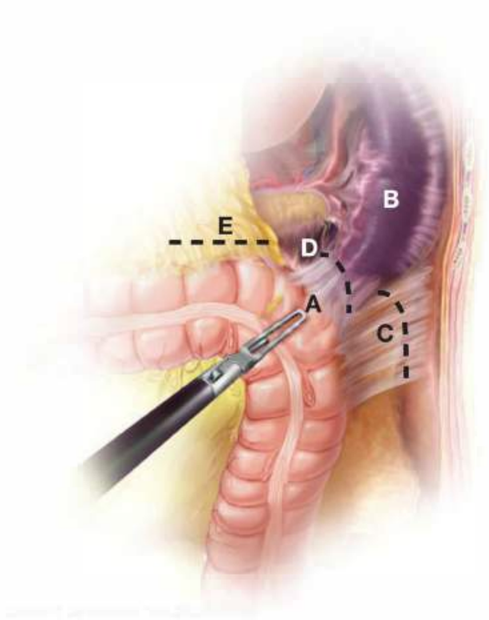

FIG 7 ● Mobilization of the splenic flexure. The phrenocolic *(C)*, splenocolic *(D)*, and gastrocolic *(E)* ligaments are transected. *A*, splenic flexure of the colon; *B*, spleen.

- A no. 10 blade scalpel is used to transect the proximal and distal colon and the specimen is passed off the field.
- Two Allis clamps are used to hold the proximal and distal colonic segments up. Using an Asepto and a poole sucker, the open colon ends are irrigated, suctioned, and cleaned of debris.
- The anastomosis is fashioned in a single layer with a running double armed 4-0 Maxon suture and placed back into the abdomen (**FIG 8B**).
- Once the anastomosis is delivered back into the abdominal cavity, the Alexis retractor is twisted and tied with umbilical tape around the Hasson port and the abdomen is reinsufflated to inspect the anastomosis (**FIG 8C**).
- The omentum is placed over the anastomosis. Closure of the mesenteric defect is not routinely performed.
- The 12-mm right lower quadrant port is closed with an inlet closure device, the 5-mm ports are taken out under direct visualization, and the abdomen is deinsufflated.

Step 9. Closure of Abdominal Wounds

- Gown and gloves are changed in an effort to prevent wound infections.
- Four clean towels are used to square off the surgical field.
- Separate closing instruments, suction, and Bovie tip are used.
- The abdominal fascia is closed with absorbable suture and the skin is closed with staples.

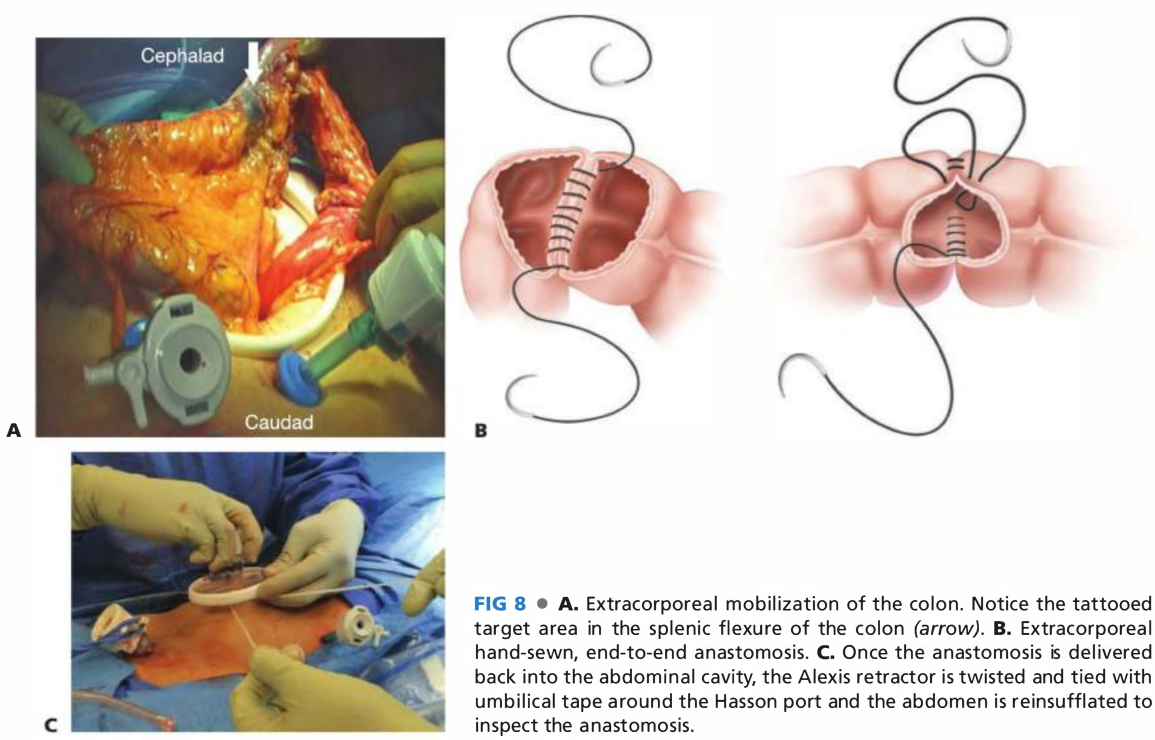

FIG 8 ● **A.** Extracorporeal mobilization of the colon. Notice the tattooed target area in the splenic flexure of the colon *(arrow)*. **B.** Extracorporeal hand-sewn, end-to-end anastomosis. **C.** Once the anastomosis is delivered back into the abdominal cavity, the Alexis retractor is twisted and tied with umbilical tape around the Hasson port and the abdomen is reinsufflated to inspect the anastomosis.

PEARLS AND PITFALLS

Preoperative imaging	■ Carefully review the CT scan as well as the colonoscopy report to determine whether the patient can be in a supine or lithotomy position. ■ Determine if ureteral stent placement will be necessary.
Positioning	■ Lithotomy position: Make sure that the legs are well padded to avoid injury to the lateral peroneal nerves.
Operative technique	■ The IMV at the ligament of Treitz is the "gateway" to the retroperitoneum. ■ Medial to lateral dissection of the retroperitoneal plane ■ Sweep ureter and gonadal vessels into the retroperitoneum. ■ Identify the letter T before IMA or left colic artery transection. ■ Facilitate splenic flexure takedown by placing a 5-mm left lower quadrant port and by standing in between the legs. ■ Make sure to free splenic flexure from all attachments to ensure full mobilization of the descending colon; this will ensure a tension-free anastomosis.
Pitfall: avoiding injury to the marginal artery	■ Once the IMV has been transected, the mesenteric bare area travels superiorly and medially about 1 cm from the lateral edge of duodenum until the middle colic is appreciated. Resist the temptation to continue toward the colon wall, resulting in injury to the marginal artery.
Pitfall: leaving retroperitoneal structures attached to the colonic mesentery	■ A common pitfall is to perform the retroperitoneal dissection one layer too deep, thereby leaving retroperitoneal structures (tail of the pancreas, left ureter, and gonadal vessels) attached to dorsal surface of the colonic mesentery. This could lead to serious injury of these structures while transecting the mesocolon. Additionally, this will significantly limit the mobility of the colon, which may result in anastomotic tension.
Pitfall: floppy descending or sigmoid colon	■ The lateral and splenic attachments are left for last. This allows the colon to be tethered up to the abdominal wall. If this colon still is not cooperative, place a 5-mm port in the right upper quadrant for the assistant to elevate the colon.
Pitfall: leaving the peritoneum of the lateral abdominal wall on the colon	■ Another location where it is easy to enter the wrong plane is during takedown of the lateral colon attachments. ■ The correct plane is immediately adjacent to the colon wall; stay medially during this phase of the dissection.

POSTOPERATIVE CARE

- An enhanced recovery after surgery (ERAS) pathway is used, which includes the following:
  - Deep vein thrombosis (DVT) prophylaxis with Lovenox starting in the morning of postoperative day (POD) 1
  - No additional antibiotics are required.
  - Pain control
    - Dilaudid patient-controlled anesthesia (PCA)
    - IV Tylenol scheduled q6h (first dose in the operating room [OR]); maximum dose: less than 4 g per day
    - IV Toradol scheduled q6h for 5 days if creatinine is normal, starting in the morning of POD 1
    - IV muscle relaxant (methocarbamol) scheduled q6h for 3 days
    - Discontinue PCA when patient tolerates oral intake well (usually late POD 1 or POD 2) and switch to Norco rather than Vicodin to decrease amount of acetaminophen administered.
  - Alvimopan (Entereg) is started preoperatively and continued twice a day until return of bowel function.
  - Only labs needed are hemoglobin/hematocrit (H/H) and basic metabolic panel (BMP) on POD 1 unless clinically indicated.
  - Diet
    - Patient leaves the OR without a nasogastric tube (NGT).
    - Okay for sips of clear liquids the evening of surgery
    - Clear liquids on POD 1 unless bloated
    - Advance diet to full liquid or soft diet on POD 2 unless bloated
    - Patient does not need to pass gas or have a bowel movement prior to advancing diet.
    - Be judicious with intravenous fluid (IVF).
  - Encourage early ambulation.
  - Foley: remove when patient begins walking, usually PODs 1 to 2.
  - Discharge: may discharge once patient has return of bowel function, usually PODs 3 to 4.

OUTCOMES

- Laparoscopic surgery leads to improvements in short-term outcomes, including a faster recovery, shorter hospital stay, and less pain.
- There is no difference in oncologic outcomes between laparoscopic and open surgery.

COMPLICATIONS

- Ureter injury: prevented by clear visualization of the retroperitoneal plane
- Sexual dysfunction (retrograde ejaculation) prevented by careful preservation of hypogastric sympathetic plexus located at the sacral promontory
- Wound infection: decreased incidence by careful attention to surgical technique
- DVT: prevented by initiating sequential compression device (SCD) therapy prior to anesthetic induction and timely initiation of pharmacologic prophylaxis.

Chapter **18**

Left Hemicolectomy: Hand-Assisted Laparoscopic Technique

Steven A. Lee-Kong   Daniel L. Feingold

DEFINITION

- Left hemicolectomy is typically defined as resection of the splenic flexure of the colon with its mesentery including the left colic artery and the left branch of the middle colic artery. This operation is most commonly performed for neoplasia and is, in general terms, a mirror image of a right colectomy whereby the colon is mobilized and the mesentery is dissected out and transected, allowing exteriorization of the loop of colon. During left colectomy for cancer, the left side of the greater omentum is usually resected en bloc with the colon. The straight laparoscopic approach to splenic flexure lesions can be challenging, especially in cases with a large neoplasm, colonic obstruction, or difficult splenic flexure ("extreme" flexure). In these circumstances, the hand-assisted laparoscopic surgery (HALS) approach to left colectomy may prove advantageous over a pure laparoscopic approach as it restores tactile sensation and improves retraction and exposure.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Prior surgical history can influence the approach to left colectomy
  - Prior colon resection
    - May affect remaining colonic blood supply and can influence the operative plan regarding what bowel segment will be used for the anastomosis
  - Extensive intraabdominal surgery
    - Extensive or dense adhesions may prohibit a minimally invasive approach.
    - Prior gastric or bariatric surgery can distort the anatomy and make for challenging dissection for left colectomy.
  - Abdominoplasty
    - May limit intraabdominal domain afforded by the pneumoperitoneum
- Morbid obesity or an abundance of intraabdominal adipose tissue may hinder a minimally invasive approach.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Contrast-enhanced cross-sectional imaging of the abdomen and pelvis is useful for planning the surgery in terms of accurate localization and in determining the site of the hand port. Imaging can also alert the surgeon of a potentially difficult splenic flexure takedown (extreme flexure, significant colon looping, bulky colon neoplasia adjacent to the spleen, etc.).
- Colonoscopy to evaluate the remaining colon. In addition, it allows to localize the target lesion with tattoos which is useful and facilitates a laparoscopic approach.

SURGICAL MANAGEMENT

Preoperative Planning

- Colonoscopy and pathology reports and relevant cross-sectional imaging should be reviewed.
- Intraoperative carbon dioxide (CO_2) colonoscopy should be available in the operating room for localization purposes (if necessary) as well as for assessment of the anastomosis, if needed.
- Mechanical bowel preparation facilitates intraoperative colonoscopy in cases where preoperative localization fails.
- In cases of neoplasia, the operative plan should be to perform a cancer operation regardless if the colonoscopy biopsies fail to demonstrate malignancy.

Positioning

- For HALS left colectomy, the authors prefer to use padded split-leg position with Ace wraps, securing the patient's legs to the operating room table (**FIG 1**). This allows the surgeon to stand between the patient's legs during the procedure. Split-leg positioning may be preferable to stirrups as the legs are maintained in a neutral position and pressure-related nerve injuries are minimized.
- The patient should be secured to the operating room table with a chest strap, as extreme positioning is often necessary.
- The right arm should be padded and tucked in a neutral position.

FIG 1 ● Patient positioning. We prefer a split-leg position to allow the surgeon to operate from between the legs and to minimize potential leg injuries.

ENTERING THE ABDOMEN AND INITIAL EXPOSURE

- A Pfannenstiel or lower midline incision is created for hand-port placement (**FIG 2**). A 5-mm camera port is placed in the supraumbilical midline and 5-mm working ports are placed in the right lower quadrant and left lower quadrant positions.
- In patients with prior abdominal surgery, laparoscopic access can be created by cut-down or Veress needle technique in a presumed safe location. This allows laparoscopic evaluation of abdominal wall adhesions, which can be lysed prior to creating the hand-port access. Alternatively, adhesions can be lysed in an open fashion through the hand-port incision; the surgeon's ability to perform adhesiolysis in this fashion may be limited. Inability to lyse these adhesions can jeopardize the laparoscopic approach.
- The patient is placed in steep Trendelenburg with the table tilted right side down.
- The greater omentum is draped over the transverse colon and liver. The small bowel is retracted out of the pelvis and toward the right upper quadrant of the abdomen, exposing the sigmoid and left colon mesentery (**FIG 3**).
  - A laparotomy pad placed intraabdominally through the hand port aides in the retraction of the small bowel and in maintaining exposure. This also facilitates cleaning the scope without having to remove the scope from the abdomen. To reduce the chance of a retained pad, a hemostat is placed on the surgeon's gown, signifying that a pad is in the belly. When the pad is removed (typically just prior to extraction), the hemostat is removed from the gown. If the surgeon goes to remove his or her gown with the hemostat still in place, the team is alerted that there may be a retained foreign body in the patient.
- A 30-degree angled scope is used at the discretion of the surgeon. Angled scopes enable the surgeon to look over the horizon (particularly useful in splenic flexure takedown) and improves laparoscopic access to the field by allowing the scope to be held away from the dissection.

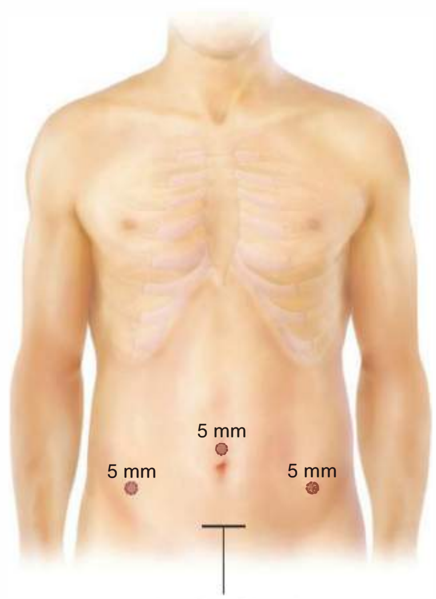

FIG 2 ● Ports, monitors, and team placement.

FIG 3 ● Left colon mesentery.

MESENTERIC DISSECTION, MEDIAL TO LATERAL

- Commonly, the sigmoid and its mesentery are mobilized in order to permit extraction and the creation of a tension-free anastomosis. In cases where this degree of mobilization is not required, these steps may be omitted.
- The surgeon stands at the patient's right hip and the assistant stands at the right shoulder holding the camera at the umbilicus. The inferior mesenteric artery (IMA) pedicle is elevated with the surgeon's right thumb and index finger (**FIG 4**) and is retracted toward the patient's left hip. The surgeon uses an energy device through the right lower quadrant port to dissect dorsal to the IMA and its superior hemorrhoidal terminal branch (**FIG 5**). The aortic bifurcation and common iliac arteries are appreciated prior to starting the dissection. The peritoneum beneath the pedicle is scored to the level of the sacral promontory.
- Palpating the right and left common iliac arteries located underneath the mesosigmoid and over the sacral promontory orients the surgeon (**FIG 6**).
- Care is taken to preserve the hypogastric nerves located dorsal to the superior hemorrhoidal vessels.

FIG 4 ● Grasping the IMA pedicle. The IMA and its terminal branch, the superior hemorrhoidal artery, are elevated off the retroperitoneum with the surgeon's right thumb and index finger.

- The retromesenteric plane is developed by sweeping the retroperitoneum down (dorsally) and elevating the mesentery (**FIG 6**). The plane is developed laterally toward the side wall, superiorly over Gerota's fascia and caudally toward the presacral space. As this is a relatively bloodless plane of dissection, bleeding is usually caused by injury to the overlaying mesentery or dissection into the floor of the space that is the retroperitoneum. Recognizing that you are not in the actual embryonic fusion plane allows you to adjust the dissection and reenter the correct plane.
- The left ureter and gonadal vessels are identified and preserved intact by sweeping these structures down into the retroperitoneum (**FIG 7**).

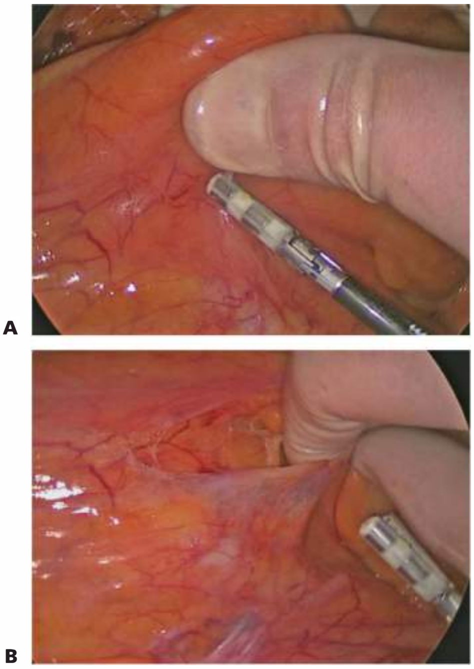

FIG 5 ● **A,B.** Scoring the peritoneum to enter the retromesenteric plane. The plane of dissection proceeds along the dorsal aspect of the superior hemorrhoidal vessels.

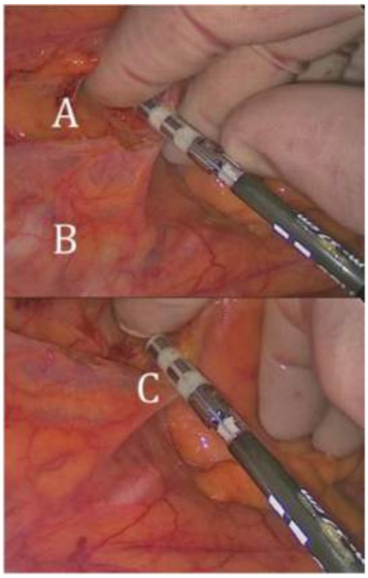

FIG 6 ● Palpating the right *(A)* and left *(B)* common iliac as well as the sacral promontory *(C)* helps orient the surgeon.

- With the hand supinated within the retromesenteric space, a mesenteric window is created between the main sigmoidal artery and the left colic artery. The takeoff of the left colic artery is then divided with the energy device (**FIG 8**) while ensuring the left ureter is preserved intact in the retroperitoneum. Tumor localization should be confirmed (by intraoperative colonoscopy, if needed) prior to vessel ligation.
- Once the left colic artery is transected, the retromesenteric space opens up, allowing further dissection in this plane laterally and cephalad. This dissection is carried along the plane located between the mesocolon and Gerota's fascia (**FIG 9**).
- The patient is then placed in slight reverse Trendelenburg position while the surgeon stands between the patient's legs and the assistant stands at the patient's right hip.

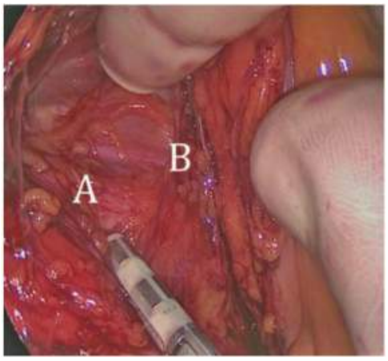

FIG 7 ● Retromesenteric dissection. The left ureter *(A)* and the left gonadal vessels *(B)* are identified and preserved intact in the retroperitoneum.

FIG 8 ● Dividing left colic artery.

- The assistant holds the camera and, using an atraumatic grasper through the right-sided port, retracts the left transverse colon cephalad. The surgeon orients himself by palpating the aorta and visualizing the ligament of Treitz (**FIG 10**). The surgeon, with his left hand in the abdomen and the energy device through the left-sided port, carefully enters the retromesenteric plane medial to the inferior mesenteric vein (IMV) by incising the peritoneum longitudinally along the medial aspect of the IMV (**FIG 11**). Care is taken to avoid injury to the small bowel in this dissection.

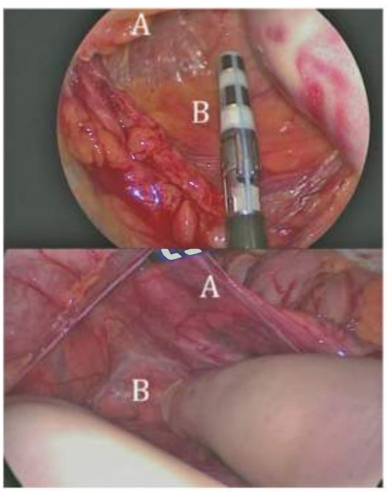

FIG 9 ● Further retromesenteric dissection. This dissection is carried along the plane located between the mesocolon *(A)* and Gerota's fascia *(B)*.

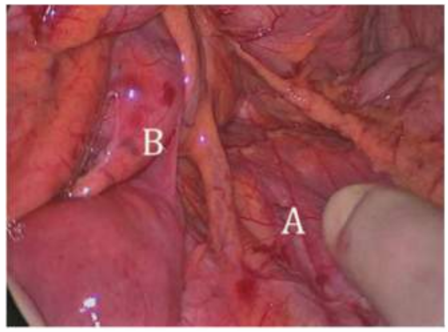

FIG 10 ● Medial to lateral dissection at the IMV. The surgeon orients himself by palpating the aorta *(A)* and visualizing the ligament of Treitz *(B)*.

  Taking down the ligament of Treitz and opening up the paraduodenal recess should be done with cold laparoscopic scissors to prevent thermal injury to the small bowel.
- The medial to lateral dissection at the IMV is the cephalad extension of the medial to lateral plane that had been already dissected at the level of the IMA. Elevating the colon mesentery off the retroperitoneum allows the two retromesenteric spaces to meet. When mobilizing the plane at the IMV, care should be taken not to enter the plane too deeply as this can injure the ureter or gonadal bundle.
- The IMV is then divided with the energy device at the cephalad extent of the dissection.
- The retromesenteric plane is then further developed cephalad to the inferior edge of the pancreas and laterally over the kidney to the splenic flexure.

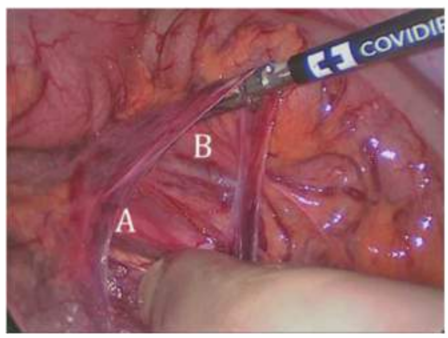

FIG 11 ● Medial to lateral dissection at the IMV. Care is taken to avoid injuring the left ureter *(A)* and gonadal vessels *(B)*.

SPLENIC FLEXURE MOBILIZATION

- The patient is placed in a steeper reverse Trendelenburg position; this delivers the plane of dissection closer to the hand port.
- The assistant retracts the greater omentum, and the surgeon's left hand applies countertraction to expose the bloodless plane between the omentum and the transverse colon (**FIG 12**). The omentum is released from the transverse colon and the lesser sac is entered at the midline. The dissection proceeds laterally, as far as possible, exposing the splenocolic ligament (**FIG 13**). The splenocolic ligament is then transected with the energy device.
- In cancer resections, the omentum adherent to the area of the cancer is resected en bloc. Care is taken to avoid injury to the short gastrics, stomach, pancreas, and spleen.

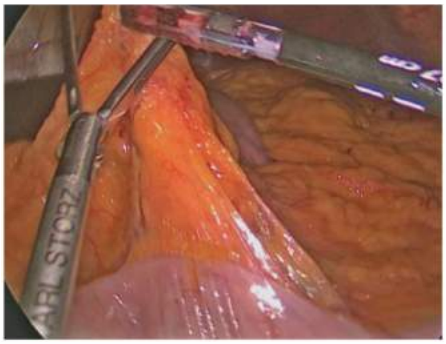

FIG 12 ● Splenic flexure mobilization. The assistant retracts the greater omentum while the surgeon retracts the transverse colon.

FIG 13 ● Mobilization of the splenic flexure: exposure of the splenocolic ligament. This ligament will be transected with the energy device.

LATERAL TO MEDIAL DISSECTION

- The descending colon has already been mobilized during the medial to lateral dissection of the mesocolon as described previously, and now the colon and is only tethered to the left gutter by the peritoneal attachments. Although the assistant retracts the colon medially by grasping an epiploic appendage, the surgeon releases the colon from the sidewall using the energy device (**FIG 14**). This dissection will immediately enter the retromesenteric dissection plane. Lateral dissection is continued superiorly until the lesser sac dissection is met and the splenic flexure is fully released.

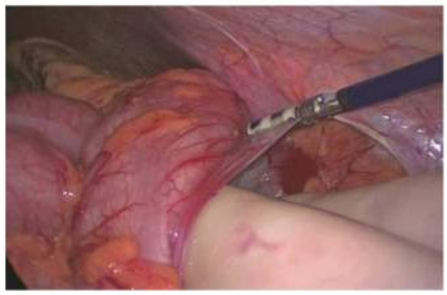

FIG 14 ● Lateral to medial dissection.

DISSECTION OF THE TRANSVERSE COLON MESENTERY

- The surgeon's supinated left hand underneath the mesentery exposes a clear space in the transverse mesocolon at the inferior border of the pancreas. Opening this mesenteric window facilitates the dissection to release the left transverse mesocolon from its retroperitoneal attachment (**FIG 15**). The transverse mesocolon is then transected with the energy device.
- The left branch of the middle colic artery is dissected out and divided at the base of the mesentery with the energy device. The anatomy of the middle colic artery is variable and more than one branch may need to be taken. The left colon is now fully mobilized (**FIG 16**).

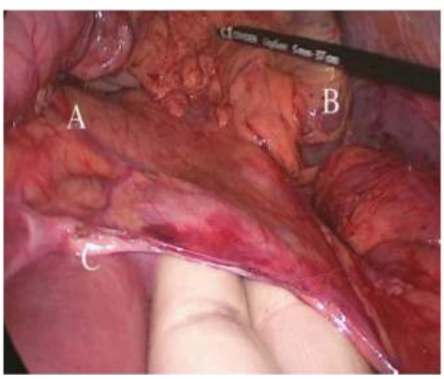

FIG 15 ● Dissection of the transverse colon mesentery. The transverse colon mesentery along the inferior border of the pancreas *(A)* between the spleen *(B)* and the ligament of Treitz *(C)* is exposed.

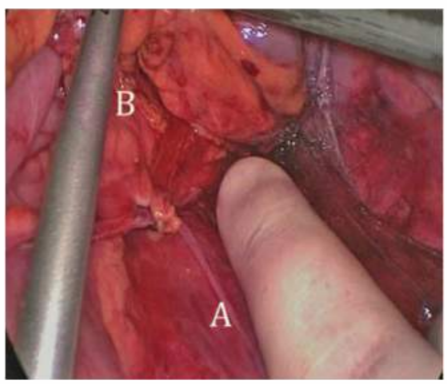

FIG 16 ● Full mobilization of the left colon is achieved. After complete mobilization of the left colon to the midline, Gerota's fascia *(A)* and the tail of the pancreas *(B)* can be visualized.

ASSESSMENT OF REACH

- Prior to exteriorization, the left upper quadrant is inspected and hemostasis is ensured. Each site of mesenteric vessel ligation is inspected as well.
- The intraabdominal laparotomy pad is extracted.
- The hand port is removed and, using a wound protector, the colon is exteriorized. Appropriate levels of transection are identified and the colon is divided with a linear stapler in open fashion, per usual. The specimen is oriented by a stitch to aide pathologic evaluation and is delivered off the field.
- Reach is assessed and no tension should be appreciated. If needed, the hand port can be replaced and further mobilization can be performed.

ANASTOMOSIS

- The anastomosis is created in stapled or hand-sewn fashion at the discretion of the surgeon (**FIG 17**).
- The authors advocate creating an omental pedicle laparoscopically (when possible) and draping this over the anastomosis.
- The mesenteric defect is broad and is not typically closed.

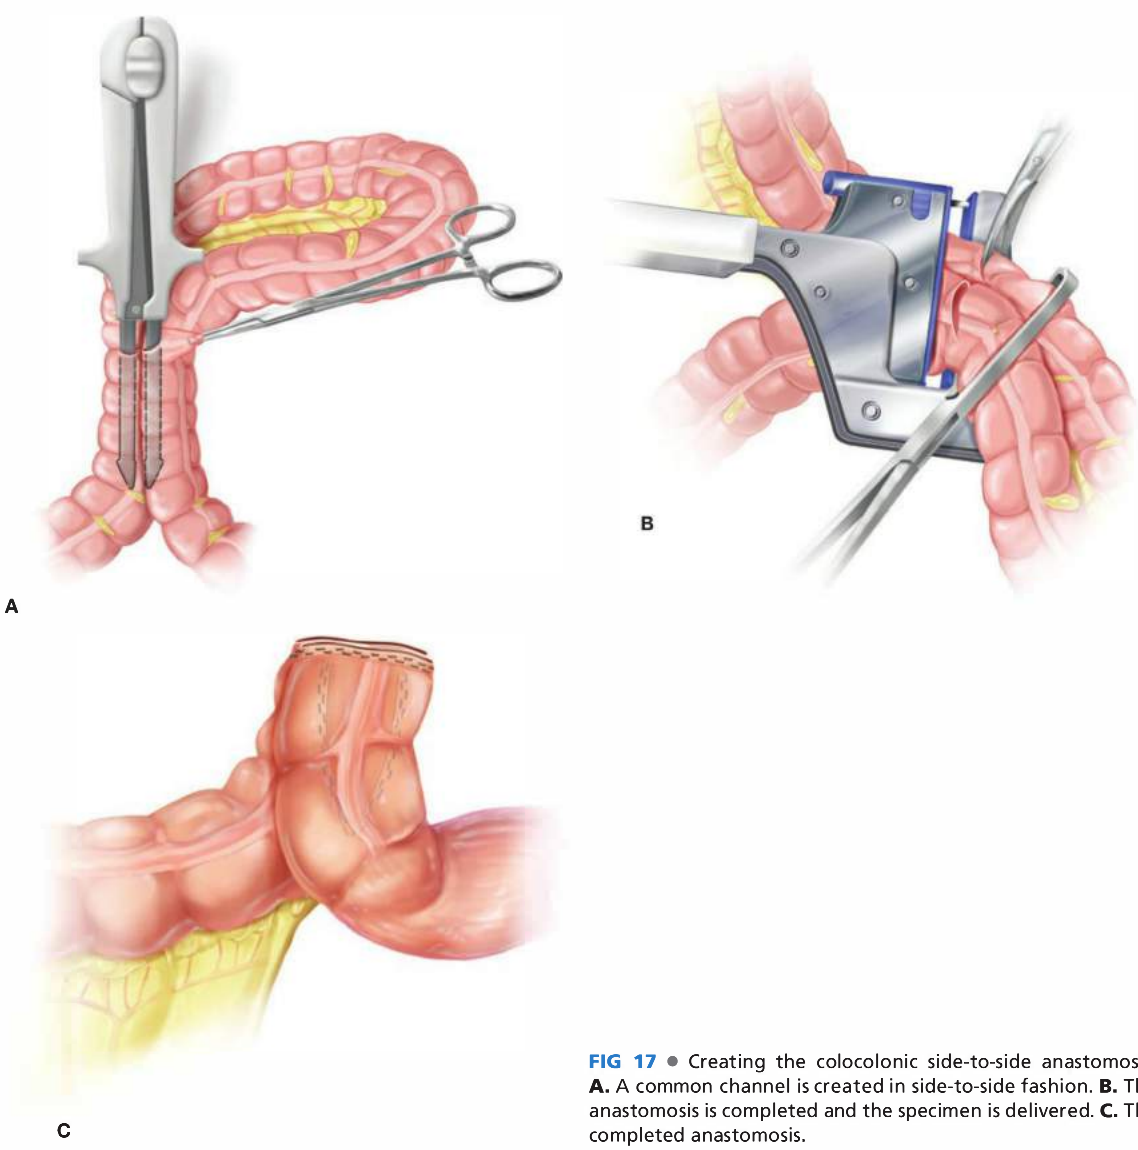

FIG 17 ● Creating the colocolonic side-to-side anastomosis. **A.** A common channel is created in side-to-side fashion. **B.** The anastomosis is completed and the specimen is delivered. **C.** The completed anastomosis.

PEARLS AND PITFALLS

Inadequate reach	Splenic flexure not completely released or transverse mesocolon not freed from inferior border of pancreas. The hepatic flexure may need to be released as well.
Inability to exteriorize the colon	Persistent attachments to the retroperitoneum or omentum need to be taken down.
Inability to identify left ureter	Retromesenteric dissection too deep into the retroperitoneum or the ureter is adherent to the mesenteric side of the dissection. Find the ureter at the level of the left colic artery instead of at the IMA.
Proximal colon ischemic after mesenteric division	Inadequate collateral colonic blood supply via the marginal artery requires further resection back to healthy colon.
Dissection not progressing	Place additional 5-mm working port(s) or convert to open procedure.
Poor access to the splenic flexure	Place patient in steeper reverse Trendelenburg and tilt the table left side up.
Splenic bleeding	Use the laparotomy pad to control the bleeding while the team prepares an energy device or absorbable hemostatic agents. Convert to open procedure if unable to achieve hemostasis.

POSTOPERATIVE CARE

- Remove the bladder catheter the morning after the operation to reduce the risk of urinary tract infections.
- Avoid immediate postoperative nasogastric tubes.
- Encourage early and progressive ambulation and pulmonary toilet.
- Use pharmacologic and mechanical deep vein thrombosis prophylaxis.
- Advance oral intake as patients tolerate rather than waiting for flatus or the first bowel movement.
- Maximize the use of nonnarcotic medications, when appropriate (ketorolac, acetaminophen, postprocedure transversus abdominis plane blocks) to help reduce narcotic use and minimize the incidence and duration of postoperative ileus.

OUTCOMES

- Minimally invasive colectomy is associated with shorter in-hospital convalescence and less narcotic use compared with open surgery.[1]
- For cancer resection, laparoscopic colectomy oncologic outcomes are similar to those of open resection.[1,2,3]
- Hand-assisted colectomy, as compared with straight laparoscopy, shortens operative times without increasing length of hospital stay or narcotic use.[4]

COMPLICATIONS

- Anastomotic dehiscence is a potential complication after any bowel anastomosis is created. This can be minimized by ensuring adequate blood supply and eliminating tension across the anastomosis.
- Extraction site wound infections can be minimized by using National Surgical Quality Improvement Program (NSQIP) approved protocols and wound protectors.

Chapter **19**

Sigmoid Colectomy: Open Technique

Wayne A.I. Frederick   Tolulope Oyetunji   Shiva Seetahal

DEFINITION

- A sigmoidectomy is the resection of the sigmoid colon to the level of the rectosigmoid junction. The extent of the lymphadenectomy will be determined by the indication (benign vs. malignant disease).
- Focal segmental sigmoid resection for benign disease can be accomplished by dividing the vessels close to the bowel wall, without the need for a high pedicle transection. A complete sigmoidectomy (described in this chapter) includes transection of the inferior mesenteric artery (IMA) at its origin and resection of the proximal superior rectal artery (SRA) and sigmoidal branches.

DIFFERENTIAL DIAGNOSIS

- Indications for sigmoidectomy include the following:
  - Sigmoid colon polyps and cancer
  - Diverticular disease (i.e., complicated diverticulitis, perforation, fistulae, etc.)
- Other indications include sigmoid volvulus, ischemic or infectious colitis, and trauma.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Most patients with early-stage colon cancer are asymptomatic, found on colonoscopy performed for screening purposes or secondary to a positive fecal occult blood test.
- Late-stage colon cancer can present with abdominal pain, unexplained weight loss, melena, iron deficiency anemia, or a change in bowel habits. Obstructive symptoms are typically secondary to circumferential tumors.
- Patients with uncomplicated diverticulitis report episodic pain in the left lower quadrant associated with fever, changes in bowel habits, and/or bloating.
- The spectrum of symptomatology for complex diverticulitis can be as benign as those for uncomplicated diverticulitis but can progress to localized or even generalized peritonitis.
- Patients with neoplastic or inflammatory erosion into adjacent organs, such as the bladder or vagina, can present with pneumaturia, fecaluria, or fecaloid vaginal discharge.
- A thorough family history of colon or rectal cancer, polyps, and/or other malignancies should be elicited.
- The physical examination should include the following:
  - Focused abdominal exam, including notation of abdominal scars
  - Digital rectal exam, focused on assessment of sphincter function
  - Rigid proctoscopy for all patients with sigmoid polyps or cancer reported by endoscopy to be within 20 cm from the anal verge. This will allow for confirmation of the site of the lesion, which oftentimes may not coincide with the endoscopy report. This information may alter the surgical and oncologic approach.
  - Rigid proctoscopy should not be performed in patients presenting with acute diverticulitis or perforation to avoid worsening of a microperforation by air insufflation.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Carcinoembryonic antigen (CEA): The baseline preoperative result and postsurgical control must be obtained as an assessment for complete tumor resection. On the other hand, the absolute presurgical value is an independent variable for survival.
- Abdominal computed axial tomography is the most sensitive and specific test for detection of intraabdominal metastases.
- Chest computed axial tomography is the most sensitive and specific test to detect mediastinal and lung metastases. It is also helpful in diverticulitis cases to evaluate for the extent of diverticular disease and for the possible presence of peridiverticular abscess, stricture, and/or fistula.
- Total colonoscopy: Regardless of the primary localization of the tumor, every patient should have a complete colonoscopy study whenever possible, because 2% to 9% of the patients may have synchronous tumors. The colonic enema with double contrast may be used in those patients in whom the colonoscopy is not possible.

SURGICAL MANAGEMENT

Preoperative Planning

- The patient should be mechanically bowel prepped the day before surgery with the GoLYTELY solution.
- The nil per os (NPO) status is then effective after midnight.
- The necessary radiologic and laboratory examination should be verified and reviewed accordingly.
- Patient should be consented appropriately for the procedure.
- We typically do not place preoperative stents for patients undergoing sigmoid colectomy for resolved diverticulitis. However, if there is any concern regarding potential difficulty in identification of the ureter, stenting should be considered.
- Appropriate intravenous antibiotic prophylaxis is given on induction.
- Consideration should be given to intravenous steroid supplementation if the patient is steroid dependent.
- Subcutaneous low-molecular-weight heparin is given on induction.
- A preoperative briefing with the entire surgical team is conducted. Items discussed include patient identification, type of surgery, type of anesthesia, expected events during the surgery, the need for blood components, prophylactic antibiotic, surgical devices availability, and potential adverse events and their prevention.

PATIENT POSITIONING AND OPERATING TEAM SETUP

- The patient should be placed in a standard supine position for induction of anesthesia.
- Following induction and securing of the endotracheal tube, a Foley catheter should be inserted.
- The patient is then placed in a low lithotomy position (**FIG 1**). Special care should be given to the positioning of the patient's legs in the stirrup devices; adequate padding and symmetrical positioning can minimize nerve injury.
- The arms should ideally be tucked at the sides with appropriate padding to afford the surgeons adequate space during the procedure and to prevent neurovascular injuries.
- Once the patient has been positioned and secured to the operating table, the rectum should be irrigated with saline solution using a piston syringe to evacuate remnant stool and bowel prep fluid.

FIG 1 ● Patient positioning. The patient is placed on a low lithotomy position, with the arms tucked to the side and the legs secured on Yellofin stirrups. Note that the thighs are parallel to the ground to prevent interference with the movement of the arms by the operating team. All pressure points are padded to prevent neurovascular injuries.

- The patient can then be cleaned and draped. The drape should have a cut-out section to allow for easy access to the perineum without disrupting the sterile field of the abdomen.
- The surgeon stands to the patient's right side, with his or her assistant standing to the patient's left side and with the scrub nurse standing to the surgeon's right side. A second assistant, if available, stands between the patient's legs (**FIG 2**).

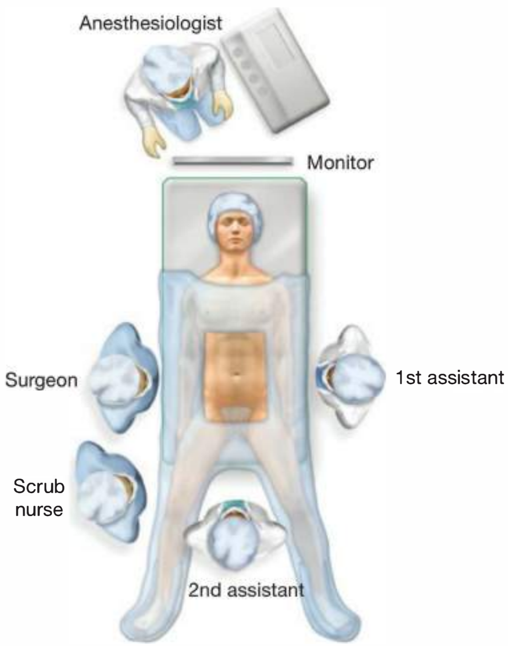

FIG 2 ● Operating team setup. The surgeon stands to the patient's right side, with his or her assistant standing to the patient's left side and with the scrub nurse standing to the surgeon's right side. A second assistant, if available, stands between the patient's legs.

LAPAROTOMY, INSPECTION, AND SURGICAL FIELD PREPARATION

- A midline incision from the umbilicus to the pubis is usually sufficient to begin the procedure. Additional access can be gained by extending the incision cranially toward the xiphoid process as necessary. Care should be taken to stay within the midline of the rectus sheath (linea alba) on opening.
- In patients with previous abdominal surgery, adherent bowel can complicate entry into the peritoneal cavity and meticulous dissection may be warranted. If possible, it might be easier to gain access into the abdomen by going above the previous scar where adhesions may be less tenuous.
- Upon entry into the peritoneal cavity, moist laparotomy pads placed around the wound edges can serve as wound protectors to reduce the likelihood of wound infection.
- A self-retaining retractor (e.g., a Balfour or Bookwalter retractor) can then be placed for adequate exposure.
- A careful and thorough examination of the abdominal cavity is critical. Evidence of metastatic disease or carcinomatosis must be appreciated before proceeding with the procedure. If present, these significantly impact both management and prognosis.
- The colon should be palpated in cases involving tumors to verify the position of the disease and assess the extent of resection. In procedures for diverticular disease, the state of the entire colon should be investigated, as this may impact the optimal scope of resection.
- Following inspection, if the decision is made to proceed, the small bowel should be eviscerated and packed to the right upper quadrant using a moist laparotomy pad or a moist towel to better facilitate exposure.

LATERAL TO MEDIAL MOBILIZATION OF THE LEFT COLON AND IDENTIFICATION OF THE LEFT URETER

- Once this has been confirmed, the supplying vessels and lymph basins should then be identified. Sigmoid colectomy usually entails resection of the sigmoid artery branches coming off of the IMA and the left colic artery with the accompanying lymph nodes that reside within that basin. The IMA or the left colic artery should be carefully identified along with the path of planned resection along the mesentery; the extent of the planned resection along the length of the sigmoid will dictate the degree to which the left colon must be mobilized.
- The patient is placed on a Trendelenburg position with the left side up to facilitate exposure.
- Mobilization of the colon is facilitated by retracting the sigmoid colon toward the midline.
- Using a combination of electrocautery and blunt dissection, release the lateral attachments of the sigmoid and descending colon by transecting the line of Toldt (FIG 3).
- Dissection along the line of Toldt should be largely bloodless, as this is an avascular plane. The dissection should then be extended both proximally along the descending colon toward the splenic flexure and also distally toward the rectosigmoid junction.
- The sigmoid and descending colon mesentery is separated from the retroperitoneum using a sharp lateral to medial dissection approach.
- At this point, care should be taken to identify the left ureter and gonadal vessels and ensure that they are kept intact in the retroperitoneum outside of the field of dissection (FIG 4A,B). In the lower abdomen, the left ureter is located medial to the gonadal vessels, close to the midline.
- Identification of the left ureter may be complicated in cases of diverticulitis where previous inflammation has created extensive adhesions. In such patients, preoperative placement of ureteric stents may be beneficial.

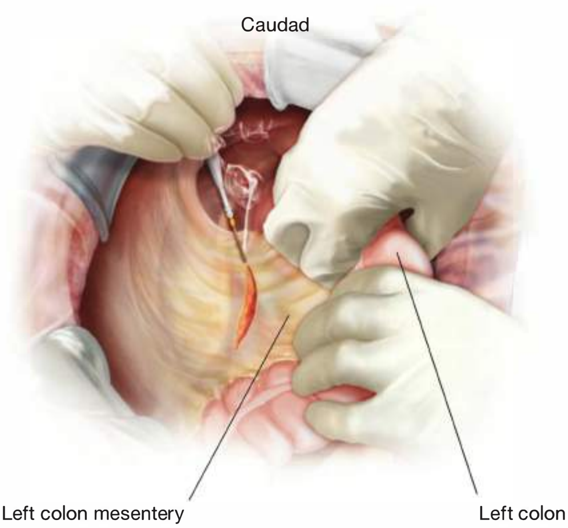

FIG 3 ● Lateral to medial mobilization of the left colon. With the sigmoid and descending colon retracted medially, the white line of Toldt is transected from the pelvic inlet to the splenic flexure.

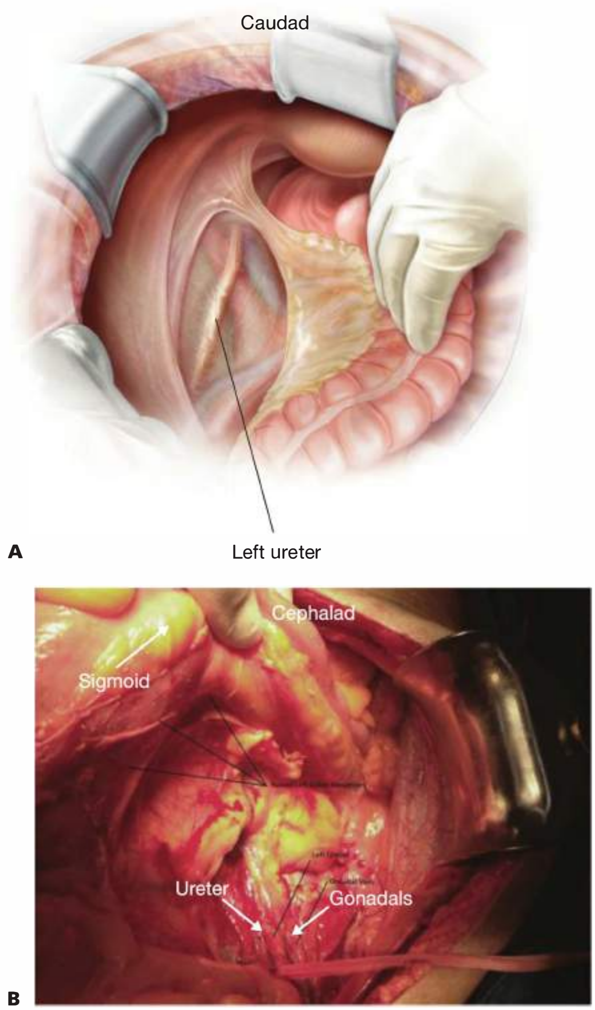

FIG 4 ● Exposure of the left ureter. The illustration **(A)** shows the view of the operative field from cephalad to caudad direction. The operative picture **(B)** shows a caudad to cephalad view of the field. In the lower abdomen, as the descending and sigmoid mesocolon are separated from the retroperitoneum by the lateral to medial dissection, the left ureter is located medial to the gonadal vessels, close to the midline.

MOBILIZATION OF THE SPLENIC FLEXURE

- Taking down the splenic flexure may be unnecessary on occasions with very redundant sigmoid but more often, it is required in order to achieve a tension-free anastomosis.
- This maneuver can be challenging, because the splenic flexure can have a very deep location in the left upper quadrant of the abdomen. Special attention should be afforded to this part of the operation, as troublesome bleeding from splenic capsular injury can be tricky. Splenic bleeding can usually be addressed using electrocautery, packing, or topical hemostatic agents.
- The lateral peritoneum sectioning is continued from the initial incision in a cephalic direction as far as possible, avoiding excessive traction of the splenic flexure in order to prevent splenic lacerations.
- The splenodiaphragmatic and splenocolic ligaments are transected with a monopolar scalpel or with a bipolar vessel-sealing device (**FIG 5**).
- The final approach to the splenic flexure should be complemented with another point of dissection that is initiated in the transverse colon to the left of the middle colic vessels. At this point, the gastrocolic ligament is transected, entering the lesser sac. The gastrocolic ligament is then transected from medial to lateral (**FIG 5**) with a monopolar scalpel or with a bipolar vessel-sealing device, until the lateral plane of dissection is reached.
- Finally, the attachments of the splenic flexure to the tail of the pancreas are divided with electrocautery. The left colon is now fully mobilized all the way to the midline.

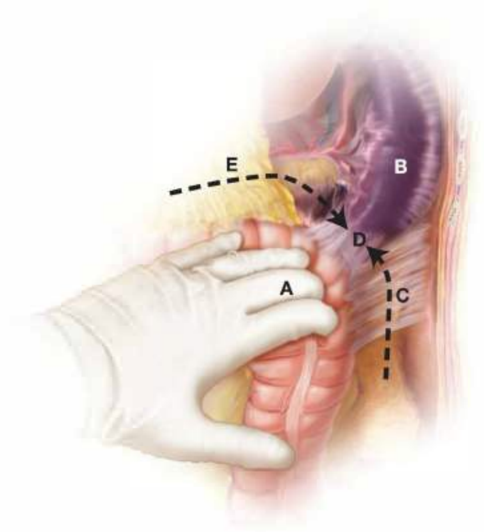

FIG 5 ● Splenic flexure mobilization. Mobilization of the splenic flexure. The surgeon retracts the splenic flexure of the colon *(A)* downward and medially, exposing the attachments of the splenic flexure to the spleen *(B)*. The phrenocolic *(C)* and splenocolic *(D)* ligaments are transected in an inferior to superior and lateral to medial direction. The gastrocolic ligament *(E)* is then transected in a medial to lateral direction until both planes of dissection meet and the splenic flexure is fully mobilized.

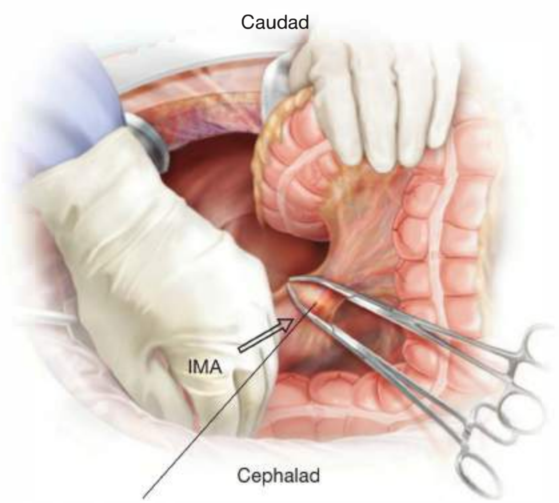
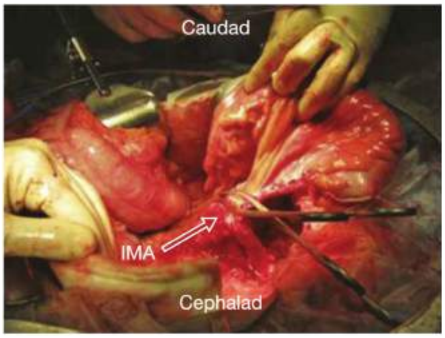
INFERIOR MESENTERIC ARTERY TRANSECTION

- With the assistant's two hands holding the proximal and distal sigmoid colon up, the root of the mesosigmoid colon is clearly visualized by the surgeon from the right side of the table. At the root of the mesentery, the arch of the superior hemorrhoidal vessels (SHV) can be seen and palpated.
- Placing the index finger behind the SHV arch allows the surgeon to incise with electrocautery the right surface of the peritoneum just under the dorsal surface of the SHV.
- This plane of dissection along the dorsal aspect of the SHV is carried distally over the promontory (leading into the presacral space) and proximally up to the origin of the IMA. The IMA is dissected circumferentially at its origin from the aorta.
- At this point, the colon mesentery is divided in between the sigmoid and descending colon with a vessel-sealing device, starting from the antimesenteric border and extending toward the origin of the IMA. The marginal arcade is transected along this dissection line close to the colon wall at the proposed anastomosis level.
- The IMA is then ligated between Sarot clamps, incised, and doubly ligated with braided 2-0 suture (**FIG 6A,B**). High IMA ligation allows for an excellent lymph node harvest.



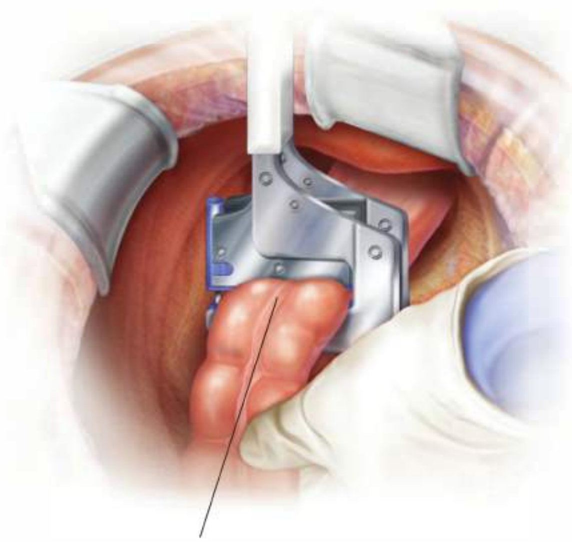


B

FIG 6 ● **A,B.** IMA transection. With the assistant holding the sigmoid colon up, the IMA is transected between clamps and will subsequently be ligated with heavy silk sutures.

COLON TRANSECTION

- Following mobilization of the left colon, the sigmoid colon can then be resected.
- We prefer to use the GIA staplers with 60-mm blue cartridges (3.1 mm) for the proximal transection. The proximal transection is performed between the sigmoidal and left colic vessel distribution, between the sigmoid and descending colon segments.
- For the distal transection, we typically employ the 90-mm transabdominal (TA) stapler to complete the resection. The distal transection is performed just distal to the rectosigmoid junction (FIG 7), which can be identified by the splaying of the tinea coli. The remaining specimen mesenteric attachments are transected with a vessel-sealing device.
- For diverticular disease, the extent of the proximal transection is variable, as it depends on the extent of diverticular disease. The distal transection, however, must always be distal to the rectosigmoid junction to ensure that there are no diverticular elements distal to the anastomosis.
- Once this part of the operation has been successfully completed, the specimen can be removed from the operative field and sent to the pathologist.



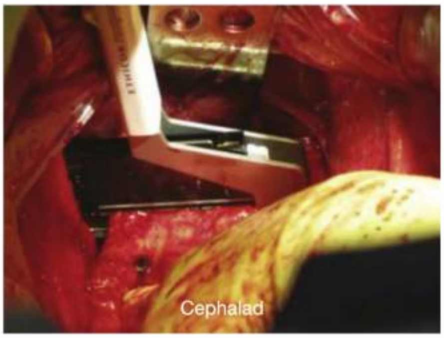


FIG 7 ● Distal specimen transection. The distal transection is performed with a 90-mm TA stapler just distal to the rectosigmoid junction, which can be identified by the splaying of the tinea coli.

ANASTOMOSIS

- There are two options for restoring intestinal continuity—hand-sewn versus stapled anastomosis. We favor a stapled anastomosis whenever possible.
- If a partial (subtotal) sigmoidectomy is all that is needed (as is the case sometimes in diverticulitis cases), then it may be feasible to perform a GIA stapled side-to-side colocolonic anastomosis in contiguity before transecting the specimen (**FIG 8A**). The anastomosis is then completed (and the specimen transected) with a TA stapler (**FIG 8B**).
- More commonly, however, when the entire sigmoid colon is removed, performing a colorectal anastomosis is best achieved by an end-to-end colorectal anastomosis using an end-to-end anastomosis (EEA) stapling device (**FIG 9**).
- The size of the stapler selected should be dictated by the caliber of the colon and rectum. If possible, a 28- to 29-Fr size is desirable to reduce the incidence of anastomotic strictures.
- The anvil of the stapler is placed in descending limb/colon via a colotomy and secured using a purse-string nonabsorbable suture, preferably a 3-0 nylon.
- One surgeon then moves to the patient's perineum and inserts the stapler into the rectum. The anal canal should be digitally dilated with lubricated fingers before inserting the EEA stapler.
- The anvil is then approximated with stapler under the guidance of the abdominal surgeon and is then fired.
- The perineal surgeon must then inspect the "donuts" from the stapler to ensure continuity; discontinuity must raise suspicion for an inadequate anastomosis and should warrant further inspection and possible interrogation of the anastomosis. We do not routinely test the anastomosis, but this may be achieved via transrectal instillation of methylene blue dye and/or air (**FIG 10**).
- Hand-sewn anastomosis is less common in the modern era, but it is a skill that should reside within the armamentarium of every general surgeon.
- We prefer to perform a double-layered closure starting with 3-0 Vicryl sutures full-thickness through the colon and rectal walls in a running fashion. This is followed by 3-0 Vicryl Lembert sutures through the serosa of the colon and adventitia of the rectum to buttress the anastomosis.
- In patients with a narrow pelvis, maneuvering may be difficult. Interrupted sutures should also be used to reinforce areas of potential leak or inadequate anastomosis following stapling. The main danger would be overzealous placement of sutures, leading to ischemia at the anastomotic tissue.
- The role of diverting colostomy or ileostomy has declined in recent years. These are rarely performed, except for cases where the integrity of the anastomosis is in question. This may include patients with positive leak tests on table or patients with risk factors for anastomotic breakdown such as steroid use or severe malnutrition. In patients whom a diverting ostomy is deemed prudent, we prefer a loop ileostomy owing to the relative ease with which these can be reversed later on.

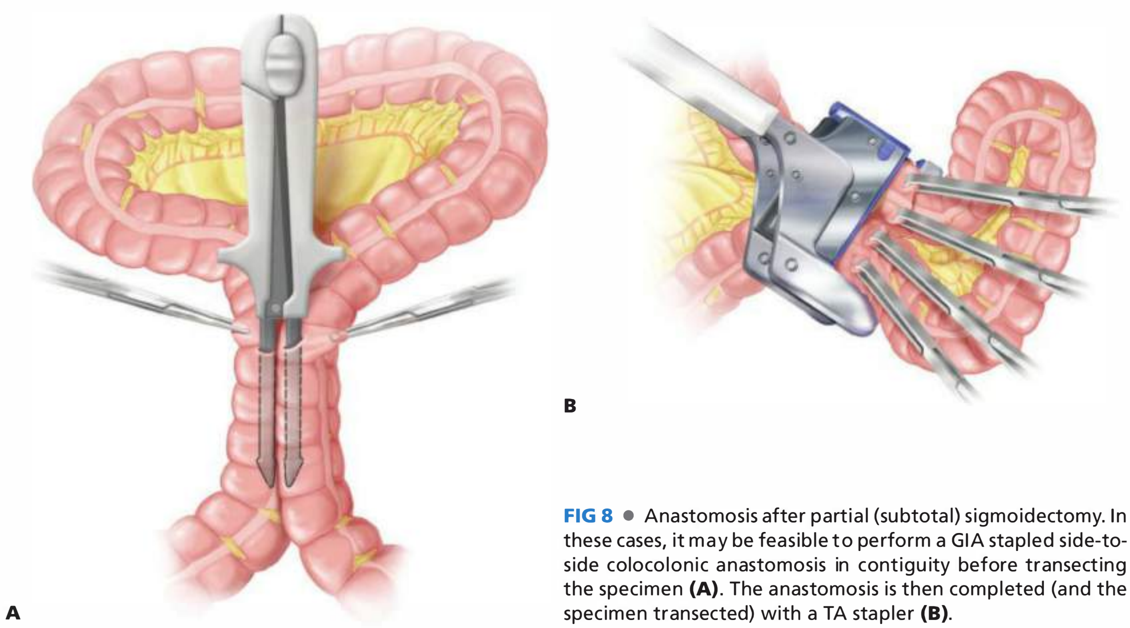

FIG 8 ● Anastomosis after partial (subtotal) sigmoidectomy. In these cases, it may be feasible to perform a GIA stapled side-to-side colocolonic anastomosis in contiguity before transecting the specimen **(A)**. The anastomosis is then completed (and the specimen transected) with a TA stapler **(B)**.

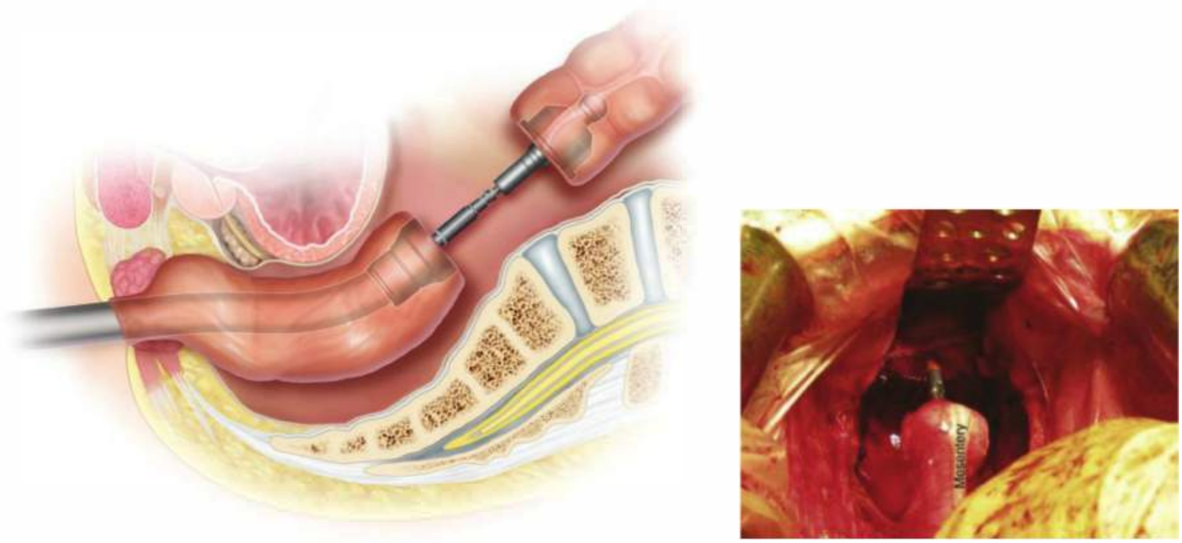

FIG 9 ● Anastomosis after a full sigmoid resection. An end-to-end EEA 29-Fr stapled anastomosis is performed.

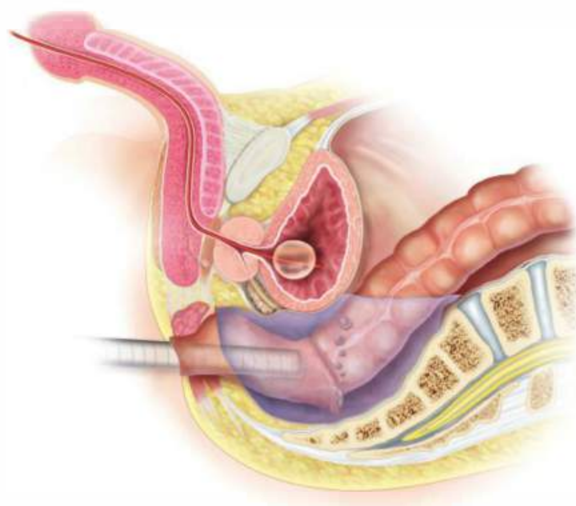

FIG 10 ● The anastomosis is then tested under water. The presence of air bubbles would indicate an anastomotic disruption, which necessitates a revision of the anastomosis.

CLOSURE

- Once intestinal continuity has been restored, a final inspection of the abdomen is usually sufficient before closure.
- All packs should be removed and counted and hemostasis should be complete before fascial closure.
- The fascia is best reapproximated using a running, double-stranded size 0 polydioxanone (PDS) suture.
- The skin can then be closed using skin staples.
- Dry dressings are adequate, although newer vacuum dressings are becoming popular owing to the preponderance for wound infections following colon surgery. We, however, still use the dry dressing and wound infection has not been a problem in our practice.

PEARLS AND PITFALLS

Localizing the target lesion	■ Preoperative colonoscopic tattooing greatly aids in the localization of the tumor intraoperatively. ■ If not available, on-table colonoscopy may be necessary.
Patient position	■ An improper position with hip flexion will make it difficult to maneuver during the whole procedure. Make sure the patient's thighs are parallel to the ground.
Identification of the left ureter	■ Identification of the left ureter is critical prior to vascular transection. ■ In difficult cases, stenting may help identify the ureter. ■ Stents do not decrease ureteral injury but aid in the intraoperative identification of the injury when it happens.
Splenic flexure mobilization	■ May not be necessary in cases with a very redundant sigmoid colon. ■ In most case, it is required to ensure a tension-free anastomosis.
Anastomosis	■ A tension-free anastomosis is the most critical element to prevent an anastomotic leak. ■ It is also paramount to preserve the proximal colonic blood supply intact (the marginal artery of Drummond) in order to have a healthy anastomosis.

POSTOPERATIVE CARE

- The Foley catheter is left in situ for 24 hours to assess fluid status and also because of the increase likelihood of urinary retention following surgery in the pelvis.
- A nasogastric tube is not routinely employed.
- The patient should be monitored closely until fully awake and stable.
- Clear fluids can be started on the evening of surgery.
- Early ambulation is essential.
- Pain control with patient-controlled analgesia or epidural analgesia is required.
- Antibiotics should be discontinued within 24 hours as per protocol.
- Pharmacologic venous thrombosis prophylaxis is instituted according to guidelines.

OUTCOMES

- The patient's prognosis depends on the tumor staging, which is determined by the histopathologic study of the specimen (pTNM).
- Many patients will require adjuvant chemotherapy according to the tumor stage.

COMPLICATIONS

- Wound infections
- Incisional hernias
- Urinary/sexual dysfunction: important to preserve hypogastric nerves and parasympathetic ganglia intact
- Ureteral injury: critical to identify the left ureter prior to IMA transection
- Anastomosis leak: It is critical to construct a well-vascularized, tension-free anastomosis.
- Deep vein thrombosis (DVT): lower risk with use of adequate DVT prophylaxis
- Cardiac and pulmonary complications
- Pelvic abscess: reduced incidence with placement of an omental pedicle flap in the pelvis
- Perineal wound breakdown is a notorious problem, especially in high-risk patients.

Chapter 20 Sigmoid Colectomy: Laparoscopic Technique

Arden M. Morris

DEFINITION

- Laparoscopic sigmoid colectomy is a laparoscopic procedure that involves complete or partial removal of the sigmoid colon most often with a primary anastomosis, which can be performed intra- or extracorporeally.

DIFFERENTIAL DIAGNOSIS

- Laparoscopic sigmoid colectomy is most often performed to treat colon cancer or diverticulitis but may also be performed to treat a benign neoplasm, which cannot be resected endoscopically, Crohn's or other fistulizing disease, intussusception, sigmoid volvulus, or other obstructive, inflammatory, or infectious conditions.

PATIENT HISTORY AND PHYSICAL FINDINGS

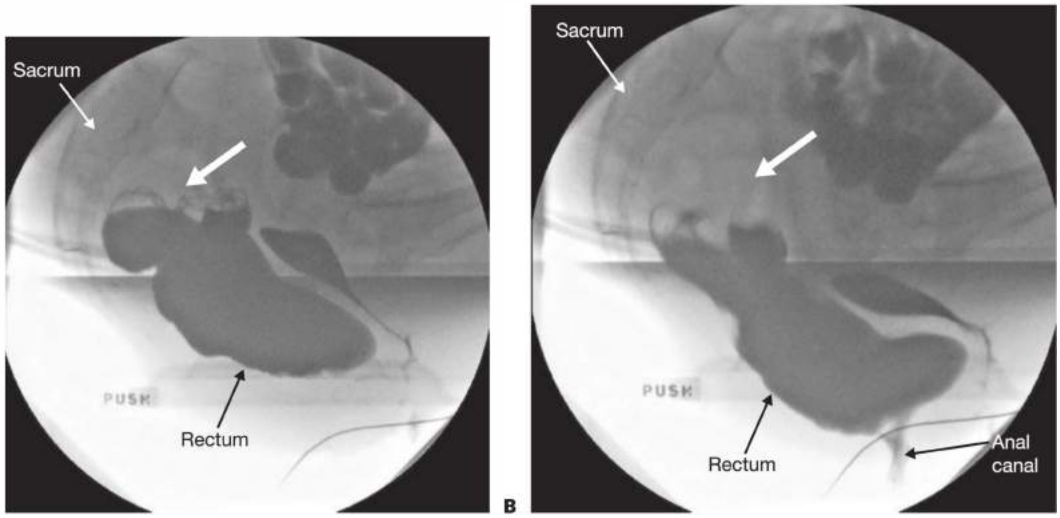
- A complete history should be tailored to the patient's primary diagnosis and should include a description of constitutional symptoms (nausea/vomiting, anorexia, weight loss or gain, fever, diaphoresis, fatigue), pain (site, quality, timing, inciting and relieving factors), dietary and bowel habits (constipation, diarrhea, frequency, continence, obstructive symptoms, bleeding), urinary habits, and sexual function.
- Physical exam includes a description of the presence and quality of distension, tenderness, guarding (voluntary or involuntary), rebound, and organomegaly. It is important to check carefully for evidence of a mass. For the sigmoid colon, this should be specifically checked by using one hand to elevate the left flank and the other hand to palpate the left lower quadrant between the iliac spine and the infraumbilical midline abdomen. The presence of involuntary guarding during this maneuver may indicate inflammation of the sigmoid colon consistent with acute or smoldering diverticulitis.
- A digital rectal exam must be performed preoperatively. The exam should include digital palpation of the coccyx, ischial tuberosities, and levators. The exam should include an assessment of sensation (anal wink), anal sphincter tone, and voluntary contraction (normal vs. diminished squeeze and normal relaxation vs. paradoxical puborectalis contraction with bearing down).

FIG 1 ● Axial CT scan of the pelvis with diverticulitis and extraluminal gas *(arrows)*.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- There are many options for preoperative diagnostic imaging. For suspected diverticulitis and/or other inflammatory or fistulizing disease, abdominal/pelvis computed tomography (CT) is the most effective means for diagnosis and operative planning. In addition, CT documentation of the presence of diverticulitis is particularly important in the event that the patient's symptoms do not abate postoperatively.
- For neoplastic disease, chest/abdomen/pelvis CT should be performed to identify possible metastases to identify the extent of the tumor if possible.
- Although CT with oral and rectal contrast is useful for both intra- and extraluminal assessment (**FIG 1**), a fluoroscopic examination with barium or water-soluble contrast enema is also useful to assess the bowel lumen especially if colonoscopy cannot be performed (**FIG 2**).
- In the case of rectal prolapse, defecography exam preoperatively can provide additional information about the extent of sigmoid colon intussusception and the presence of an enterocele or rectocele (**FIG 3**).
- Full colonoscopy should be performed preoperatively to assess the proximal colon and to tattoo the colon proximally and distally to neoplastic lesions (**FIG 4**).

FIG 2 ● Water-soluble contrast enema displaying a sigmoid volvulus *(block arrow)*. Notice the "omega loop" configuration of the sigmoid volvulus pointing to the right upper quadrant of the abdomen and the "bird's beak" narrowing at the entrance of the pelvis *(dashed arrow)*.



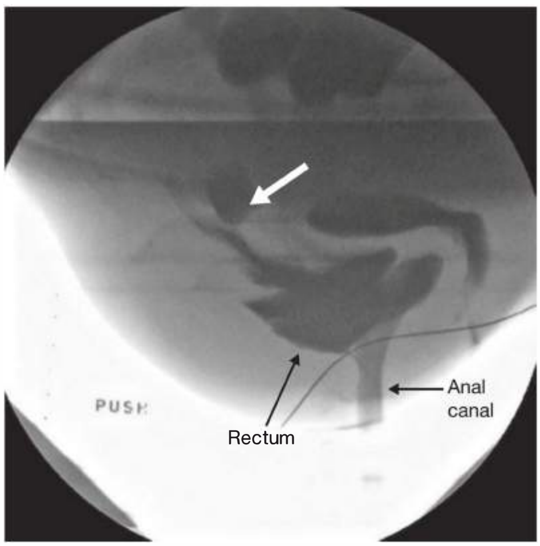


FIG 3 ● **A–C.** Defecography displaying redundant sigmoid progressively intussuscepting into the rectum *(block arrows)* and thereby causing obstructed defecation.

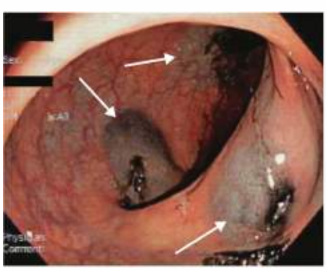

FIG 4 ● Colonoscopy with submucosal injection of India ink *(arrows)* to mark the area of concern prior to operation. The colon is injected in three separate locations distal to the target lesion in order to maximize intraoperative localization of the target lesion.

SURGICAL MANAGEMENT

Preoperative Planning

- Although the use of a full mechanical bowel preparation continues to be debated, at a minimum the sigmoid and rectum should be cleansed of stool using enemas the night before and morning of surgery in order to drive an anastomotic stapler through the rectum for reattachment. If a complete mechanical bowel preparation is undertaken, oral antibiotics should be included.
- Although use of laparoscopy has reduced risk of wound infections among patients undergoing colon surgery, risk of deep-space organ infections remains. Broad-spectrum intravenous antibiotics should be given within 30 minutes prior to the abdominal incision. Intraoperatively, antibiotic redosing should be discussed by the surgeon and anesthesiologist for any operation that lasts 4 hours or longer.

- Risk of deep venous thrombosis is increased among patients with a diagnosis or cancer or inflammatory bowel disease, patients who undergo abdominal or pelvic surgery, and those who have prolonged operations. Patients who undergo laparoscopic sigmoid colectomy fulfill several of these criteria and therefore are at substantially increased risk of venous thrombosis. To reduce this risk, sequential compression devices should be applied to bilateral lower extremities and initiated *preinduction*, when they are most effective at countering the effects of periinduction venous pooling. After induction, 5,000 units of heparin should be delivered subcutaneously.

Patient Positioning

- After endotracheal general anesthesia has been induced, the patient is placed in a split-leg or dorsal lithotomy position and secured in a beanbag, with careful attention to padding the extremities, tucking the right arm at the side, and lowering the thighs to be parallel to the floor if possible. If the hips are flexed, the thighs are higher than the abdomen and can hinder the laparoscopic dissection (**FIG 5**).
- Tape the patient across the chest over a towel to secure him or her to the operating room (OR) table.
- A urinary catheter is placed to decompress the bladder and assist with monitoring urine output during the operation. If the normal anatomic location of the left ureter has been compromised by previous surgery or by an inflammatory condition such as diverticulitis, which can shorten the mesentery and pull the ureter medially, then placement of a ureteral stent or a lighted ureteral stent should be considered.

FIG 5 ● Patient positioning. The patient is placed on a low lithotomy position with the legs on Yellofin stirrups. The thighs are positioned parallel to the ground to avoid conflict with the surgeon's arms. The patient is placed on a beanbag with both arms tucked and taped to the table over a towel. All pressure points are padded to prevent neurovascular injuries.

- An orogastric tube is placed to decompress the stomach.
- If the mechanical bowel preparation or preoperative enemas are inadequate, the surgeon should perform a rigid sigmoidoscopy to clear the rectum of stool after endotracheal general anesthesia has been induced.
- Most hospitals in the United States now require a robust time-out that includes a verbal statement of the patient's identification, diagnosis, medications and allergies, the planned procedure, and positioning, as well as the names and roles of the operating team and a list of necessary equipment and potential problems.

TECHNIQUES

PORT PLACEMENT AND OPERATING TEAM SETUP

- The surgeon stands to the patient's right side, with the scrub nurse next to him or her. The assistant stands to the left side of the table (**FIG 6**). Two monitors, facing the surgeon and the assistant, are used.
- A 12-mm umbilical incision is created sharply and extended to the level of the fascia. The fascia is elevated with 2-0 Vicryl tacking sutures and then opened sharply. The Hasson port is then placed within the peritoneal cavity and tacking sutures are pulled up and clamped. This will be used as the camera port.
- Insufflation with carbon dioxide (CO_2) at high flow is initiated to an appropriate pressure of approximately 14 mmHg.
- After inspection of the abdominal cavity with the laparoscope, three additional 5-mm working ports are placed under visualization in the right upper, right lower, and left lower quadrants of the abdomen (**FIG 7**).

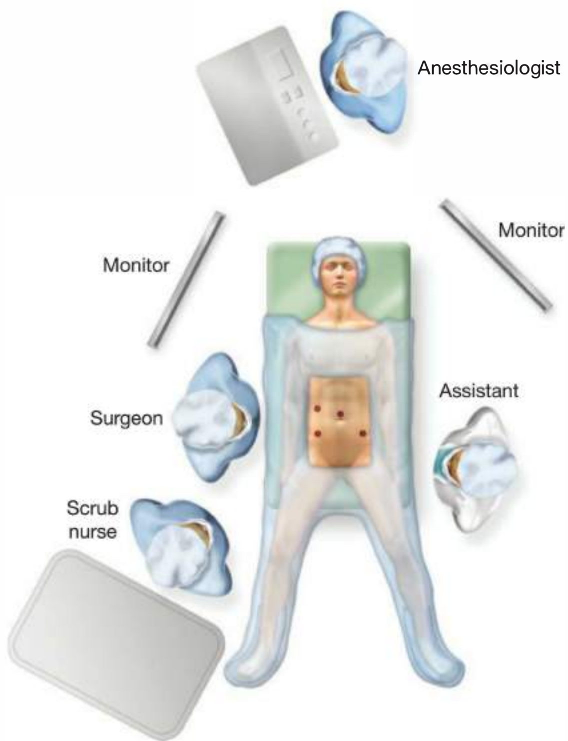

FIG 6 ● Operating team setup. The surgeon stands to the patient's right side, with the scrub nurse next to him or her. The assistant stands to the left side of the table. Two monitors, facing the surgeon and the assistant, are used.

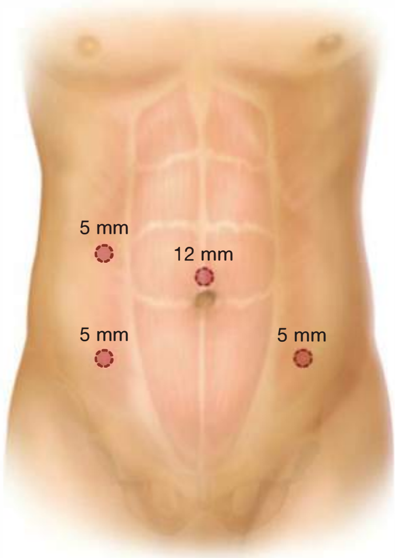

FIG 7 ● Port placement. A 12-mm camera port is inserted supraumbilically using a Hasson technique. After insufflation of the pneumoperitoneum, three additional 5-mm working ports are placed under visualization in the right upper, right lower, and left lower quadrants of the abdomen.

INFERIOR MESENTERIC ARTERY TRANSECTION

- The sigmoid colon is inspected and, if necessary, adhesions are lysed. The omentum and small intestine are retracted into the right upper quadrant and the operating table is rotated into Trendelenburg and right side down positions as needed for bowel retraction.
- The sigmoid colon is grasped broadly with a bowel grasper and elevated toward the anterior abdominal wall to expose the sacral promontory and the medial peritoneal fold (**FIG 8**). The peritoneum is incised below (dorsal) the inferior mesenteric artery (IMA) and its terminal branch, the superior hemorrhoidal artery (SHA).
- The dissection is continued from medial to lateral, beginning the separation of the mesocolon and the retroperitoneum, exposing the left ureter and gonadal vessels, which are identified and preserved intact in the retroperitoneum (**FIG 9**).
- The IMA is dissected circumferentially. Lifting up on the IMA and its terminal branches, the SHA and the left colic artery, will form what appears to be a letter "T" (**FIG 10**).
- The IMA is then transected at its origin off the aorta with a vascular load stapler (**FIG 11**) or an energy device.
- The mesentery of the colon is then transected with an energy device, from the IMA stump up to the colon wall, at the level of the planned proximal transection (typically between the sigmoid and descending colon).

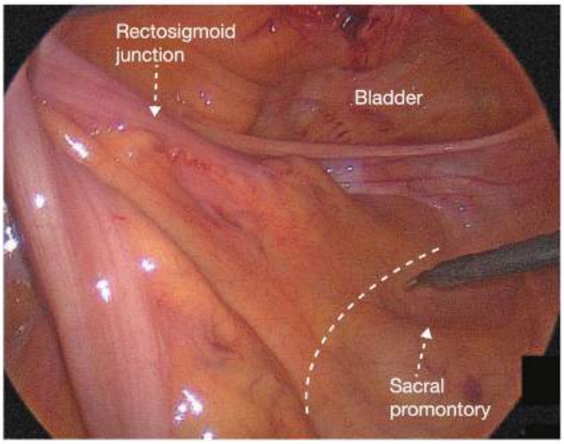

FIG 8 ● Vascular pedicle dissection. The sigmoid colon is pulled toward the anterior abdominal wall, tenting out the base of its mesentery peritoneum at the sacral promontory. The peritoneum is incised along the root of the mesocolon *(dotted line)*, dorsal to the IMA/SHA arteries, across the promontory, and toward the right posterolateral cul-de-sac.

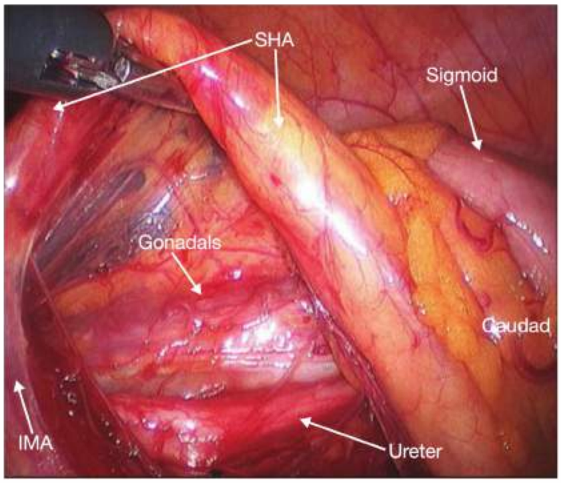

FIG 9 ● Identification of the ureter. With the SHA, distal to its origin of the IMA, tented up toward the anterior abdominal wall, the mesosigmoid is separated from the retroperitoneum. This exposes the left ureter and gonadal vessels, which are identified and preserved intact in the retroperitoneum.

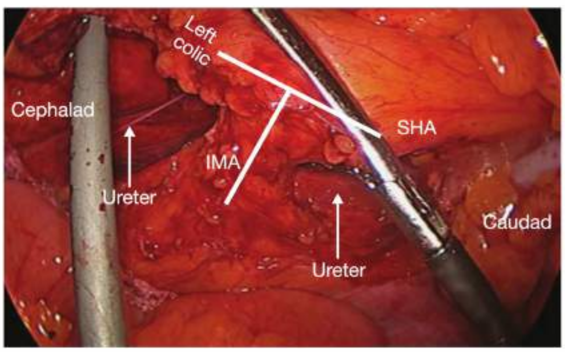

FIG 10 ● The IMA is dissected circumferentially. Lifting up on the IMA and its terminal branches, the SHA and the left colic artery will form what appears to be a letter "T." The ureter can be seen safely preserved in the retroperitoneum.

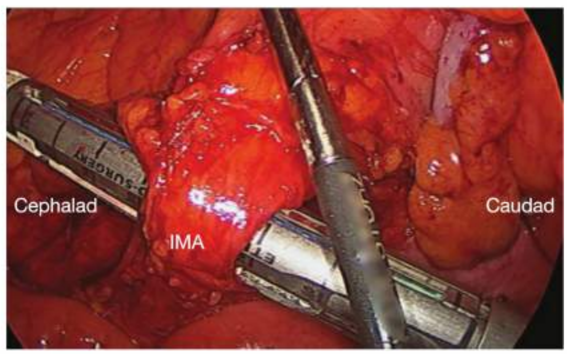

FIG 11 ● IMA transection. The IMA is then transected at its origin off the aorta with a vascular load stapler.

MEDIAL TO LATERAL MOBILIZATION

- The sigmoid and descending mesocolon are dissected off the retroperitoneum via a medial to lateral approach (**FIG 12**).
- With the assistant helping hold the mesocolon up, the surgeon gently dissects along the transition between the two fat planes (Gerota's fascia in the retroperitoneum, dorsally, and the mesocolon, ventrally).
- This dissection is carried laterally to the lateral abdominal wall, inferiorly to the level of the pelvic inlet and superiorly until you separate the tail of the pancreas from the posterior aspect of the splenic flexure. Completion of this step will greatly facilitate all subsequent steps of this operation.
- The left ureter and gonadal vessels should be identified and preserved intact in the retroperitoneum.

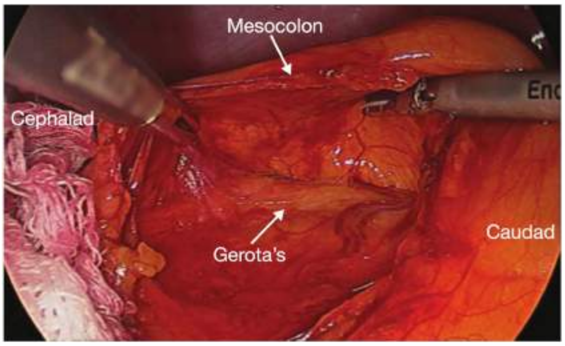

FIG 12 ● Medial to lateral mobilization. The sigmoid and descending mesocolon are dissected off the retroperitoneum via a medial to lateral dissection approach. With the assistant helping hold the mesocolon up, the surgeon gently dissects with an energy device along the transition between the two fat planes (Gerota's fascia in the retroperitoneum, dorsally, and the mesocolon, ventrally). This dissection is carried laterally to the lateral abdominal wall, inferiorly to the level of the pelvic inlet, and superiorly until you separate the tail of the pancreas from the posterior aspect of the splenic flexure. Completion of this step will greatly facilitate all subsequent steps of this operation.

DIVISION OF THE LATERAL PERITONEAL ATTACHMENTS AND MOBILIZATION OF THE SPLENIC FLEXURE

- After completing the medial to lateral portion of the descending colon mobilization from the sacral promontory to the splenic flexure and over Gerota's fascia, the lateral sigmoid colon retroperitoneal attachments are divided with scissors (**FIG 13**) and/or an energy device.
- The splenic flexure is now encountered. Full mobilization of the splenic flexure (**FIG 14**) is often needed in order to ensure a tension-free anastomosis.
- The patient is placed on a reverse Trendelenburg position, helping bring the splenic flexure into view.
- The surgeon and the assistant retract the splenic flexure inferiorly and medially, exposing the splenocolic and phrenocolic ligaments. These ligaments are then transected with a 5-mm energy device (**FIG 15**) in an inferior to superior and lateral to medial fashion.
- At this point, it is often easier to start the transection of the gastrocolic ligament medially, entering the lesser sac and proceeding with the transection of the gastrocolic ligament in a medial to lateral dissection (**FIG 14**) until the lateral dissection plane around the splenic flexure is encountered.
- The splenic flexure and descending colon are now completely free of any attachments and fully mobilized toward the midline.
- Mobilization of the splenic flexure is greatly facilitated by having completed the medial to lateral mobilization of the splenic flexure in the previous step.

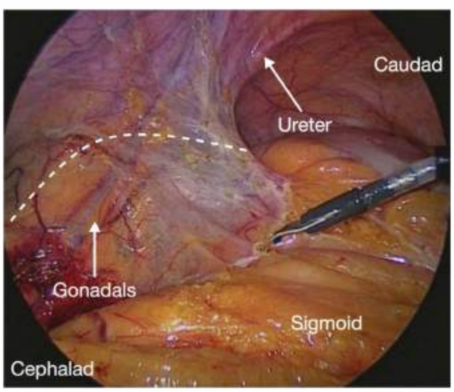

FIG 13 ● Lateral sigmoid colon mobilization. The lateral retroperitoneal attachments of the sigmoid colon are divided *(dotted line)*, readily entering the previous medial to lateral dissection plane. The left ureter and gonadal vessels are visualized in the retroperitoneum.

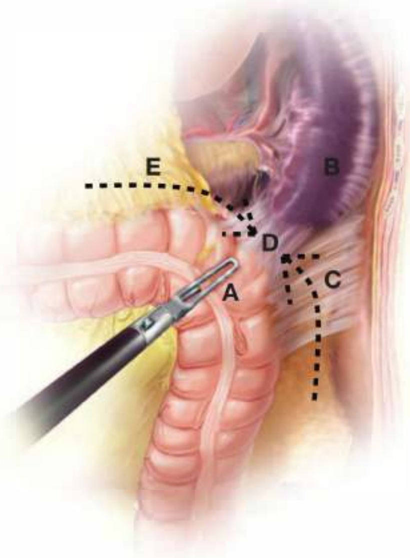

FIG 14 ● Mobilization of the splenic flexure. The surgeon retracts the splenic flexure of the colon *(A)* downward and medially, exposing the attachments of the flexure to the spleen *(B)*. The phrenocolic *(C)* and splenocolic *(D)* ligaments are transected in an inferior to superior and lateral to medial direction. The gastrocolic ligament *(E)* is transected in a medial to lateral direction until both planes of dissection meet and the splenic flexure is fully mobilized.

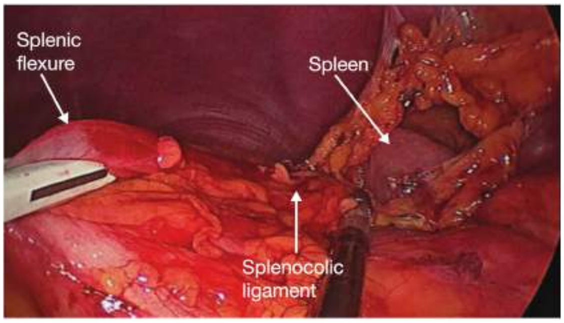

FIG 15 ● Mobilization of the splenic flexure: transection of the splenocolic ligament.

DIVISION OF THE SIGMOID COLON

- An endostapler is inserted into the 12-mm port and used to divide the sigmoid colon distal to the rectosigmoid junction (**FIG 16**), which can be identified by the splaying of the tinea coli.

FIG 16 ● Distal transection. An endostapler is inserted into the 12-mm port and used to divide the sigmoid colon distal to the rectosigmoid junction.

- The abdomen is desufflated, the umbilical port is extended to a 4-cm incision, and a wound protector is placed.
- The sigmoid colon is grasped at its transected distal end and pulled through the 4-cm incision to an appropriate location on the descending colon for the proximal side of the anastomosis.
- If an end-to-end colorectal anastomosis will be constructed, a bowel clamp and purse-string device are applied to the descending colon, which is divided to permit removal of the sigmoid colon. The anvil for a size 31-mm end-to-end anastomosis (EEA) stapler is placed in the descending colon and the purse string is drawn up snugly and tied.
- If a side-to-end anastomosis will be constructed, the descending colon is transected between clamps; the anvil of the EEA stapler device is inserted through the open distal end of the colon and the anvil (with a spear attached to it) is delivered through the antimesenteric aspect of the descending colon approximately 5 cm from the opened distal end. The distal end is closed with a linear stapler.
- The sigmoid colon is removed from the field.

CREATING AND TESTING THE ANASTOMOSIS

- The colon end with the anvil in place is dropped back into the abdomen and the fascial incision is closed. Insufflation with CO_2 is reinitiated.
- With laparoscopic visualization, an EEA stapler is inserted through the anal canal and into the rectum. When the stapler reaches the proximal-most portion of the rectum, the spike is advanced through the rectal wall adjacent to the staple line.
- A grasper is used to remove the spike from the stapler shaft. The spike must be carefully placed in a uniform location in order to avoid losing it within the peritoneal cavity. Using graspers, the spike and anvil are then married (**FIG 17A**) and the EEA stapler is closed and deployed (**FIG 17B**). The stapler is then removed from the anal canal and the anastomotic donuts are inspected. Two intact donuts should be observed. The spike is removed from the abdomen.
- To test for leakage, the anastomosis is covered with sterile saline and the proximal colon is gently compressed. A rigid or flexible sigmoidoscope is inserted through the anal canal and into the rectum, insufflating the rectum with air until it escapes the anal canal. The staple line is carefully inspected for evidence of air bubbles (**FIG 18**). When no air bubbles are seen, the rectum is desufflated and the sigmoidoscope is removed. Air bubbles would indicate an anastomotic leak and would necessitate either revision of the anastomosis and/or performance of a proximal diverting ostomy, depending on the severity of the leak as well as on patient and operative circumstances.

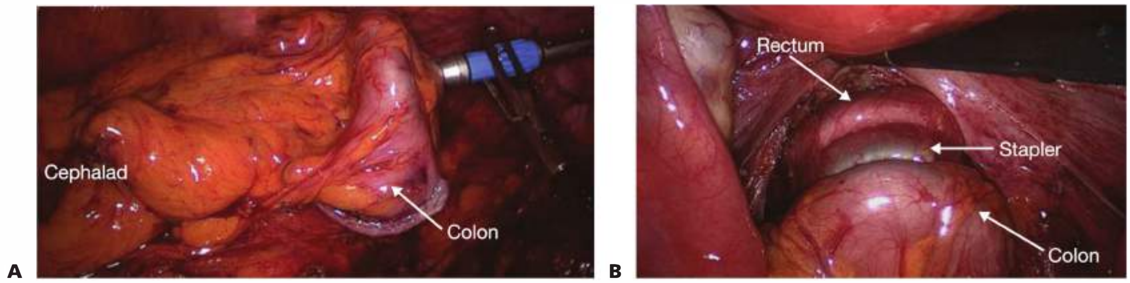

FIG 17 ● Intracorporeal stapled anastomosis: A side-to-end stapled EEA is constructed. Using graspers, the spike (rectal side) and anvil (colon side) are married (**A**) and the EEA stapler is closed and deployed (**B**), creating the anastomosis.

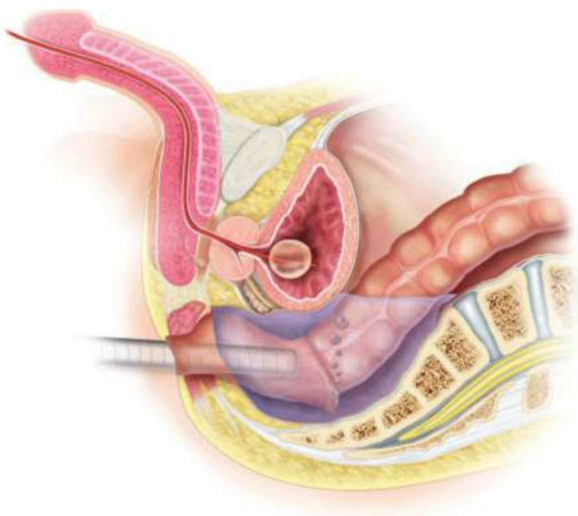

FIG 18 ● Air leak test. The completed colorectal anastomosis is tested under water. Air bubbles identified during insufflation of the anastomosis indicate an anastomotic leak.

WOUND CLOSURE

- Port sites are closed at the skin in the preferred manner.
- The umbilical fascia closure is inspected and completed if necessary. Subcutaneous tissue is irrigated with sterile saline and skin is closed as desired.

PEARLS AND PITFALLS

Preoperative planning	■ For any neoplastic lesion, use of preoperative colonoscopic tattoo can help to avoid resecting the incorrect colon segment. ■ This practice is particularly important for laparoscopic resection as the colon cannot be palpated prior to the first division.
IMA division	■ The nerve plexus adjacent to the IMA takeoff is associated with sexual function in males. Therefore, the dissection should proceed directly beneath the pedicle and extend laterally. ■ Patients should be informed preoperatively that even with great care, it is possible to injure the nerves, which may lead to impaired sexual function.

Anastomosis	▪ In some cases, mobilization for a tension-free anastomosis will be facilitated with extra port placement. For example, an additional suprapubic 5-mm port can greatly assist visualization during the mesenteric dissection toward the splenic flexure. ▪ If the descending colon is in spasm or if it is difficult to insert a size 31-mm stapler anvil, the bowel can be relaxed with administration of 0.5 to 1 mg intravenous glucagon in the absence of hypotension. ▪ Careful attention to the location of spike placement is of utmost importance. The most common site for placement is the left gutter just distal to dissection. The spike should be removed from the abdomen prior to the air leak test.
Avoiding ureteral injury	▪ The ureters must be carefully visualized after the initial mesentery division and again during division of the lateral peritoneal attachments. If there is a concern for ureteral injury, intravenous indigo carmine should be administered, followed by a search for extravasation of blue dye.

POSTOPERATIVE CARE

- The orogastric tube and any ureteral stents should be removed prior to awakening the patient from anesthesia. Within 24 hours of surgery, the urinary catheter should be removed.
- Persuasive evidence indicates that an enhanced recovery program of limited intraoperative intravenous fluids, early postoperative ambulation, early feeding, and minimization of narcotic pain medication can lead to a more rapid recovery and earlier discharge. Such early discharge has not been associated with increased risk for readmissions.

OUTCOMES

- Functional outcomes after laparoscopic sigmoid colectomy may include reduced pain and spasms prior to bowel movements if the patient suffered from an obstructive or inflammatory diagnosis.
- Although many patients report defecatory urgency and increased frequency in the 30-day postoperative period, in most cases the urgency resolves and frequency declines after 4 to 6 weeks.

COMPLICATIONS

- Peroneal nerve injury (positioning)
- Ureteral injury
- Postoperative bleeding
- Wound infection
- Anastomotic leak
- Anastomotic stenosis
- Sexual dysfunction
- Bowel dysfunction (urgency and frequency)

Chapter **21**

Hand-Assisted Laparoscopic Sigmoidectomy

Daniel A. Anaya   Daniel Albo

DEFINITION

- A sigmoidectomy is the resection of the sigmoid colon to the level of the rectosigmoid junction. The extent of the lymphadenectomy will be determined by the indication (benign vs. malignant disease).
- Focal segmental sigmoid resection for benign disease can be accomplished by dividing the vessels close to the bowel wall, without the need for a high pedicle transection. A complete sigmoidectomy (described in this chapter) includes transection of the inferior mesenteric artery (IMA) at its origin and resection of the proximal superior hemorrhoidal artery (SHA) and sigmoidal branches.
- A hand-assisted laparoscopic (HAL) sigmoidectomy approach uses a hand access port to aid with the dissection and resection. This approach increases the use of minimally invasive surgery, reduces conversion rates, and decreases operative times while maintaining all the short-term outcome advantages when compared to conventional laparoscopic surgery.

DIFFERENTIAL DIAGNOSIS

- Indications for sigmoidectomy include the following:
  - Sigmoid colon polyps and cancer
  - Diverticular disease (i.e., complicated diverticulitis, perforation, fistulae, etc.)
  - Other indications include sigmoid volvulus, ischemic or infectious colitis, and trauma.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with sigmoid pathology can be asymptomatic, with abnormalities found during screening colonoscopy.
- The most common symptoms are bleeding (occult/anemia or overt), obstruction, and pain.
- The initial history should include the following:
  - Time course of presenting symptoms, including bleeding, constipation, and pain
  - Presence/absence of rectal incontinence
  - History of sexual function (erection and ejaculation for males, dyspareunia for females)
  - Information regarding associated urologic symptoms such as recurrent urinary tract infections, dysuria, pneumaturia and/or fecaluria, which suggest a possible fistula with the urinary tract
  - Presence of systemic symptoms such as fever and weight loss
  - Previous surgical history, specifically regarding abdominal and/or pelvic surgery
  - Personal and/or family history of prior colon cancer/polyps, inflammatory bowel disease, diverticular disease
- The ***physical exam*** should include the following:
  - Focused abdominal exam, including notation of abdominal scars
  - Digital rectal exam, focused on assessment of sphincter function
  - Rigid proctoscopy, for all patients with sigmoid polyps or cancer reported by endoscopy to be within 20 cm from the anal verge. This will allow for confirmation of the site of the lesion, which oftentimes may not coincide with the endoscopy report. This information may alter the surgical and oncologic approach.
  - Rigid proctoscopy should not be performed in patients presenting with acute diverticulitis or perforation to avoid worsening of a microperforation by air insufflation.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- A complete colonoscopy should be performed to rule out synchronous disease.
- For cancer and/or polyps, a tattoo must be placed just distal to the lesion at three different points within the circumference to allow for intraoperative localization of the target.
- A computed tomography (CT) of the abdomen and pelvis is obtained to rule out adjacent organ involvement, to evaluate for extraluminal complications (e.g., abscess, fistula), and to rule out metastatic disease in patients with cancer. A CT of the chest completes the metastatic workup.
- A carcinoembryonic antigen (CEA) level is obtained in all cancer cases.

SURGICAL MANAGEMENT

Preoperative Planning

- An informed consent, including discussion of the need for a possible ostomy, is obtained.
- We do not routinely ask patients to complete a formal bowel preparation. Fleet enemas are prescribed to facilitate the performance of the anastomosis.
- All patients should receive preoperative prophylactic antibiotics, following published guidelines. We administer 1 to 2 g of ertapenem within 1 hour of surgical incision.
- Pharmacologic deep vein thrombosis (DVT) prophylaxis should be given to patients perioperatively, based on current recommendations and guidelines.

Patient Positioning and Operating Room Setup

- Proper patient position and operating room (OR) setup is critical for successful performance of minimally invasive surgery (**FIG 1**).
- The patient is placed in a modified lithotomy position using Yellofin stirrups with the heels firmly planted in the stirrups.
- Pressure-bearing areas in the calf and lateral legs are padded to prevent DVT and lateral peroneal nerve injury.
- The patient's toes, knee, and contralateral shoulder are aligned.
- The thighs are placed parallel to the ground to prevent conflict with the surgeon's arms.
- The patient's buttocks are placed at the edge of the table to allow for smoother introduction of the end-to-end anastomosis (EEA) stapler at time of reconstruction.

FIG 1 ● Patient and OR setup. The patient is placed in a modified lithotomy position with the thighs parallel to the floor and the arms tucked. The patient is secured to the OR bed using a chest tape-over-towel technique.

- Both arms are tucked at the sides, with padding added to protect against nerve injuries.
- The patient is taped to the table across the chest over towels to avoid slipping.
- All laparoscopic elements (CO_2 line, camera, light cord) exit through the right upper side. All energy device cords exit through the upper left side. This allows for a clutter-free working space for the operative team.

Team Positioning and Draping

- The patient is prepped with chlorhexidine and draped to facilitate easy access to the perineum.
- The surgeon stands at the patient's right lower side, with the assistant to his or her left side and the scrub nurse to his or her right side (FIG 2).
- Two monitors are placed in front of the team at eye level on the patient's left side.

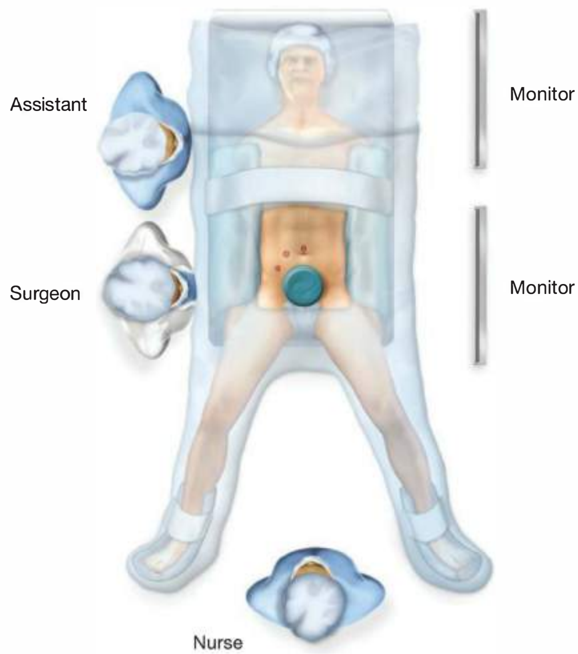

FIG 2 ● Team and monitor setup. The surgeon stands at the patient's right lower side with the assistant to his or her left and the scrub nurse to his or her right. The monitors are placed in front of the team at eye level.

PORT PLACEMENT

- Insert the GelPort through a 5- to 6-cm Pfannenstiel incision. This incision will be also used for specimen extraction. It results in better cosmesis, lowers the incidence of wound infections and hernias, and allows for more working space between the hand and the instruments.
- Ports: Insert a 5-mm working port in the right upper quadrant (RUQ), a 12-mm working port in the right lower quadrant, and a 5-mm camera port above the umbilicus. These three ports are triangulated, with the camera port at the apex of the triangle. This setup avoids conflict between instruments and camera and prevents disorientation (avoids "working on a mirror") (FIG 3).

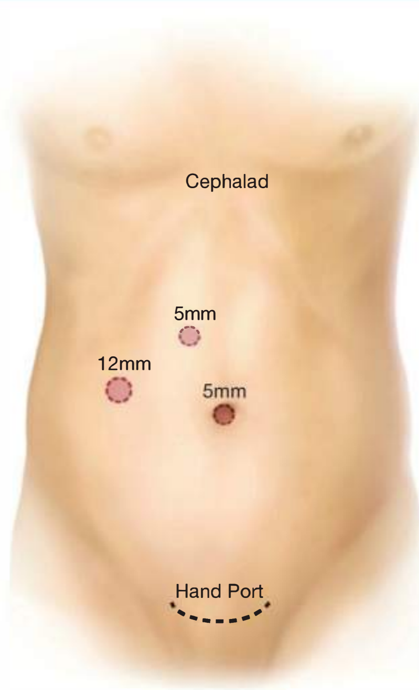

FIG 3 ● Port placement. The hand port is inserted through a 6-cm Pfannenstiel incision at the projected extraction site. A 5-mm camera port is inserted supraumbilically. A 5-mm and a 12-mm working port are inserted in the right upper and right lower quadrants, respectively.

OPERATIVE STEPS

- Our HAL sigmoidectomy operation is highly standardized and consists of nine steps:
  - Transection of the inferior mesenteric vein (IMV)
  - Transection of the IMA
  - Medial to lateral dissection of the descending mesocolon
  - Sigmoid colon mobilization off the pelvic inlet
  - Descending colon mobilization
  - Mobilization of the splenic flexure
  - Intracorporeal distal transection
  - Extracorporeal proximal transection
  - Intracorporeal anastomosis

Step 1. Transection of the Inferior Mesenteric Vein

- This is the critical "point of entry" in this operation. We favor it over starting at the IMA level due to the IMV's constancy in location, the ease of its visualization by the ligament of Treitz, and the absence of structures that can be harmed around it (no iliac vessels or left ureter nearby). This will be the only time during the operation when a virgin tissue plane is entered. Every step will set up the following ones, opening the tissue planes sequentially.
- The patient is placed on a steep Trendelenburg position with the left side up. Using the right hand, move the small bowel into the RUQ and the transverse colon and omentum into the upper abdomen. If necessary, place a laparotomy pad to hold the bowel out of the field of view, especially in obese patients. This pad can also be used to dry up the field and to clean the scope tip intracorporeally. Make sure the circulating nurse notes the laparotomy pad in the abdomen on the white board.
- Identify the critical anatomy: IMV, ligament of Treitz, and left colic artery (FIG 4).
- If there are attachments between the duodenum/root of mesentery and mesocolon, transect them with laparoscopic scissors. This will allow for adequate exposure of midline structures.

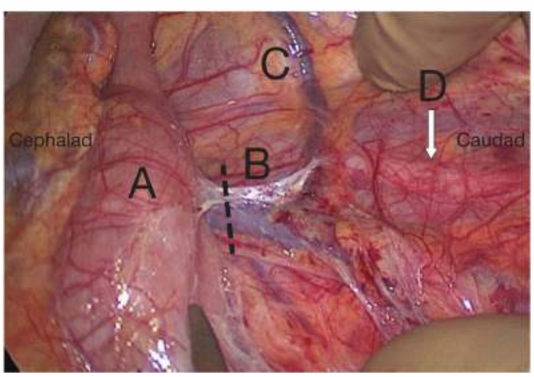

FIG 4 ● Step 1: Key anatomy. Ligament of Treitz *(A)*. IMV *(B)*. Left colic artery *(C)* as it separates from the IMV and goes toward the splenic flexure of the colon. The left ureter *(D)* is located far from the IMV transection point *(dotted lines)*.

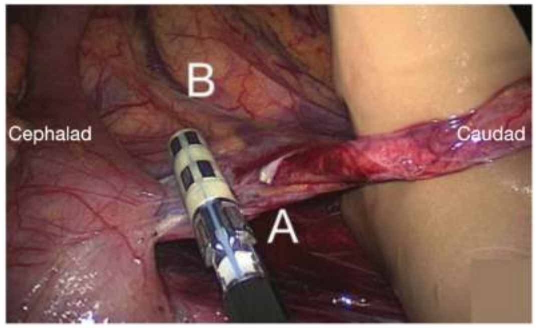

FIG 5 ● Step 1: The surgeon holds the IMV *(A)* anteriorly with his or her right hand and transects it cephalad of the left colic artery *(B)* with a 5-mm energy device.

- Pick up the IMV with the right hand. Incise the peritoneum under the IMV and dissect in front of Gerota's fascia with endoscopic scissors, starting at the level of the ligament of Treitz. Proceed with the dissection caudally towards the IMA. The assistant provides upward countertraction with a grasper.
- Transect the IMV (FIG 5) cephalad of left colic artery, which moves away from the IMV and toward the splenic flexure of the colon, with the 5-mm energy device, thus preserving intact the left-sided marginal arterial arcade, and preserving the blood supply to the anastomosis.

Step 2. Transection of the Inferior Mesenteric Artery

- Identify the critical anatomy: the "letter T" formed between the IMA and its left colic and superior SHA terminal branches (FIG 6).

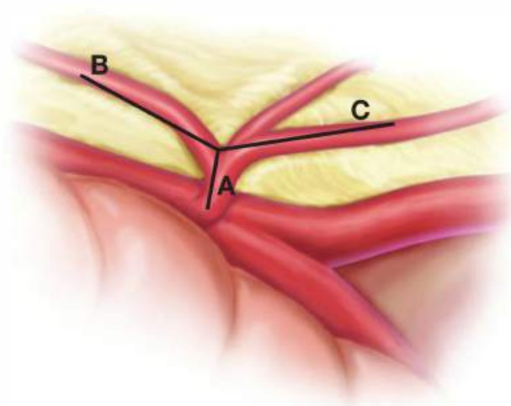

FIG 6 ● Step 2: Critical anatomy. Identify the letter T formed between the IMA *(A)* and its left colic artery *(B)* and SHA *(C)* terminal branches.

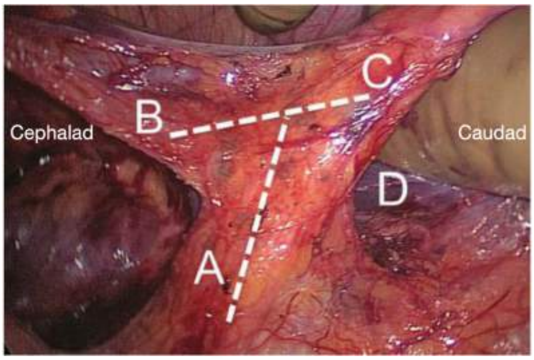

FIG 7 ● Step 2: The letter T dissected: IMA *(A)*, left colic artery *(B)*, and SHA *(C)*. Notice the left ureter *(D)* in the retroperitoneum. The IMA takeoff is just cephalad from the aortic bifurcation *(dotted lines)*. The thumb and index finger are lifting the SHA off the groove located anterior to the right common iliac artery.

- Using the hand, the aorta is identified and tracked down to the level of its bifurcation. The IMA will originate 1 to 2 cm proximal to this level.
- Holding the SHA up with the right hand, dissect the plane along the palpable groove between the SHA and the left iliac artery using laparoscopic scissors. After scoring the peritoneum under the SHA, use a 5-mm energy device to dissect (by gently pushing downward toward the retroperitoneum) along the avascular plane located between the meso-descending colon, anteriorly, and the retroperitoneum, posteriorly. This avascular plane can be identified by the transition between the two distinctive fat planes.
- Preserve the sympathetic nerve trunk intact in the retroperitoneum. Identify the left ureter, located in front of the left iliac artery and psoas muscle and medial to the gonadal vessels, before transecting any structure.
- You can now visualize the dissected letter "T" (**FIG 7**). Dissect with your thumb and index finger around and behind the IMA and transect the IMA at its origin with a vascular load stapler (**FIG 8**, *dotted line*) or energy device. This ensures excellent lymph node harvest and great exposure for step 3.

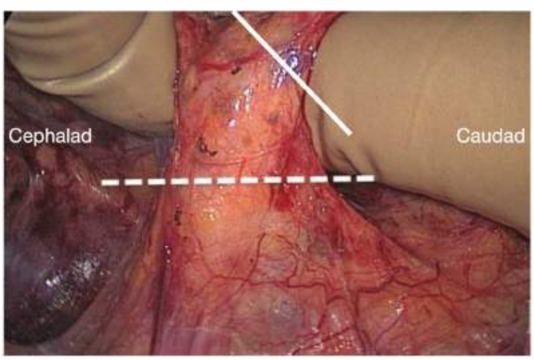

FIG 8 ● Step 2: The IMA is now completely encircled and will be transected at its origin *(dotted line)* with a stapler or energy device. Alternatively, the vascular transection can be done at the takeoff of the SHA and sigmoidal vessels *(solid line)*, preserving the IMA and left colic vessels intact and ensuring prograde blood flow into the descending colon.

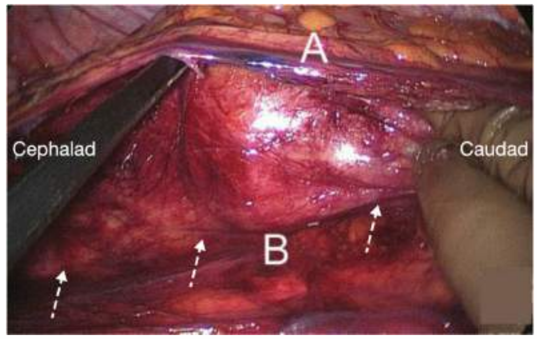

FIG 9 ● Step 3: Medial to lateral dissection of the descending mesocolon. The surgeon's hand is holding the descending mesocolon and colon anteriorly *(A)*, separating them from Gerota's fascia and other retroperitoneal structures *(B)*. The dissection proceeds along the transition between the two distinct fat planes *(arrows)*.

- Alternatively, the vascular transection can be done at the takeoff of the SHA and sigmoidal vessels (**FIG 8**, *solid line*), preserving the IMA and left colic intact and ensuring prograde blood flow into the descending colon segment that will be eventually used for the anastomosis. The drawback is that this makes the medial to lateral dissection step somewhat more challenging, because the IMA will keep the mesocolon tethered to the retroperitoneum.

Step 3. Medial to Lateral Dissection of the Descending Mesocolon

- The surgeon's right hand and the assistant's grasper hold the descending mesocolon up, creating a working space between the mesocolon and the retroperitoneum (**FIG 9**). The plane between the mesocolon and Gerota's fascia, readily identified by the transition between the two fat planes, is dissected by gently pushing it downward with the 5-mm energy device.
- Dissect caudally toward the pelvic inlet; this will greatly facilitate performance of step 4.
- Dissect laterally until you reach the lateral abdominal wall; this will greatly facilitate performance of step 5.
- Dissect cephalad, under the splenic flexure of the colon, until reaching the inferior border of the pancreas. This is critical for an easy mobilization of the splenic flexure during step 6.

Step 4. Sigmoid Colon Mobilization off the Pelvic Inlet

- The surgeon pulls the sigmoid colon medially, exposing the lateral sigmoid colon attachments (**FIG 10A**). Transect the attachments between the sigmoid and the pelvic inlet with laparoscopic scissors in your left hand, staying medially, close to the sigmoid and mesosigmoid, to avoid injuring the ureter/gonadal vessels.
- Dissect caudally until reaching the entrance to the left pelvic inlet.
- The left ureter and gonadal vessels, dissected in step 3, should be visible (**FIG 10B**).

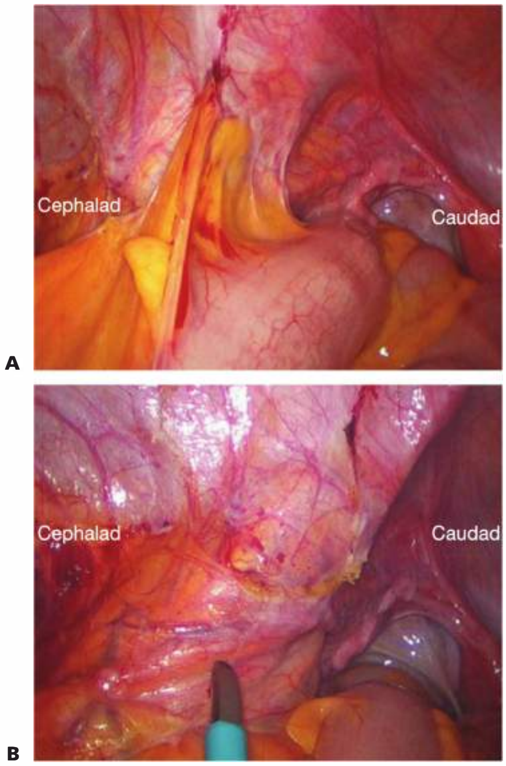

FIG 10 ● Step 4. Panel **(A)**: Medial traction on the sigmoid exposes its lateral attachments to the pelvic inlet. Panel **(B)**: After the sigmoid mobilization is completed, the left ureter is visualized as it crosses over the left iliac artery.

Step 5. Descending Colon Mobilization

- Retract the descending colon medially with your left hand. Transect the white line of Toldt up to the splenic flexure using endoscopic scissors. You should readily enter the retroperitoneal dissection plane dissected during step 3 (**FIG 11**).

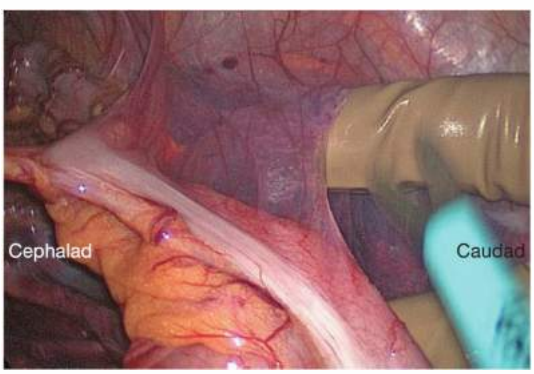

FIG 11 ● Step 5: Transection of the lateral descending colon attachments. Notice that the hand has entered the retroperitoneal dissection plane previously dissected during step 3.

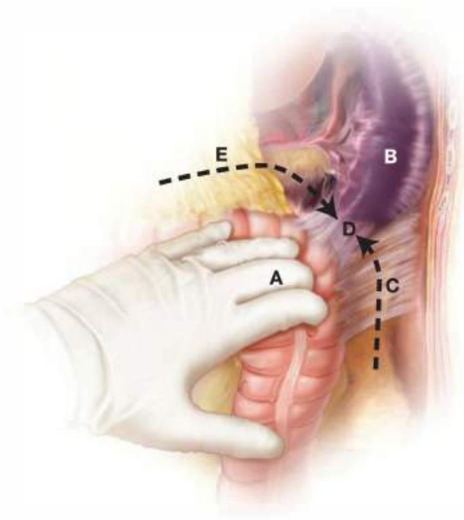

FIG 12 ● Step 6: Mobilization of the splenic flexure. The surgeon retracts the splenic flexure of the colon *(A)* downward and medially, exposing the attachments of the flexure to the spleen *(B)*. The phrenocolic *(C)* and splenocolic *(D)* ligaments are transected in an inferior to superior and lateral to medial direction. The gastrocolic ligament *(E)* is transected in a medial to lateral direction, until both planes of dissection meet and the splenic flexure is fully mobilized.

Step 6. Splenic Flexure Mobilization

- Place the patient on reverse Trendelenburg position with the left side up to help displace the splenic flexure down out of the left upper quadrant.
- We use a two-way approach to the splenic flexure mobilization, with an upward lateral dissection and a medial to lateral dissection meeting around the splenic flexure (**FIG 12**).
- Now, turn your attention medially. With the assistant pulling the transverse colon downward with a grasper, the surgeon lifts the stomach up with his or her left hand and transects the gastrocolic ligament in between the stomach and transverse colon using a 5-mm energy device through the RUQ port site (**FIG 13A**). This allows for entrance into the lesser sac and provides for an excellent view of the splenic flexure.
- Transect the gastrocolic ligament (from medial to lateral) with the 5-mm energy device, staying close to the transverse colon and avoiding the spleen. Proceed laterally toward the splenic flexure.
- Because the medial to lateral dissection performed in step 3 completely separated the splenic flexure of the colon from the retroperitoneum, the surgeon can now slide his or her right hand under the splenic flexure, connecting the two planes of dissection around the flexure, with the index finger "hooked" under the splenocolic ligament. This allows for an easy transection of the splenocolic ligament with an energy device (**FIG 13B**). The left colon should be now fully mobilized to the midline.

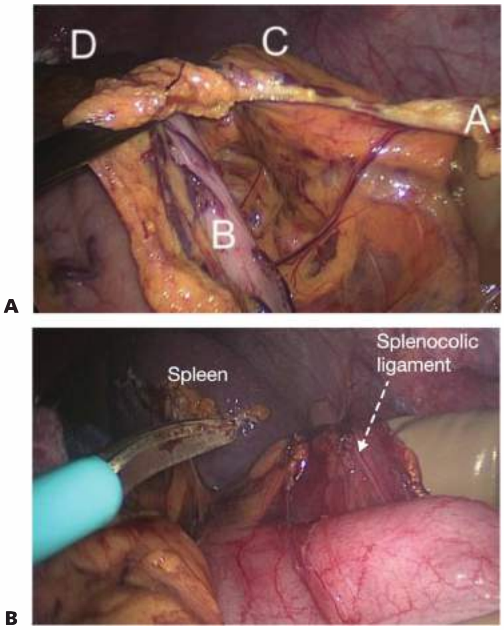

FIG 13 ● Step 6: Mobilization of the splenic flexure. Panel **(A)**: The partially transected gastrocolic ligament is visible between the transverse colon *(A)* and the stomach *(B)*. Notice the excellent view of the lesser sac laterally toward the splenic flexure of the colon *(C)* and the spleen *(D)*. Panel **(B)**: The surgeon is "hugging" the splenic flexure with his or her right hand and is "hooking" his or her index finger under the splenocolic ligament, allowing for an excellent exposure and transection of this ligament with an energy device.

Step 7. Intracorporeal Distal Transection

- Dissect the rectosigmoid junction circumferentially. The rectosigmoid junction can be identified by the splaying of the teniae coli. Transect the upper mesorectum with the 5-mm energy device at the level of the projected distal bowel transection.
- While pulling on the sigmoid upward with the left hand, transect the bowel intracorporeally just distal to the rectosigmoid junction with a linear Endo GIA stapler device (**FIG 14**).
- At this point, transect the mesocolon between the sigmoid and left colic vessels with the 5-mm energy device. Start at the stapled IMA stump on the specimen side, and move up toward the colon wall, transecting the left colic artery (at its origin, off the IMA stump) and the marginal artery (close to the colon wall).

Step 8. Extracorporeal Proximal Transection

- Deliver the sigmoid and descending colon through the Pfannenstiel incision site with the Alexis wound protector in place to protect the wound from oncologic/infectious contamination.
- There should be absolutely no tension during the extraction of the specimen. Otherwise, mesenteric tears that could lead to troublesome bleeding may occur. If there is tension during the extraction phase, completely mobilize the splenic flexure if you have not done so already.

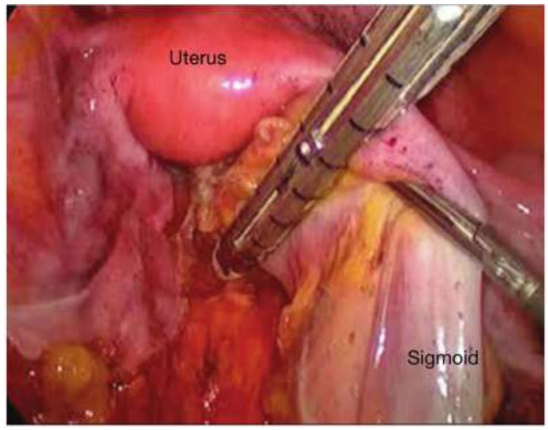

FIG 14 ● Step 7. The intracorporeal distal transection is performed with a linear stapler just distal to the rectosigmoid junction.

- Transect the colon between Kocher clamps between the sigmoidal and left colic vessel distribution, at the point where the mesocolon was previously transected intracorporeally during the previous step. Send the specimen to the pathologist for evaluation.
- Now place the anvil of a 29-mm EEA stapler device into the descending colon and exteriorize it through the antimesenteric border with the spike approximately 5 cm proximal to the open end of the colon. Close the distal end of the descending colon with a linear stapler cartridge.
- Reintroduce the descending colon with the anvil in place into the abdomen in preparation for the anastomosis. Close the hand access port and reinsufflate the pneumoperitoneum.

Step 9. Intracorporeal Colorectal Anastomosis

- You are now ready to perform the intracorporeal side-to-end colorectal anastomosis (**FIG 15**).
- The assistant introduces the 29-mm EEA stapler device into the rectum and opens the spear through the rectal stump, anterior to the staple line, under direct laparoscopic visualization.
- Making sure the mesentery is facing medially and that there are no twists in the bowel, the two ends of the stapler are brought together and the stapler is closed, while avoiding any additional tissue to slip in between the two ends. Once fully closed, the stapler is fired and the EEA carefully pulled back out of the rectum.
- To ensure that the anastomosis is intact, we check for the two donuts to be complete and subsequently test the anastomosis by insufflating it under water, ensuring that it is airtight (**FIG 16**).

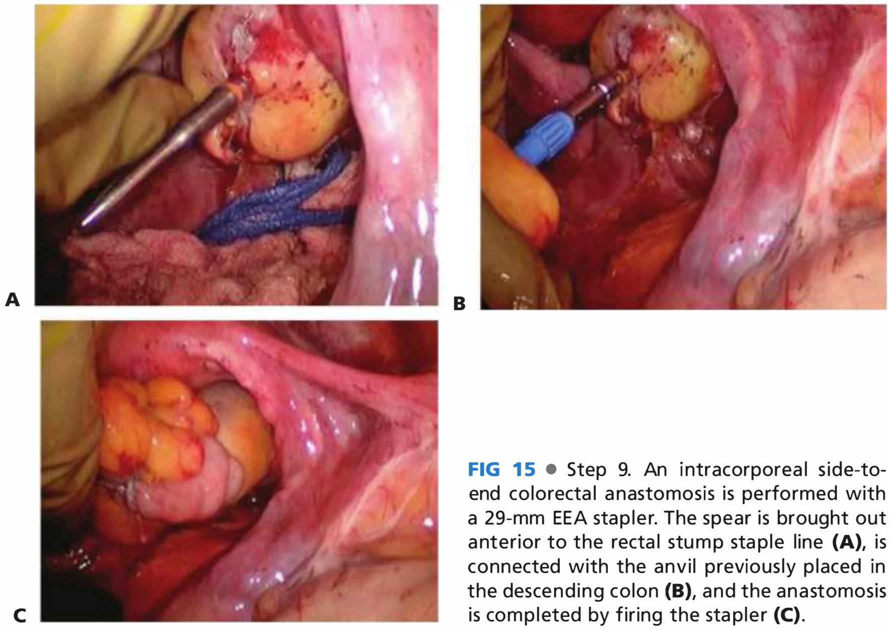

FIG 15 ● Step 9. An intracorporeal side-to-end colorectal anastomosis is performed with a 29-mm EEA stapler. The spear is brought out anterior to the rectal stump staple line **(A)**, is connected with the anvil previously placed in the descending colon **(B)**, and the anastomosis is completed by firing the stapler **(C)**.

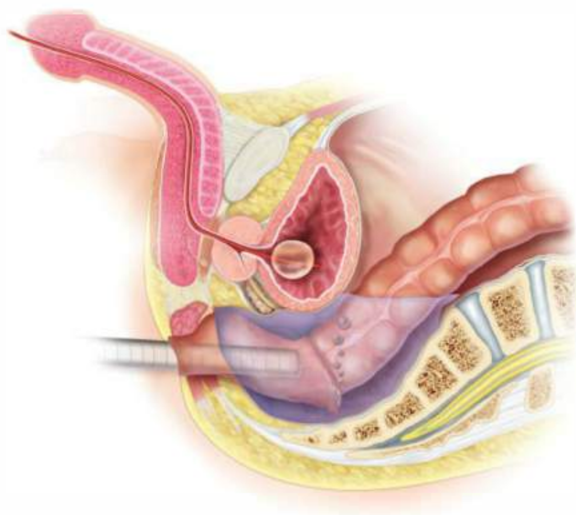

FIG 16 ● The completed colorectal anastomosis is tested under water. Air bubbles identified during insufflation of the anastomosis indicate an anastomotic leak.

WOUND CLOSURE

- The Pfannenstiel incision is closed using no. 1 polydioxanone (PDS) suture in a running fashion. All skin incisions are closed with 4-0 PDS subcuticular sutures. Dermabond is applied to seal off all wounds.
- We do not routinely use drains for this operation.

PEARLS AND PITFALLS

Indications	■ For benign cases, a segmental sigmoid resection, with vascular transection close to the bowel wall, may be enough. ■ For malignant cases, a complete sigmoidectomy, with a high vascular pedicle transection is necessary to ensure adequate lymphadenectomy.
Positioning	■ Secure the patient to the table while protecting all pressure-bearing areas. ■ Make sure that all anesthesia lines and monitors are working appropriately after positioning the patient; there will be limited access to the arms during the procedure. ■ Avoid unnecessary clutter of cables/lines; open up the working space for the operating team.
Port placement	■ Triangulate all ports. ■ Place the hand access port in a Pfannenstiel location.
Vascular transection	■ Transection of the IMV is the *safest* point of entry for this operation. ■ A high IMA transection facilitates the medial to lateral dissection and ensures an excellent lymphadenectomy. ■ It is essential to identify the left ureter above prior to IMA transection.
Mesenteric dissection	■ A complete medial to lateral dissection of the mesentery is critical to facilitate all subsequent steps of this operation.
Distal transection	■ The distal transection is easier to perform intracorporeally than extracorporeally. ■ The distal transection is performed just distal to the rectosigmoid junction, identified by the splaying of the teniae coli.
Intracorporeal anastomosis	■ Make sure the anastomosis is tension-free and that both ends are adequately perfused. ■ Always test the integrity of the anastomosis and be ready to repair or redo it if a leak is identified.

POSTOPERATIVE CARE

- Fast-track or enhanced recovery after surgery (ERAS) programs have shown to expedite postoperative recovery and to minimize postoperative complications following colon surgery. No postoperative antibiotics are used. DVT prophylaxis with heparin products is used routinely.
- We do not use a nasogastric tube.
- Remove the Foley catheter on the first postoperative day.
- Encourage early ambulation, minimize postoperative use of narcotics and promote early feeding as tolerated.
- Patients usually meet criteria for discharge on postoperative days 3 to 4.

OUTCOMES

- The outcomes following HAL sigmoidectomy are excellent.
- HAL colectomy is associated with all the short-term outcome benefits of conventional laparoscopic surgery over open surgery, including less postoperative pain, earlier return of bowel function, and shorter length of stay.
- HAL colectomy is associated with a higher usage rate and a lower rate of conversion to an open approach (2% to 6% vs. 20% to 25%) when compared to conventional laparoscopic colectomy.
- Postoperative complications are equivalent for HAL and conventional laparoscopic sigmoid colectomy.
- HAL sigmoidectomy for cancer yields similar long-term oncologic outcomes compared to open surgery.

COMPLICATIONS

- Surgical site infection
- Anastomotic leak
- Postoperative bleeding
- Postoperative small bowel obstruction
- Urinary retention
- Dehiscence/hernia
- Medical complications: DVT/pulmonary embolism (PE), urinary tract infection, myocardial infarction, and so forth

Chapter 22

Sigmoid Colectomy: Single-Incision Laparoscopic Surgery Technique

Rodrigo Pedraza Eric M. Haas

DEFINITION

- Single-incision laparoscopic sigmoidectomy is a minimally invasive technique in which a sigmoid colectomy is performed laparoscopically through a single-port device. The entirety of the procedure is accomplished using one sole incision through which all the laparoscopic instruments are placed.
- Reduced port single-incision laparoscopic sigmoidectomy is a modified technique in which the single-port device is placed through a Pfannenstiel incision and an additional port is placed through the umbilicus. This technique is also called "single plus one" sigmoidectomy[1] and is used to facilitate operative exposure, avoid instrument conflict, and benefit from the Pfannenstiel incision—diminished infection, dehiscence, and hernia rates.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Single-incision laparoscopic sigmoidectomy is safe and feasible for essentially all benign and malignant sigmoid diseases requiring resection.[2–4] The most common indications include diverticular disease, cancer, and polyps.
- Patients with diverticular disease typically present with recurrent episodes of diverticulitis or complications such as perforation or obstruction. Left lower quadrant pain and tenderness are commonly encountered and may be accompanied with nausea, vomiting, and fever. Lower gastrointestinal (GI) bleeding is rarely present.
- Cancer and polyps of the sigmoid colon are frequently diagnosed incidentally during screening colonoscopy. Those with large polyps or malignancy may present with hematochezia, bowel obstruction, perforation, or lower abdominal or pelvic pain.
- Single-incision laparoscopic sigmoidectomy is contraindicated in patients who cannot tolerate major abdominal surgical procedures, such as those with severe hemodynamic instability, recent myocardial infarction, or severe thromboembolic event.
- History of prior abdominal surgery may lead to a prolonged procedure due to extensive lysis of adhesions; nonetheless, it is not an absolute contraindication to the use of the single-incision approach.
- The procedure may be performed in patients with high body mass index (BMI). However, the high complexity and high conversion rates make this a less ideal scenario for single-incision sigmoidectomy. In patients with high BMI, conventional multiport or hand-assisted laparoscopic technique may be more suitable.
- Large, bulky tumors may require further incision lengthening during the procedure, losing pneumoperitoneum, thus hindering the ability to complete the case with the single-incision technique. Nevertheless, some single-port devices allow incision lengthening without compromising the pneumoperitoneum.
- Surgeons without experience with single-incision colectomy may encounter technical difficulties. Before offering this approach, competency with conventional multiport and/or hand-assisted laparoscopic techniques is recommended. Additionally, it is suggested that the surgeon becomes proficient in single-incision sigmoidectomy in those with benign disease prior to performing oncologic resections.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Regardless of the procedure indication, all patients necessitate appropriate preoperative evaluation with endoscopic and radiologic studies.
- For patients with diverticular disease, colonoscopy or flexible sigmoidoscopy is warranted to assess the length of the affected bowel, to determine resection levels, and to confirm the diagnosis. Furthermore, a computed tomography (CT) scan of the abdomen and pelvis is mandatory to evaluate the severity of the pericolonic disease. Some patients with severe active disease demonstrated on the CT scan may benefit from a course of antibiotics or even abscess drainage prior to the procedure.
- If the indication for the sigmoidectomy is a colonic polyp or malignancy, endoscopic tattooing of the lesion is required to ensure proper location during the laparoscopic procedure (**FIG 1**).

A  B

FIG 1 ● Tattooing the lesion in at least three quadrants of the bowel wall during colonoscopy (panel **A**) facilitates proper location of the pathology during the laparoscopic approach (panel **B**).

- For malignant cases, a complete oncologic workup is mandatory. A multidisciplinary approach involving surgeon and medical oncologist is preferable. Lymph node and distant organ involvement are evaluated with the CT scan of the abdomen and pelvis and positron emission tomography (PET) scan. Patients with lower tumors in the rectosigmoid junction may need magnetic resonance imaging (MRI) to evaluate tumor local progression into the pelvis and lymph node status.

SURGICAL MANAGEMENT

Preoperative Planning

- Bowel preparation is traditionally achieved through a polyethylene glycol–based laxative solution and oral antibiotics. This practice has recently been called into question. An accepted alternative is the use of a modified bowel preparation with preoperative enema to clear out the distal stool.
- In the operating room and under anesthesia, rigid proctosigmoidoscopy is recommended to ensure the level of the lesion is above the rectum and to ensure that the bowel is clean of fecal matter.
- For noncontaminated cases, prophylactic antibiotics are administered according to the Surgical Care Improvement Project (SCIP) measures.
- If the cases involve active infection such as those with recurrent diverticulitis or perforation, broad-spectrum antimicrobials with gram-negative and anaerobe bacterial coverage are chosen.

Positioning

- The patient is placed in a modified lithotomy position with both arms tucked at the patient's side. The patient is secured with adhesive tape over the chest, without compromising chest expansion (**FIG 2**). Antislip rubber pads may be used to further secure the patient to the operating room table. It is imperative to ensure proper and secured positioning, as later in the procedure, Trendelenburg position will be required.
- The optimal modified lithotomy position is achieved with a 25- to 30-degree thigh flexion and with moderate thigh abduction (**FIG 2**). This positioning allows adequate surgeon maneuverability, avoiding conflict with the patient's thighs while affording proper perineal access.
- For abdominal entry, laparoscopic exploration, and lysis of adhesions, the patient is in supine position. In this portion of the procedure, the surgeon and assistant are located on the right and left side, respectively.
- Thereafter, the patient is placed in Trendelenburg position with the left side elevated. The surgeon and assistant are located on the right side of the patient with the laparoscopic monitor on the left (**FIG 3**).

FIG 2 • Patient positioning. The patient is placed in a modified lithotomy, 25- to 30-degree thigh flexion, and with moderate thigh abduction to allow adequate surgeon maneuverability, avoiding conflict with the patient's thighs while affording proper perineal access. It is imperative to further secure the patient to the table—we use adhesive tape over the chest, avoiding compromising chest expansion.

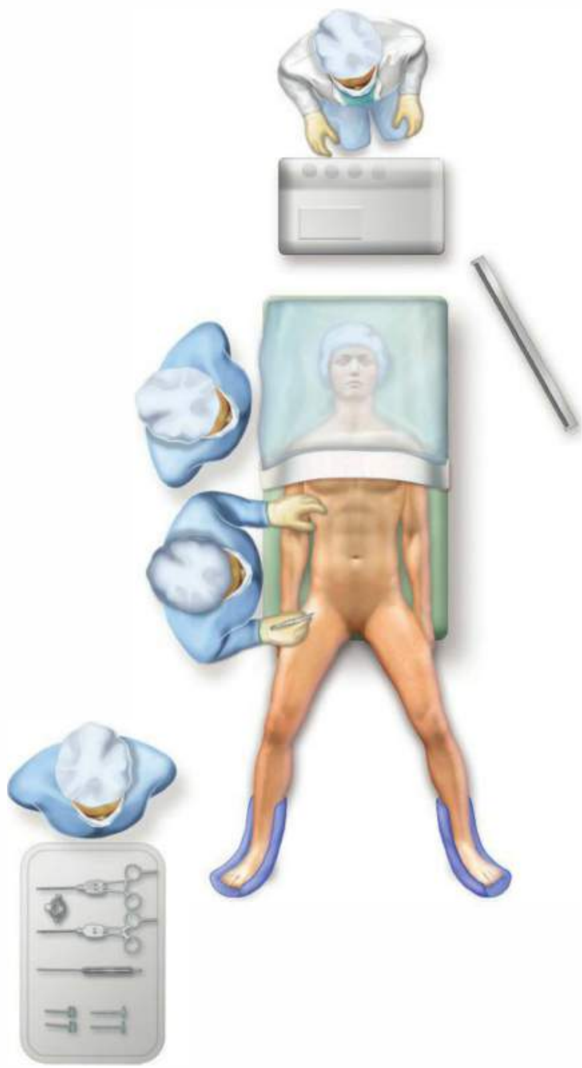

FIG 3 • Operative room patient/surgeon configuration for single-incision laparoscopic sigmoid colectomy.

INCISION AND PORT PLACEMENT

- Typically, a 2.5-cm vertical umbilical skin incision is performed (**FIG 4**). The umbilical stump is divided, affording fascial lengthening to 4 cm without modifying the skin incision (**FIG 4**). Following entry into the abdominal cavity, the single-port device is placed.
- An alternative approach is the abdominal entry using a 4-cm Pfannenstiel incision (**FIG 5**). This modification improves cosmetic outcomes while decreasing wound infection and hernia rates. This approach is challenging, as the instruments are in close proximity with the target operative field, limiting maneuverability. Thus, when this approach is used, we favor a single plus one technique using a Pfannenstiel incision with an additional 5-mm incision for the camera in order to avoid instrument conflict (**FIG 5**).
- Prior to port placement, a surgical sponge may be introduced into the abdominal cavity to facilitate retraction later in the procedure.

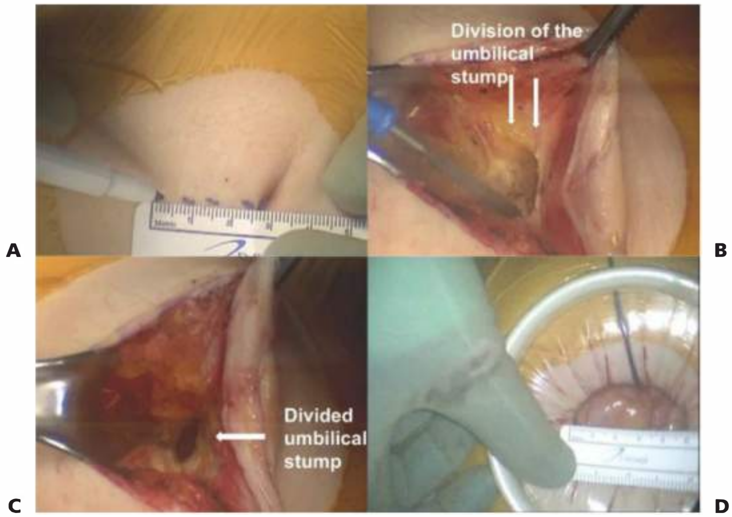

FIG 4 ● Umbilical incision. **A.** The skin incision is 2.5 cm in length, but after division of the umbilical stump (**B** and **C**), the fascial incision size is lengthened to 4 cm **(D)**.

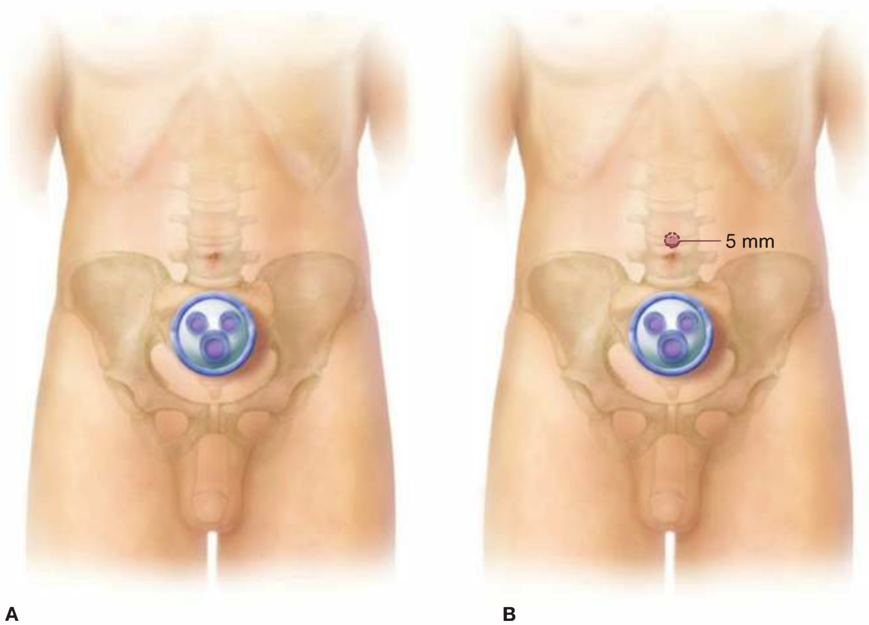

FIG 5 ● **A.** Pfannenstiel incision port configuration for single-incision laparoscopic sigmoid colectomy. **B.** "Single plus one" technique: The addition of a 5-mm camera port in the umbilicus facilitates steps during the procedure and minimizes instrument and surgeon/assistant conflict.

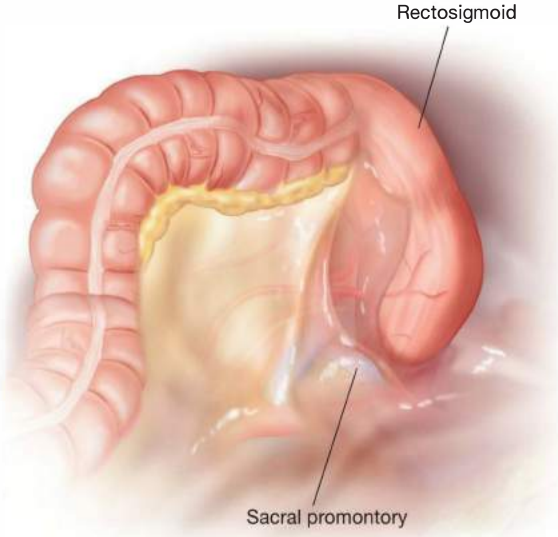
- Port placement varies depending on the single-port device used. Once the port is placed, pneumoperitoneum is created and the laparoscopic camera and instruments are introduced.
- A 30-degree camera and traditional straight laparoscopic instruments are used. Alternatively, articulated instruments may be employed.
- In order to afford maximal operative reach and to avoid internal and external instrument conflict, bariatric and standard length instruments may be used simultaneously. Moreover, a right-angle light cord adaptor may be used to further decrease conflict.

EXPLORATION AND LYSIS OF ADHESIONS

- The abdominal cavity is thoroughly examined to assess the disease process and, in oncologic cases, to evaluate the presence of metastatic disease.
- If required, lysis of adhesions may be safely performed laparoscopically.

DEVELOPMENT OF THE PRESACRAL PLANE

- With the patient in Trendelenburg position and the left side elevated, the small bowel loops are retracted superiorly and to the right to expose the target operative field. The surgical sponge facilitates small bowel retraction.
- The sigmoid and rectosigmoid junction are identified and retracted anteriorly and laterally (FIG 6).
- The sacral promontory is identified and the peritoneum is incised medially with either a monopolar or bipolar energy device (FIG 6). An avascular presacral plane is created and further developed using blunt and sharp dissection with a bipolar tissue-sealing device (FIG 6). During this dissection, anatomic landmarks include the sacral promontory, superior rectal artery, left ureter, left gonadal vein, and left iliac vein. The concept of single-incision triangulation is used. In this technique, one instrument elevates the tissue anteriorly while the other—from the surgeon's dominant hand—performs dissection in a "hand-over-fist fashion."
- The dissection plane is developed without excessive deep dissection to avoid pelvic plexus injury. Furthermore, it is imperative to identify and to preserve the left ureter.
- Once the presacral plane is fully developed, attention is then drawn to the identification of the left colic artery.



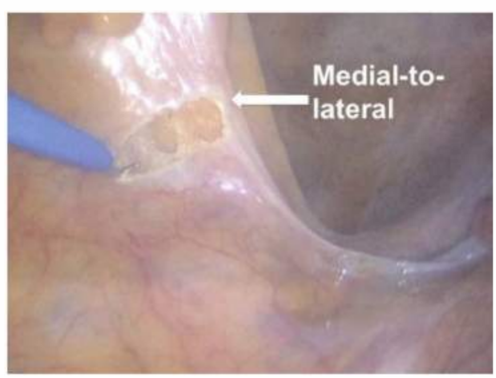


FIG 6 ● Presacral plane development. **A.** The rectosigmoid is retracted laterally and anteriorly; the sacral promontory is identified as landmark prior to the peritoneal incision. **B.** The peritoneum is incised in a medial-to-lateral fashion. *(continued)*

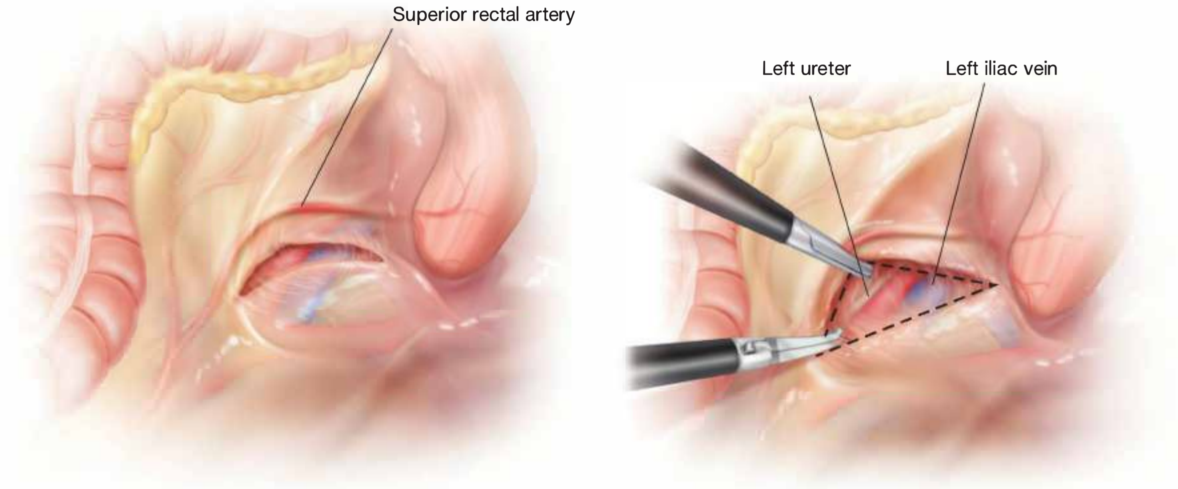

FIG 6 ● *(continued)* **C.** The presacral dissection continues and the superior rectal artery is identified. **D.** The plane is further developed using a triangulation technique with one instrument elevating the tissue while the other instruments carrying out the dissection. Additional critical structures are identified and preserved, including the left ureter and left iliac vein.

DEVELOPMENT OF THE RETROPERITONEAL PLANE

- Once identified, the left colic artery is grasped and elevated. A peritoneal incision is made medial to the vessel and the retroperitoneal plane is created using either a monopolar or bipolar energy device (**FIG 7**).
- The retroperitoneal plane is further developed, making use of the triangulation technique described previously. The dissection is carried out anterior to Gerota's fascia, along the inferior border of the pancreas, and moving laterally toward the white line of Toldt. The superior portion of the left ureter is identified and preserved.

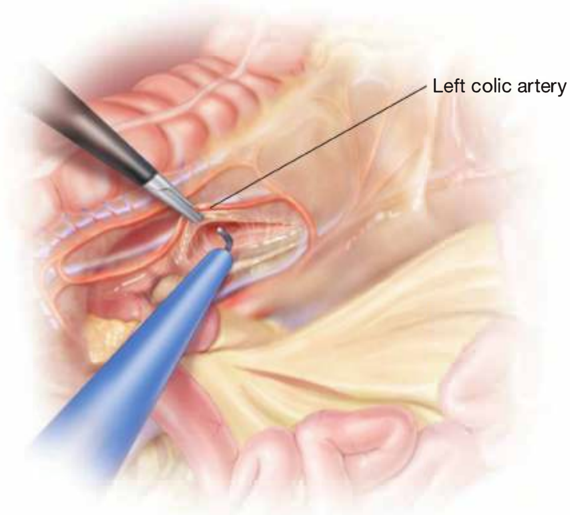

FIG 7 ● The left colic artery is grasped and elevated. A peritoneal incision is made medial to the vessel and the retroperitoneal plane is created and further developed using a triangulation technique. The dissection is carried out anterior to Gerota's fascia and toward the white line of Toldt.

HIGH VASCULAR DIVISION—THE EAGLE SIGN

- At this point, the left colic and superior rectal arteries are isolated and elevated to readily identify the inferior mesenteric artery (IMA). This maneuver results in the exposure of the "eagle sign." The "body" of the "eagle" is the IMA, the superior "wing" the left colic artery, and the inferior wing the superior rectal artery (**FIG 8**). The identification of this sign facilitates appropriate vascular identification and division. The IMA is now safely divided at its origin with a bipolar energy device or linear stapler. The inferior mesenteric vein is then identified and divided. In those with benign disease, a high ligation technique is not required and division takes place at the level of the superior rectal artery.

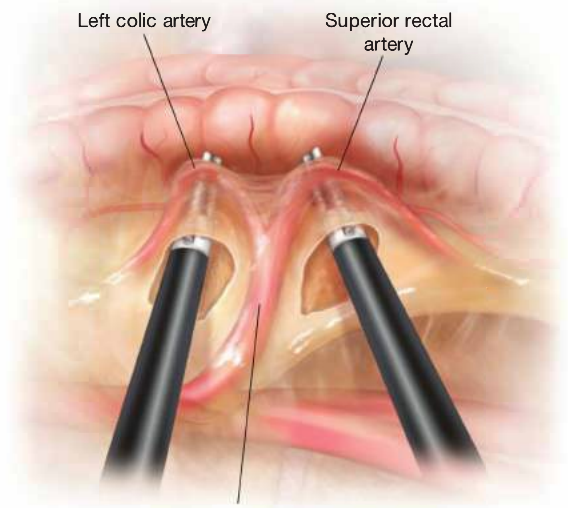

FIG 8 ● **A.** The eagle sign: The body of the eagle is the inferior mesenteric artery (IMA), the superior wing the left colic artery, and the inferior wing the superior rectal artery. **B.** The IMA is now safely divided at its origin with a bipolar energy device or linear stapler.

LATERAL ATTACHMENTS AND SPLENIC FLEXURE TAKEDOWN

- Some cases may require splenic flexure mobilization to afford a tension-free anastomosis. This is achieved by detaching the gastrocolic ligament at the level of the distal transverse colon, allowing entry to the lesser sac. At this level, the splenocolic ligament is readily taken down, affording a complete splenic flexure mobilization.
- The lateral attachments of the descending colon are taken down from the pelvic brim to the splenic flexure. The descending colon is grasped and retracted medially while the attachments are released with a bipolar tissue-sealing device (**FIG 9**).
- In order to fully mobilize the left colon, additional rectosigmoid pelvic attachments are taken down. This also achieves proper upper rectum mobilization, which is beneficial for the specimen division.

FIG 9 ● Lateral-to-medial dissection. The lateral attachments of the sigmoid and descending colon are taken down in an inferior-to-superior direction from the pelvic brim to the splenic flexure, which is readily mobilized if required.

BOWEL DIVISION

- The rectosigmoid is flipped in a medial-to-lateral direction and its mesentery is divided (**FIG 10**). A window is created in the mesentery through which the linear stapler will be placed. The rectosigmoid is then placed in normal anatomic position and it is divided tangentially using a laparoscopic linear stapler.
- The instruments and single-port device are removed and the specimen is exteriorized. The level of the proximal division is chosen and the bowel is divided extracorporeally (**FIG 10**).

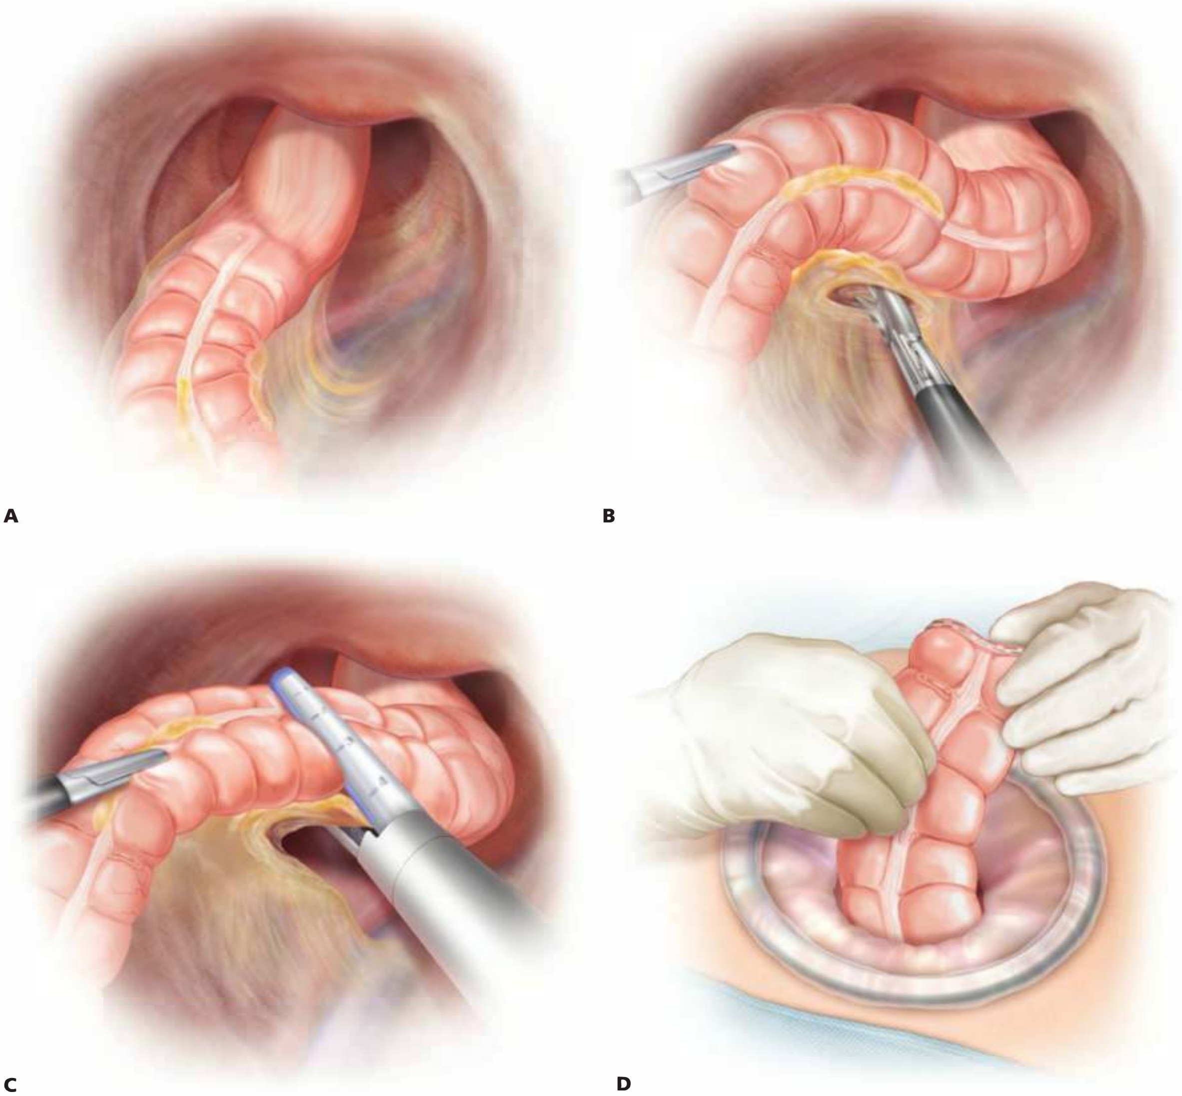

FIG 10 ● **A.** The rectosigmoid is fully mobilized and ready for division. **B.** A window is created in the mesentery to introduce the stapler in preparation for specimen division. **C.** Rectosigmoid division with a linear stapler. **D.** Extracorporeal mobilization of the bowel for proximal division and preparation for bowel anastomosis.

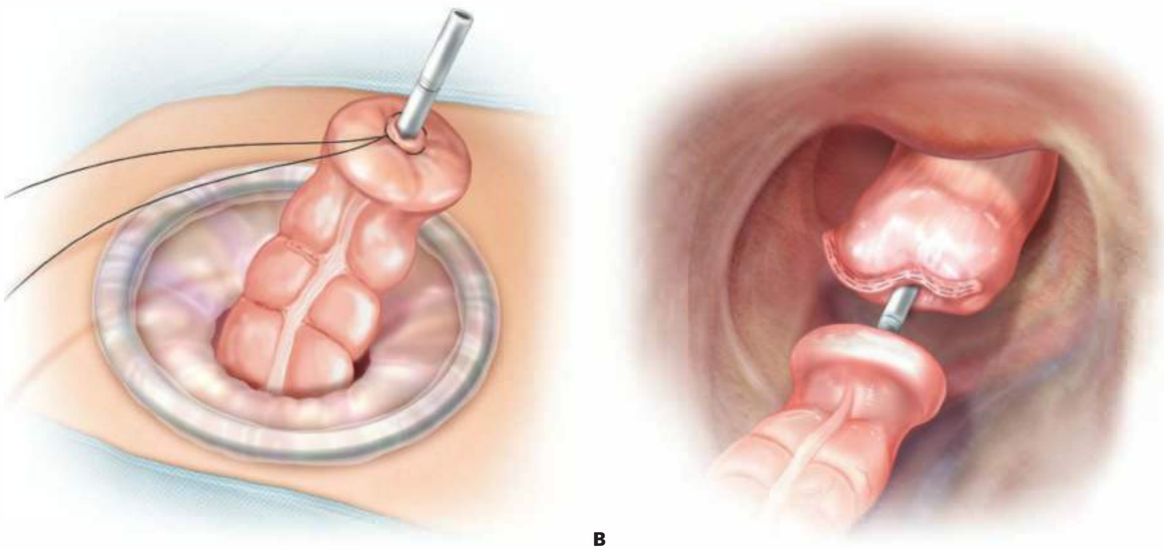
ESTABLISHMENT OF BOWEL CONTINUITY

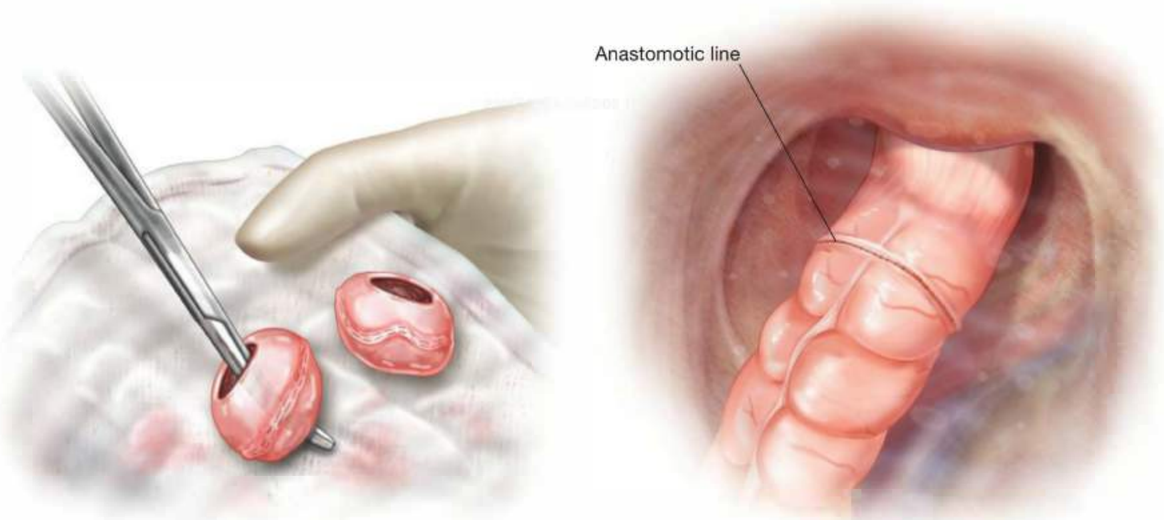
- An end-to-end anastomosis is performed with a circular stapler in a traditional fashion.
- We prefer to use a circular stapling device of 29-mm size. Smaller sizes are prone to result in stricture formation and should be avoided, and larger sizes may result in tearing of the bowel wall.
- The anvil of the stapler is introduced into the proximal bowel and is secured with a purse-string suture (FIG 11). The bowel is introduced back into the peritoneal cavity and the pneumoperitoneum is reestablished.
- The assistant inserts the stapler handle transanally and advances it to the level of the staple line.
- The anvil and the handle of the stapler are aligned and the stapler is closed under direct laparoscopic visualization (FIG 11). Before performing the anastomosis, it is important to ensure that the bowel is not twisted. Once proper bowel alignment is corroborated, the stapler is fired and then removed transanally.



A B

FIG 11 ● End-to-end colorectal anastomosis. **A.** The anvil of the stapler is introduced and secured into the proximal bowel with a purse-string suture. **B.** After the bowel is reintroduced into the abdomen, the anvil and the handle of the stapler are aligned and the stapler is closed under direct laparoscopic visualization.

- Confirmation of a proper anastomosis is performed in three stages. Proctoscopy is performed to visualize the integrity and viability of the anastomosis. The anastomotic rings (donuts) are examined to ensure they are intact circumferentially (**FIG 12**). Finally, an air insufflation test is then performed to confirm that the anastomosis is airtight (**FIG 12**). If the anastomosis is found to be inadequate, modifications may be required as well as consideration of diversion of the fecal stream, depending on the characteristics of the individual case.



A B

FIG 12 ● Anastomotic confirmation. **A.** The anastomotic rings are inspected to confirm that they are intact. **B.** An air insufflation test is performed to confirm the absence of anastomotic leak.

BOWEL DIVERSION

- For cases in which it is unsafe to perform a primary end-to-end colorectal anastomosis, sigmoid resection with end colostomy or, alternatively, anastomosis with a protective loop ileostomy may be performed.

TECHNICAL ALTERNATIVES

- Single-incision laparoscopic sigmoidectomy may be also performed with a lateral-to-medial dissection approach.
- We favor the medial-to-lateral approach because it allows identification of critical structures such as the left ureter, facilitating its preservation. Furthermore, we believe that is a more "natural" approach, as the instruments are located in the midline, simplifying the procedure.
- For the lateral-to-medial approach, the procedure initiates with the release of the lateral attachments of the descending colon, establishment of the retroperitoneal plane, followed by vascular identification and division. Once the sigmoid/left colon is mobilized, the extracorporealization, bowel division, and anastomosis are performed as described previously.

PEARLS AND PITFALLS

Indications	■ Sigmoid diverticulitis, colon cancer, large colon polyps, inflammatory bowel disease
Preoperative evaluation	■ Colonoscopy with lesion tattooing for polyps and cancer ■ Abdominopelvic CT scan ■ PET scan selectively
Incision	■ 2.5-cm umbilical or 4-cm Pfannenstiel ■ Single plus one technique: 4-cm Pfannenstiel and 5-mm umbilical port for camera port
Technique	■ Medial-to-lateral dissection. Early identification and preservation of the left ureter. ■ Vascular dissection to visualize the eagle sign and high IMA ligation in malignancy ■ Specimen division with end-to-end anastomosis with 29-mm circular stapler ■ Proper anastomosis confirmed with proctoscopy, evaluation of anastomotic rings, and air insufflation test
Postoperative care	■ Patients benefit from the use of a fast-track perioperative protocol.

POSTOPERATIVE CARE

- Postoperative care following minimally invasive colorectal surgery is enhanced with use of a standardized fast-track protocol.[5]
- Orogastric or nasogastric tube is avoided, and diet is resumed with clear liquids 8 to 12 hours after the procedure and advanced with resumption of bowel activity.
- Bladder catheter is removed on postoperative day 1.
- Ambulation is achieved the first night of surgery.
- Postoperative analgesia is accomplished with a combined modality to reduce opioid use. Local infiltration with a long-acting anesthesia can be accomplished with liposomal bupivacaine. Intravenous acetaminophen and nonsteroidal antiinflammatory drugs can be given in a staggered fashion. Use of opioid can be limited to breakthrough pain, and alvimopan can be used to eliminate the effects of opioids in the GI tract.

OUTCOMES

- Most patients following sigmoid colectomy managed with a fast-track perioperative protocol have an average length of hospital stay of 3 days.[2,4]
- Complications may warrant longer hospital stays and should be managed on an individual basis.
- Hernia rates can be reduced by use of the Pfannenstiel incision versus the umbilical incision.
- Those with malignancies should be placed on oncologic surveillance protocols.

COMPLICATIONS

- Vascular injury with intraperitoneal bleeding
- Ureteral injury
- Sexual and/or urinary dysfunction secondary to autonomic nerve injury

- Prolonged postoperative ileus
- Wound complications (e.g., hematoma, seroma, infection, and dehiscence)
- Anastomotic dehiscence
- Intraabdominal abscess
- Hernia formation

Chapter 23

Surgical Management of Complicated Diverticulitis: Perforation and Colovesical Fistula

Scott E. Regenbogen

DEFINITION

- Diverticulitis is acute or chronic inflammation and/or infection caused by perforation of a colonic diverticulum. Acute, simple diverticulitis results from localized, contained contamination, without features of complex disease, and is typically amenable to medical therapy alone.
- Complicated diverticulitis includes free perforation with peritonitis, abscess formation, fistula, or stricture and will typically require operation. Chronic or recurrent diverticulitis may be an indication for resection if the episodes are frequent, incur substantial morbidity, or fail to resolve with medical therapy.

DIFFERENTIAL DIAGNOSIS

- Diverticulitis is often a clinical diagnosis. The syndrome of left lower quadrant pain, fever, and abdominal tenderness may also be consistent with irritable bowel syndrome, gastroenteritis, stercoral perforation, appendicitis, inflammatory bowel disease, urinary tract infection, aortic dissection or aneurysmal rupture, nephrolithiasis, pelvic inflammatory disease, ovarian torsion, and a variety of other causes of acute abdominal pain.
- When diverticulitis is identified on computed tomography (CT) of the abdomen as segmental colon inflammation associated with diverticulosis, it must be distinguished from other causes of segmental colitis, including perforated neoplasm, ischemia, and Crohn's disease. Details of clinical history, family history of colorectal cancer, and previous colon evaluation are helpful in excluding the latter two.
- Except in the emergency setting, malignancy must be excluded, either by endoscopic evaluation or other means, because the principles of oncologic resection, including wide lymphadenectomy and en bloc resection, are typically violated in surgery for benign diverticular disease.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with diverticulitis typically present with abdominal pain and fever. Because more than 90% of diverticulitis occurs in the sigmoid colon, the symptoms will typically localize to the left lower quadrant.
- Free perforation may present as generalized peritonitis and/or sepsis.
- In the presence of colovesical fistula, the patient may have irritative urinary symptoms or even pneumaturia or fecaluria, and there may be air or enteral contrast visible in the bladder. Occasionally, patients with colovesical fistula may not report a preceding episode of acute diverticulitis; rather, their initial presentation may be with symptoms of the fistula itself. Passage of urine per rectum is not common with colovesical fistulae from diverticulitis.
- The clinical history should focus on the presence or absence of repeated episodes and symptoms suggesting fistulizing disease—gas or stool in the urine or per vagina.
- In consideration of the differential diagnosis, the examiner should elicit any history consistent with inflammatory bowel disease or ischemic colitis and assess the patient's risk factors for colorectal cancer (age, personal and family history of cancer or polyps, and whether any previous colorectal cancer screening evaluations have been performed).
- Physical examination in the acute setting will reveal localized or generalized abdominal tenderness. Focal guarding in the left lower quadrant is typical. Diffuse rebound tenderness suggests generalized peritonitis from free feculent perforation or purulent peritonitis from abscess rupture. Abdominal wall erythema may suggest incipient colocutaneous fistula. In the chronic setting, patients may have fullness or a palpable mass.
- Traditional recommendations for elective colon resection after two episodes of uncomplicated diverticulitis have generally been abandoned. Instead, elective colectomy is recommended on a case-by-case basis, depending on age, comorbidity, severity and frequency of attacks, and the success of medical therapy.
- Elective resection is often advised after recovery from an episode of complicated diverticulitis managed with medical therapy and/or percutaneous drainage.
- Urgent operation may be indicated for free perforation with sepsis.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Typical findings on CT scan of the abdomen include segmental colonic inflammation and pericolonic fat stranding within an area of diverticulosis. There may be extraluminal air or fluid or a contained abscess. Intravenous and oral contrast administration is helpful, although not essential. Rectal contrast is generally unnecessary, except to help with delineating a fistula.
- CT is the most sensitive test for diagnosing colovesical fistula (**FIG 1**). Other options include contrast enema (**FIG 2**), CT or fluoroscopic cystography, cystoscopy, colonoscopy, or oral administration of undigested material (e.g., charcoal, poppy seeds) to be observed for in the urine. In some cases, colovesical fistula may be a clinical diagnosis based on the presence of pneumaturia and/or fecaluria alone.

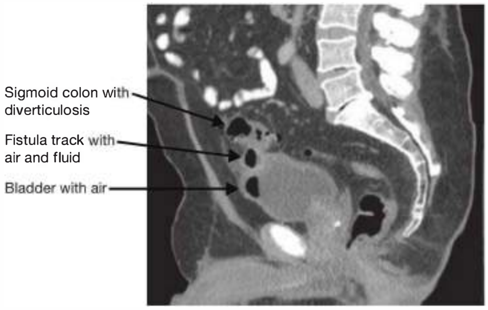

FIG 1 ● Sagittal CT image demonstrating sigmoid diverticulitis with a fistula track and air in the bladder consistent with colovesical fistula.

FIG 3 ● Colonoscopic image of colonic diverticulosis.

- Colonoscopy (**FIG 3**) is advisable for evaluation of diverticulitis and colovesical fistula in order to exclude a perforated malignancy, which can have similar clinical presentation and radiographic appearance. The presence of malignancy would warrant an oncologic mesenteric lymphadenectomy and en bloc resection of involved bladder wall, whereas the fistula may simply be divided in cases with benign inflammatory etiology.

SURGICAL MANAGEMENT

Preoperative Planning

- When patients present with diffuse peritonitis and sepsis, urgent operation may be required. Broad-spectrum antibiotics should be administered and the patient should be well resuscitated with intravenous fluid prior to surgery.
- Every effort should be made before surgery to mark acceptable sites on the abdominal skin for stoma creation bilaterally. Consideration may be given to placement of ureteral stents preoperatively if it can be performed without undue delay.
- Decision making should be centered on the patient's clinical condition, the severity of pelvic sepsis, the suitability for colorectal anastomosis, and the ability to safely resect the inflammatory segment.
- Options for surgical approach in the emergency setting include
  - Proximal diversion without resection
  - Resection with end colostomy and rectal stump closure (Hartmann procedure)
  - Resection with primary anastomosis, with or without diverting loop ileostomy
  - Laparoscopic lavage and drainage
- Complete colonoscopy in the elective setting should be performed in order to exclude a perforated malignancy that presented as perforated diverticulitis or synchronous malignancy.
- Cystoscopy and urine cytology may be considered in cases of colovesical fistula if there is suspicion for a primary bladder malignancy.
- Consideration should be given to prophylactic placement of ureteral catheter(s) to assist with identification of the ureter, if it appears to be involved with the inflammatory segment.
- Laparoscopic approaches to complex diverticular disease and colovesical fistula are appropriate in hemodynamically stable patients among surgeons with adequate laparoscopic colorectal surgery skills and training. Hand-assisted and straight laparoscopic techniques have similar short- and long-term reported outcomes.
- If inflammation is severe and there is intention to perform a Hartmann procedure with end colostomy or a colorectal anastomosis with diverting loop ileostomy, the patient should undergo preoperative evaluation and counseling by an enterostomal therapist, including marking suitable locations for a stoma on the abdomen, either unilaterally or bilaterally, if the operative plan will depend on intraoperative findings.
- Mechanical bowel preparation with or without oral antibiotics is a controversial topic. There is no definitive evidence for or against bowel preparation. However, if there is intention to use a circular end-to-end stapling device placed per anus, mechanical bowel preparation or rectal enema should be administered to clear stool from the rectum. If a colorectal anastomosis and diverting loop ileostomy is planned, mechanical bowel preparation is recommended to avoid leaving a column of stool between the ileostomy and the downstream anastomosis.

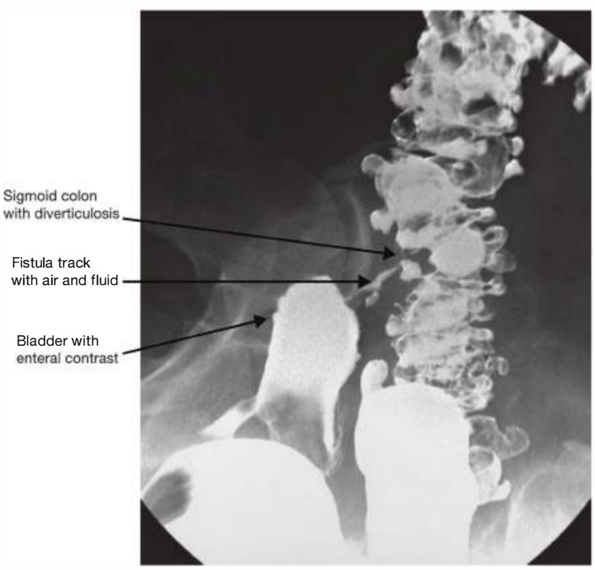

FIG 2 ● Barium enema demonstrating sigmoid diverticulosis with a fistula track and contrast filling the bladder.

- Prophylactic antibiotics to cover skin flora, enteric gram negatives, and anaerobic bacteria should be administered before making the incision.
- Appropriate pharmacologic and/or mechanical prophylaxis for venous thromboembolism is recommended.

Positioning

- The patient is placed in modified lithotomy position (**FIG 4A**) or supine with legs abducted on a split-leg table (**FIG 4B**) to provide access to the anus.
- If a laparoscopic approach is used, consideration may be given to a position-assisting device, such as a beanbag, to prevent the patient from sliding during extreme positioning changes.
- If stoma markings were performed preoperatively, these should be redrawn with a marker that will remain visible after skin preparation.

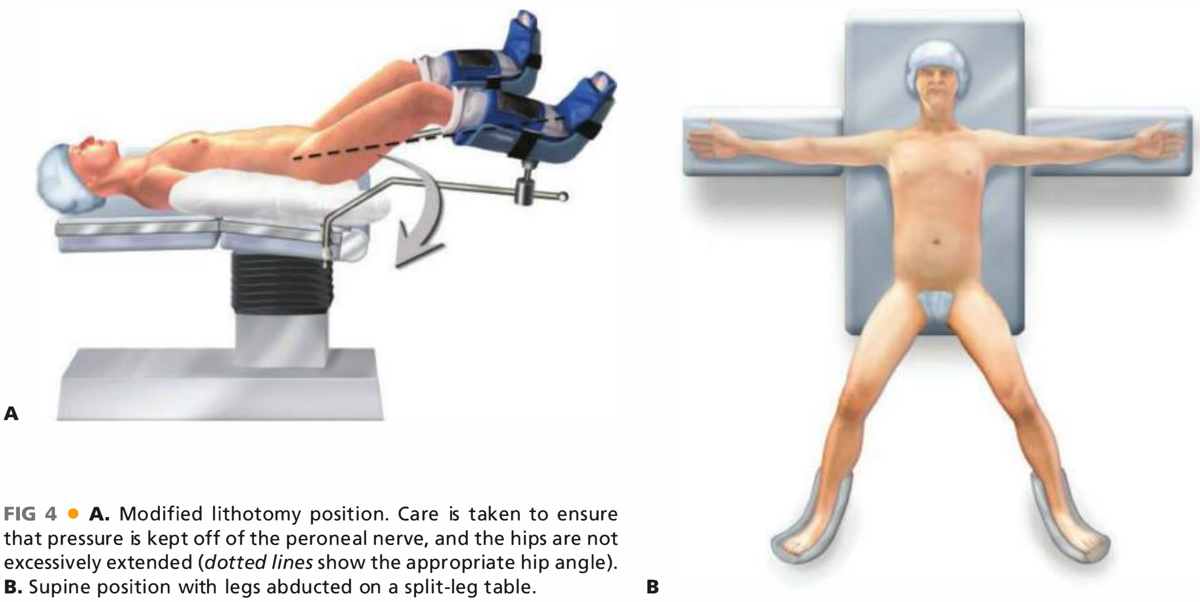

FIG 4 ● **A.** Modified lithotomy position. Care is taken to ensure that pressure is kept off of the peroneal nerve, and the hips are not excessively extended (*dotted lines* show the appropriate hip angle). **B.** Supine position with legs abducted on a split-leg table.

LAPAROSCOPIC ELECTIVE SIGMOID COLECTOMY, BLADDER REPAIR

Abdominal Access and Port Placement

- The abdomen may be accessed via a percutaneous Veress needle or an open Hasson cannula technique.
- Typical port placement is depicted in **FIG 5**. A 12-mm camera port is placed at the umbilicus. Three working ports are inserted, including a 5-mm port in the right upper quadrant, a 12-mm port in the right lower quadrant (preferably at a potential diverting loop ileostomy site), and a 5-mm port in the left lower quadrant (preferably at a potential colostomy site).

Isolation and Division of the Inferior Mesenteric Artery Pedicle

- In order to gain access to the proximal inferior mesenteric artery (IMA), the gastrocolic omentum is elevated over the transverse colon, into the upper abdomen, with the patient in steep Trendelenburg position, with the operating table tilted toward the right. The small bowel is brought to the right upper quadrant and out of the pelvis.
- Elevation of the rectosigmoid mesentery with a grasper through the left lower quadrant port toward the left lower quadrant, demonstrates the IMA as a ridge in the sigmoid colon mesentery and exposes a plane between the mesentery and the retroperitoneum on the medial peritoneal fold of the mesentery. With cautery attached to Endo Shears brought through the right lower quadrant port, a long incision is made in the medial peritoneal fold of the mesentery along a clear space seen between the IMA and the retroperitoneum (**FIG 6**).
- Through this incision, the left ureter, gonadal vessels, and retroperitoneal tissues are identified and dissected down off of the vessel and the mesentery (**FIG 7A**). If the left iliac artery and/or left psoas muscle are exposed, the plane of dissection must be brought more anteriorly. The left ureter is identified definitively by visualizing peristalsis.
- Once the left ureter has been identified and protected in the retroperitoneum, the IMA is encircled. The IMA and its terminal branches, the left colic artery, and the superior hemorrhoidal artery form what appears to be a "letter T," facilitating the identification of these critical vascular structures (**FIG 7B**). The IMA is then divided.

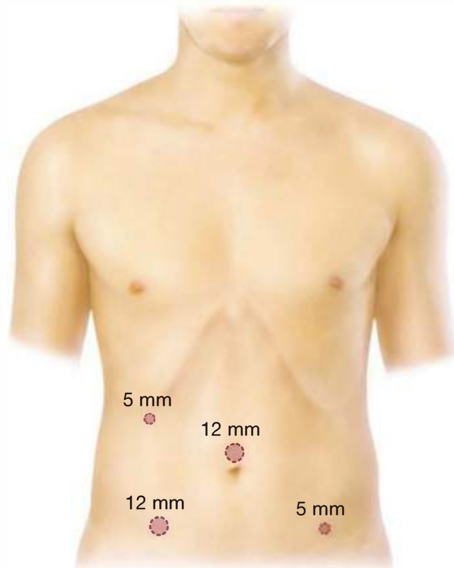

FIG 5 ● Laparoscopic port placement for sigmoid colectomy. A 12-mm camera port is placed at the umbilicus. Three working ports are inserted, including a 5-mm port in the right upper quadrant, a 12-mm port in the right lower quadrant (preferably at a potential diverting loop ileostomy site), and a 5-mm port in the left lower quadrant (preferably at a potential colostomy site).

I prefer a bipolar vessel-sealing device (**FIG 8A**) but choices include vascular clips, endoscopic staplers (**FIG 8B**), or endoloops. When using an energy device for division, it is advisable to have endoloops available in the room as a backup to control bleeding from the divided pedicle in case of device failure.

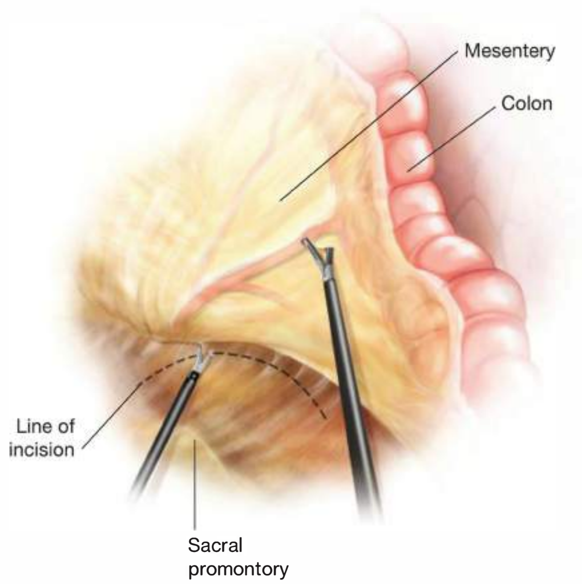

FIG 6 ● The sigmoid colon is elevated, placing tension on the IMA pedicle, and an incision is made in the medial peritoneal fold dorsal to the IMA *(dotted line)*.

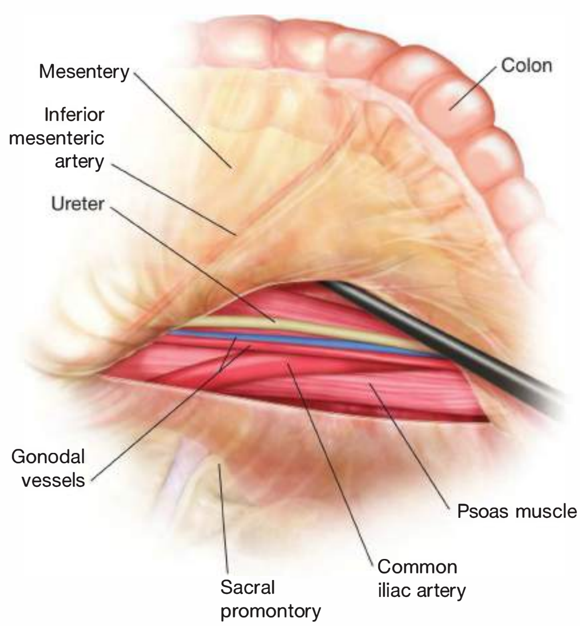
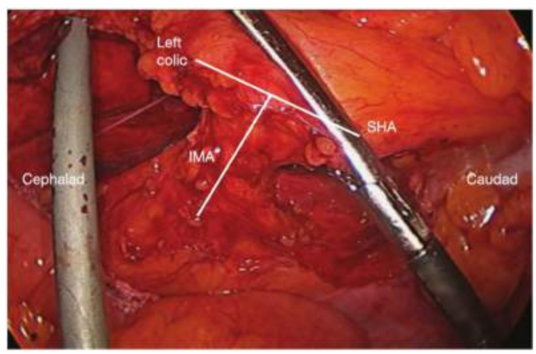
Mobilization of the Descending Colon and Splenic Flexure

- The "medial-to-lateral" dissection of the mesocolon is performed by elevating the divided vascular pedicle, identifying the line of separation between the posterior side of the colon mesentery ventrally and Gerota's fascia overlying the kidney and retroperitoneum dorsally

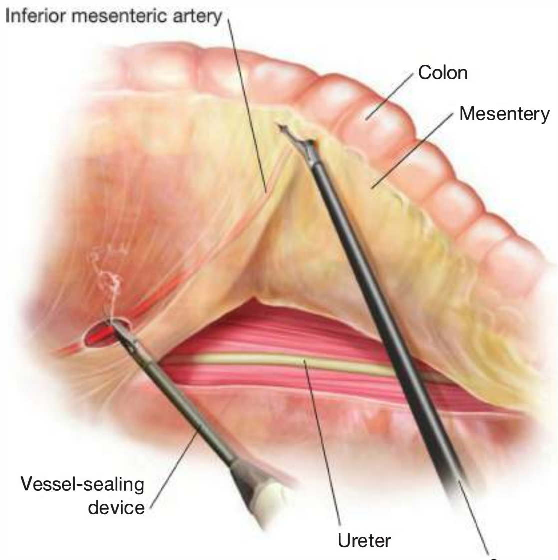


A

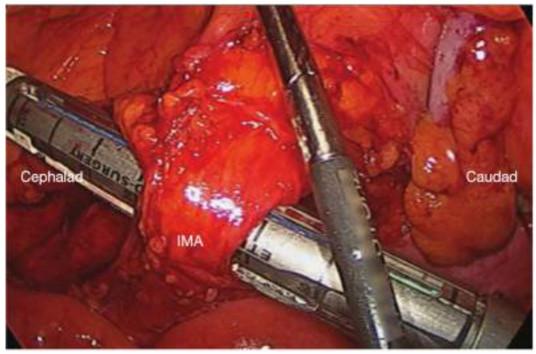


B

FIG 7 ● **A.** The mesenteric vessels are isolated by sweeping the retroperitoneal tissues, including the left ureter and gonadal vessels, posteriorly off the mesentery of the sigmoid colon. The left ureter is identified as it crosses under the colon mesentery and is protected in the retroperitoneum. **B.** The IMA and its terminal branches, the left colic artery, and the superior hemorrhoidal artery (SHA) form what appears to be a "letter T," facilitating the identification of these critical vascular structures.



A

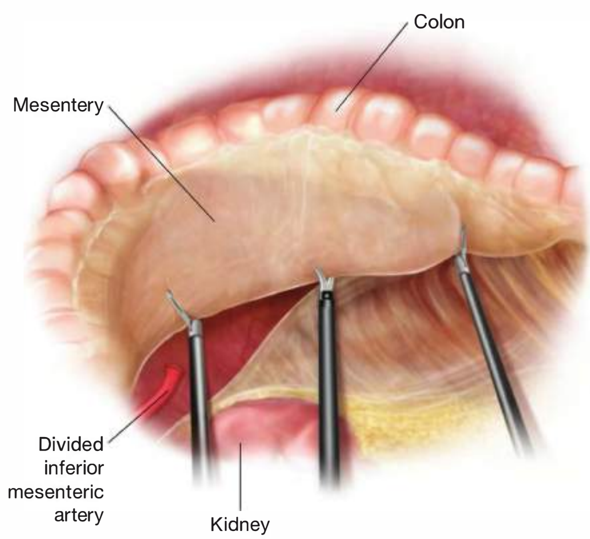


B

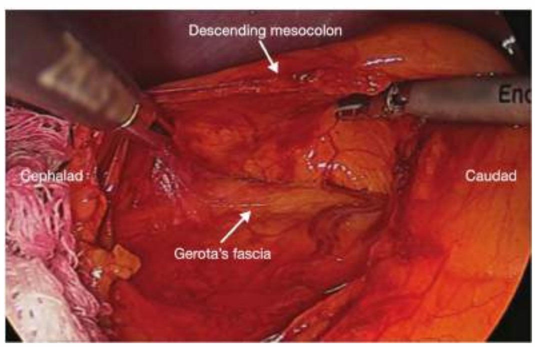
FIG 8 ● The IMA is encircled at its base and divided with a **(A)** bipolar vessel-sealing device or **(B)** endoscopic stapler, ensuring that the ureter is not ensnared during the division.

(**FIG 9A,B**). The retroperitoneal tissues are swept down (dorsally) with a combination of cautery and blunt dissection. This dissection continues laterally to the abdominal side wall and superiorly to the inferior border of the pancreas and the superior edge of the distal transverse colon and splenic flexure. This will greatly facilitate the mobilization of the splenic flexure later during the case.

- The lateral dissection is then performed by retracting the colon medially and dividing the white line of Toldt from the pelvic brim to the splenic flexure (**FIG 10**). As the dissection continues superiorly, the patient's position is gradually altered, going from steep Trendelenburg toward slight reverse Trendelenburg position. The rightward tilt is maintained. If the medial dissection has been performed completely, there should be only a single tissue layer to divide before meeting the medial plane of dissection.
- At this point, the splenic flexure is mobilized. It is often helpful to access the lesser sac first by transecting the gastrocolic ligament with a tissue-sealing device from the distal transverse colon (**FIG 10**). The splenic flexure is then fully mobilized by transecting the splenocolic and phrenocolic ligaments superolateral to the colon with



A



B

FIG 9 ● **A,B.** A medial-to-lateral dissection of the mesocolon is performed by elevating the divided vascular pedicle and sweeping the Gerota's fascia and retroperitoneal tissues dorsally, laterally to the abdominal wall, and superiorly to the tail of the pancreas and posterior to the splenic flexure of the colon.

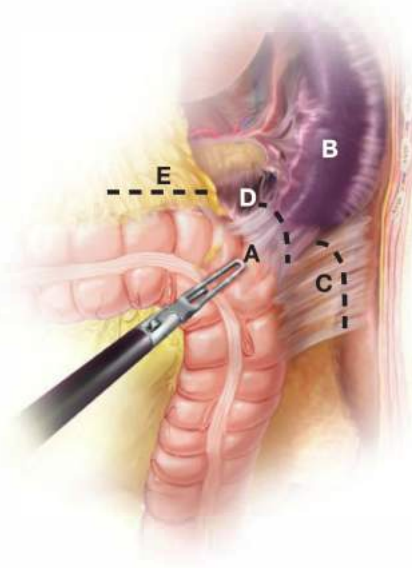


FIG 10 ● Mobilization of the splenic flexure. The phrenocolic *(C)*, splenocolic *(D)*, and gastrocolic ligaments *(E)* are transected in order to separate the splenic flexure *(A)* from the spleen *(B)*.

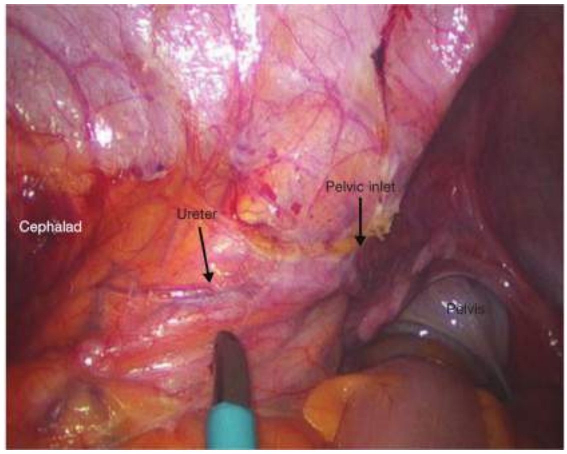

FIG 11 ● Mobilization of the sigmoid of the pelvic inlet. The left ureter can be seen crossing the left common iliac artery at the level of the left pelvic inlet.

cautery or a tissue-sealing device (**FIG 10**). To check for adequate length, healthy descending colon above the area of inflammation should be able to reach to the pelvis without any tension.

Mobilization of the Rectosigmoid, Separation, and Repair of the Fistula

- The sigmoid colon typically has attachments to the left sidewall at the pelvic inlet. These can be incised with cautery after the ureter has been reidentified, crossing the left common iliac artery at the level of the left pelvic inlet (**FIG 11**). Peritoneal incisions down each side of the rectosigmoid to the level of the upper rectum will allow identification of the upper mesorectum.
- The fistula is divided with a combination of sharp dissection and cautery. If it cannot be safely achieved laparoscopically, the extraction incision may be made at this time and separation accomplished by finger fracture.
- Once the colon and bladder are separated, the bladder may be repaired with one or two layers of absorbable suture material if a full-thickness defect is exposed. The closure can be leak tested by irrigation through the urinary catheter with methylene blue dye to enhance visualization of a potential urinary leak.
- A closed suction drain may be left in the pelvis if the bladder repair is extensive; but often, the actual hole in the bladder is quite difficult to identify definitively and drainage is not required for most cases.
- The upper rectum is then divided distal to the coalescence of the teniae coli by bluntly creating a window between rectum and mesorectum. The mesorectum is divided at this level using a tissue-sealing device. The upper rectum is then transected either with an endoscopic stapler via the right lower quadrant port site or through the extraction incision.

Extraction Incision, Colon Division, and Anastomosis

- The specimen may be extracted through a lower abdominal incision of choice. I prefer a small Pfannenstiel incision with a transverse curvilinear fascial incision.
- The specimen is exteriorized through the extraction incision.
- Before division of the bowel, I prefer to clamp the marginal artery distally, then divide it sharply within the mesentery, at a point on the descending colon proximal to the area of inflammation, just beyond the intended point of division. The presence of arterial bleeding from the proximal end indicates adequate blood supply for the future anastomosis.
- The colon is then divided, either with a linear stapler or a purse-string application device.
- A 31-Fr anvil of an end-to-end anastomosis (EEA) device is sewn into the divided end of the colon, and care should be taken to be sure that the mesentery is not twisted as the anvil is brought to the pelvis.
- The handle of the stapler is advanced transanally, up to the rectal staple line, and an end-to-end stapled EEA colorectal anastomosis is performed (**FIG 12A**). The resected "donuts" should be examined. The integrity of the anastomosis is tested by insufflating it under water. The presence of an air leak would indicate an anastomotic disruption and would require repair or revision of the anastomosis, with or without proximal diversion (**FIG 12B**).

Closure

- If the omentum can be mobilized to the pelvis, it is placed between the anastomosis and the bladder repair as a vascularized soft tissue flap.
- The extraction incision is closed in layers. The large laparoscopic ports may be closed from the outside or with the use of a laparoscopic suture passer. The small ports are closed at skin level only.

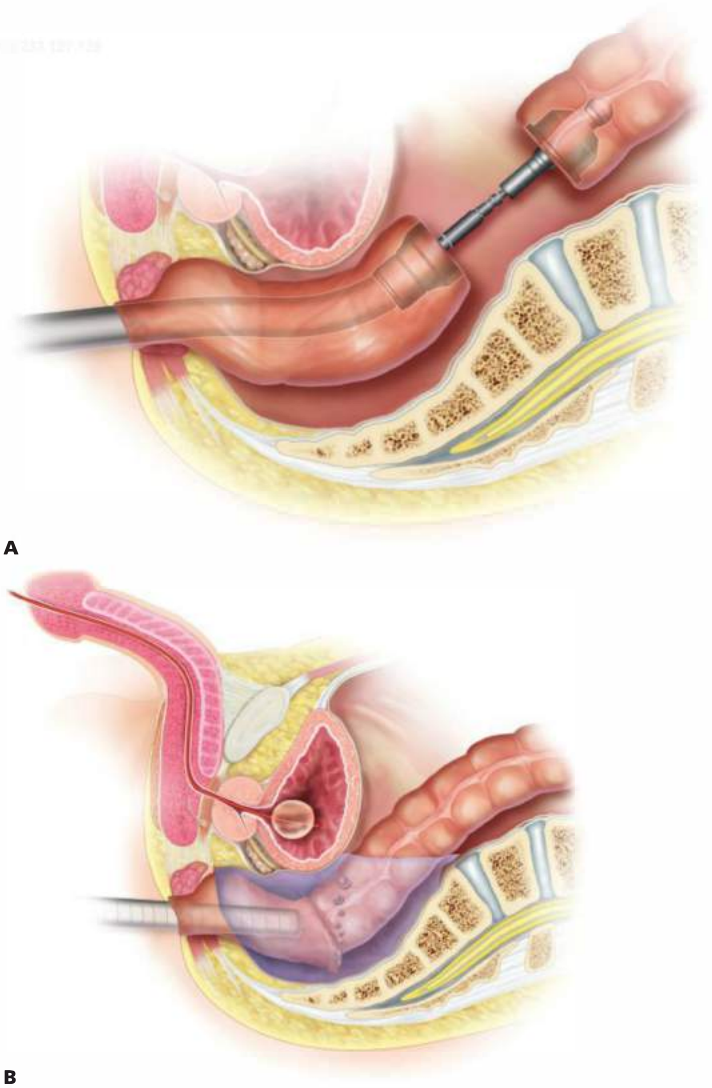

FIG 12 ● The colorectal anastomosis. **A.** A stapled EEA colorectal anastomosis is performed. **B.** The integrity of the anastomosis is tested by insufflating it under water. The presence of an air leak would indicate an anastomotic disruption and would require a revision of the anastomosis.

HARTMANN PROCEDURE

Abdominal Entry, Containing Contamination

- In an emergency setting, a lower midline laparotomy, occasionally with extension above the umbilicus, facilitates rapid and ample exposure.
- In case of purulent or feculent peritonitis, contamination should first be evacuated and irrigated clean. Often, there will be a contained collection or phlegmon overlying a necrotic perforation. Blunt finger fracture will provide exposure of the perforation, then contamination should again be contained rapidly.

Colon Mobilization and Resection

- Mobilization should be kept to the minimum necessary. Unlike in elective sigmoidectomy for diverticulitis, it is not essential to resect the rectosigmoid junction or to mobilize the splenic flexure. Rather, the goal should be to resect the grossly perforated colon segment, divide the colon proximal and distal to the acutely inflamed segment, and maintain as much vascular supply as possible for the future colostomy takedown.

- The descending colon should be mobilized only as much as is required for the divided colon to reach the abdominal wall without tension at the intended colostomy aperture. Excessive mobilization only exposes additional tissue planes into which contamination may extend and establish a future abscess.
- The rectosigmoid may be left in place, and the divided colon/rectal stump marked with a permanent suture. The status of the superior hemorrhoidal artery should be documented in the operative report and dissection in the pelvis should be minimized in order to preserve tissue planes for the potential future colostomy closure.

Abdominal Closure and Stoma Creation

- The colostomy aperture is typically created in the left abdomen, ideally at a site marked preoperatively.
- The abdomen is closed in layers. Depending on the extent of contamination, the skin incision may be closed primarily, closed in a delayed primary fashion, closed over gauze wicks, or left open to heal by secondary intention.
- The colostomy is matured in a standard fashion.

LAPAROSCOPIC LAVAGE AND DRAINAGE

Abdominal Access and Port Placement

- The abdomen may be accessed via a percutaneous Veress needle or an open Hasson cannula technique. Port placement is then chosen, depending on the location of perforation and presence of adhesions to the anterior abdominal wall. A typical port distribution is depicted in **FIG 13**.

Identification and Control of the Perforation

- After laparoscopic assessment, sharp adhesiolysis is performed with scissors and cautery to free adhesions to the anterior abdominal wall.
- Purulent fluid is aspirated and a sample obtained for aerobic and anaerobic bacterial culture.
- Blunt dissection is used to separate omentum and small bowel from the perforated sigmoid colon, exposing loculated fluid collections.
- Copious irrigation (4 L or more) with sterile saline, with or without dilute iodine and/or antibiotics, is used to clear any residual contamination.
- If a small perforation is identified, it may be sutured closed with absorbable Lembert sutures. It is desirable to buttress this closure with a patch of omentum or epiploic appendage, if easily mobilized, to cover the perforation (**FIG 14**).

Drain Placement and Closure

- Two large closed suction drains are placed through the laparoscopic port incisions and left to reside in the pelvis near the site of perforation.
- The laparoscopic incisions are closed with subcuticular suture, and the drains are sutured to the skin and connected to bulb suction.

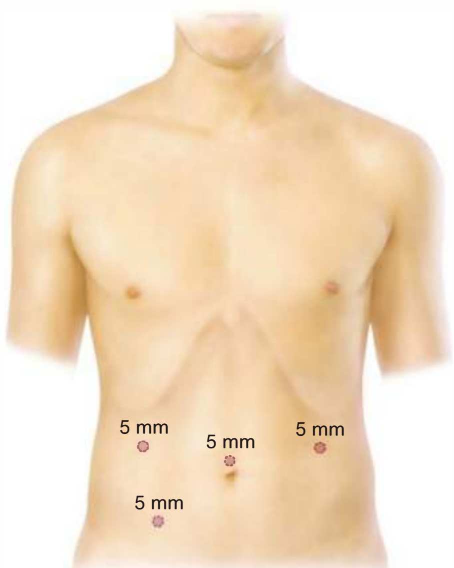

FIG 13 ● Laparoscopic port placement for laparoscopic lavage and drainage. Four 5-mm ports are inserted as shown.

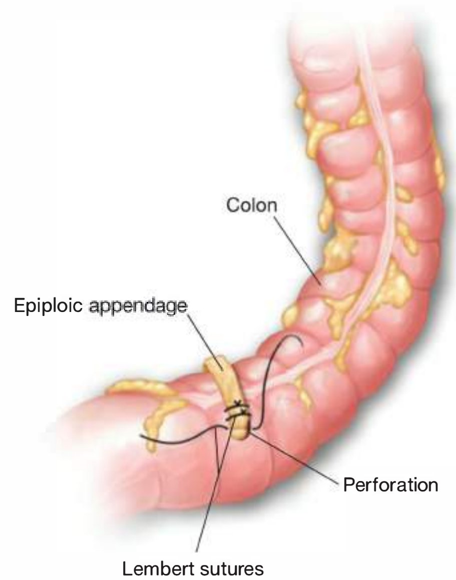

FIG 14 ● Laparoscopic lavage and drainage. If a small perforation is identified, it may be sutured closed with absorbable Lembert sutures. It is desirable to buttress this closure with a patch of omentum or epiploic appendage, if easily mobilized, to cover the perforation.

PEARLS AND PITFALLS

Indications	■ Traditional recommendations for elective resection after two uncomplicated episodes of diverticulitis have generally been abandoned. ■ Resection is indicated after nonoperative management of complicated diverticulitis, including free perforation, abscess, and fistula. ■ Free perforation with clinical sepsis is an indication for urgent operation.
Preoperative planning	■ Stoma sites should be marked preoperatively, if there is a possibility of colostomy or ileostomy. ■ Ureteral stent(s) should be considered in cases in which severe retroperitoneal inflammation is suspected based on preoperative imaging. ■ In elective cases, colonoscopy should be performed preoperatively to exclude a perforated neoplasm. ■ Mechanical bowel preparation in elective cases remains a controversial topic, left to the discretion of the surgeon, except in cases in which colorectal anastomosis and proximal diverting ileostomy is planned; in which case, bowel preparation should be administered to empty the diverted colon. ■ Appropriate antibiotics and venous thromboembolism prophylaxis should be administered perioperatively.
Choice of operation	■ Proximal diversion without resection ■ Resection with end colostomy and rectal stump closure (Hartmann procedure) ■ Resection with primary anastomosis, with or without diverting loop ileostomy ■ Laparoscopic lavage and drainage
Postoperative management	■ Postoperative antibiotics are not required in elective cases and are left to surgeon discretion in emergency cases with purulent or feculent peritonitis. ■ Cystogram may be used to verify repair of bladder fistula prior to removal of urinary catheter.

POSTOPERATIVE CARE

- Postoperative care should include combined analgesia with acetaminophen, nonsteroidal antiinflammatory medications, narcotics, and/or regional or epidural anesthesia. Mechanical and/or pharmacologic prophylaxis against venous thromboembolism should be provided. Early mobilization and early enteral feeding are both associated with shorter duration of postoperative ileus and should be encouraged. Routine postoperative nasogastric intubation is not recommended.
- Duration of urinary catheterization should be minimized to reduce the risk of urinary tract infection. After repair of colovesical fistula, however, an indwelling urinary catheter is typically left in place for 5 to 10 days, depending on the complexity of the bladder repair. A cystogram may be performed to confirm an intact repair before Foley catheter removal.
- Antibiotics are not given postoperatively after elective resection for colovesical fistula but may be continued for a varying duration after urgent operations for frank perforation with purulent or feculent peritonitis.

OUTCOMES

- The likelihood of recurrent diverticulitis after elective resection is determined largely by the level of anastomosis—less than 5% with a colorectal anastomosis but more than 12% with a colosigmoid anastomosis.
- Complication rates after Hartmann procedure are high. The most common complications are wound infection, sepsis, stoma necrosis, and intraabdominal abscess.
- Less than half of patients who undergo emergency Hartmann procedure go on to have their colostomy reversed.
- After laparoscopic lavage, about 6% of patients will require early reoperation for clinical deterioration. About half of the remaining patients will eventually require elective resection, and the remainder recover without further operative intervention.

COMPLICATIONS

- Anastomotic leak
- Abscess
- Ureteral injury
- Bowel obstruction
- Hemorrhage
- Stoma complications (necrosis, dehiscence, obstruction)
- Bladder leak

Chapter 24

Total Abdominal Colectomy: Open Technique

Tarik Sammour   Andrew G. Hill

DEFINITION

- Total abdominal colectomy is defined as the removal of the entire colon, following which the distal ileum is anastomosed to the rectum or an end ileostomy is created.

DIFFERENTIAL DIAGNOSIS

- Inflammatory bowel disease (IBD)
- Severe acute colitis (various etiologies)
- Polyposis syndromes, including familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer (HNPCC)
- Slow-transit constipation
- Malignancy

PATIENT HISTORY AND PHYSICAL FINDINGS

- Specific history and examination findings will depend on the indication for total abdominal colectomy.
- History of previous abdominal surgery is important, particularly in the setting of IBD. If the patient has had multiple small bowel resections and is at risk of short-gut syndrome, then total abdominal colectomy is contraindicated.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Endoscopy: Colonoscopy is required to diagnose the disease for which total colectomy is required, and an up-to-date flexible sigmoidoscopy is needed to assess the state of the rectum and ensure it is disease/polyp-free.
- Patients with IBD also require small bowel imaging (preferably computed tomography [CT] or magnetic resonance imaging [MRI] enteroclysis) to ensure that the small bowel is free of diseased segments.
- Patients with severe constipation require a colonic transit study to confirm functional colonic disease.
- Patients with malignancy require a staging CT scan of the chest/abdomen/pelvis.

SURGICAL MANAGEMENT

Preoperative Planning

- The surgeon obtains informed consent from the patient, explaining the procedure, expected recovery, and risks and benefits of the operation. Consent should also be obtained for a stoma should this be required.
- The patient's nutritional status should be optimized prior to surgery.
- A suitably qualified nurse should carry out preoperative stoma marking.
- Blood crossmatching is performed (at least two units available).
- A preoperative sodium phosphate enema is administered.
- Enhanced recovery after surgery (ERAS) perioperative care protocols are applied.[1,2]
- A midthoracic epidural should be inserted preoperatively.[3]
- An indwelling Foley catheter is inserted preoperatively.
- Appropriate intravenous antibiotic prophylaxis is given on induction.[4]
- Consideration should be given to intravenous steroid supplementation if the patient is steroid-dependent.
- Subcutaneous low-molecular-weight heparin is given on induction.
- Calf compression stockings are applied.
- Note: Mechanical bowel preparation is not recommended.[5]

Positioning

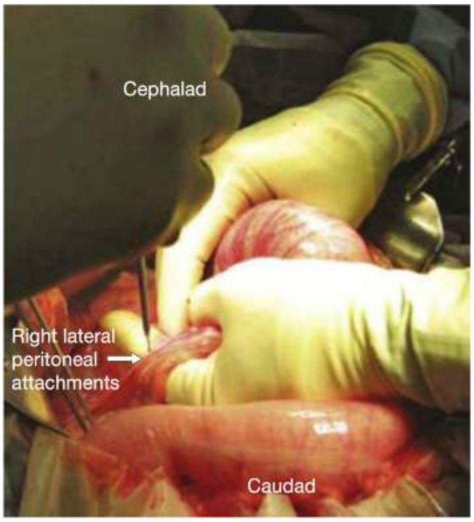
- The patient should be placed on a supine position with the arms out. Ensure that the arms are not hyperabducted to avoid brachial plexopathy.
- The patient should be as far down the bed as possible (to provide access to the anus). Ensure that the buttocks remain well supported on the bed.
- The legs should be placed in lithotomy braces with adequate padding. Ensure that there is no pressure on the common peroneal nerves bilaterally.
- A strap should be placed across the pelvis to hold the patient on the bed.
- Once the patient is positioned, a digital rectal examination and proctoscopy should be performed to ensure that there is no rectal abnormality.
- The patient's skin is prepped and draped from the xiphisternum to the pubis, ensuring access to the anus.
- The surgeon stands on the patient's left side, and the first assistant stands on the opposite side.

INCISION AND ACCESS

- A generous midline laparotomy is performed.
- A suitable laparotomy retractor is inserted.
- After general inspection, the small bowel is packed with moist, large swab packs into the upper abdominal cavity.

ASCENDING COLON MOBILIZATION

- The ascending colon is mobilized by medial traction and dissection along the right paracolic gutter using diathermy (FIG 1).
- Care is taken to identify, and avoid damage to, the right gonadal vessels, the right ureter, and the duodenum.



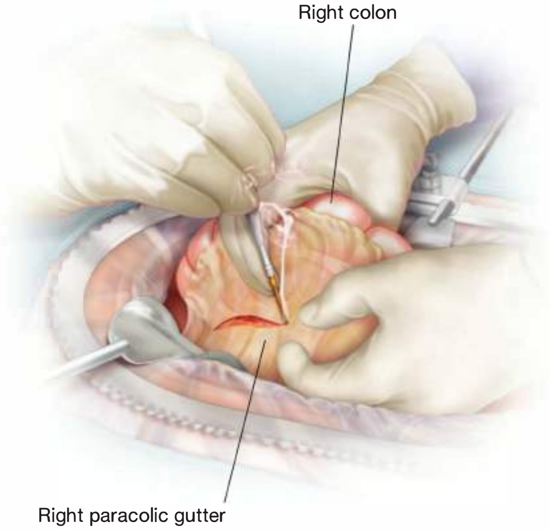


FIG 1 ● Ascending colon mobilization. The surgeon retracts the ascending colon medially. Dissection proceeds along the right paracolic gutter.

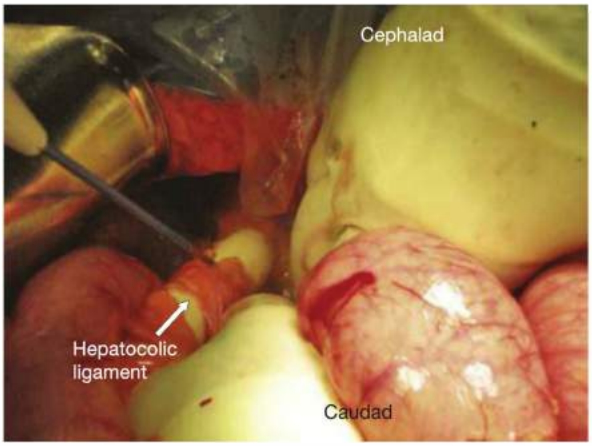
TRANSVERSE COLON MOBILIZATION

- The hepatic flexure is mobilized by dividing adhesions between the gallbladder and liver. Gentle traction on the hepatocolic ligament exposes the hepatocolic ligament, which is then transected with electrocautery (FIG 2).
- The gastrocolic ligament is exposed as the assistant retracts the greater omentum superiorly while the surgeon retracts the transverse colon anteroinferiorly.
- Diathermy is used to separate the greater omentum from the anterior leaf of the transverse mesocolon.
- The splenocolic ligament is divided as close to the colon as feasible, avoiding undue traction on the spleen. The splenocolic ligament needs to be approached from both sides to facilitate ease of mobilization of the splenic flexure. Once the gastrocolic ligament has been completely transected, transection of the lateral peritoneal



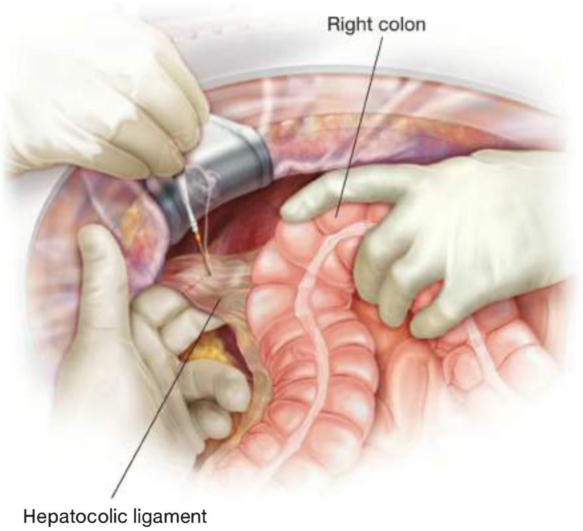


FIG 2 ● Hepatic flexure mobilization. Gentle traction on the hepatic flexure of the colon exposes the hepatocolic ligament, which is then transected with electrocautery.

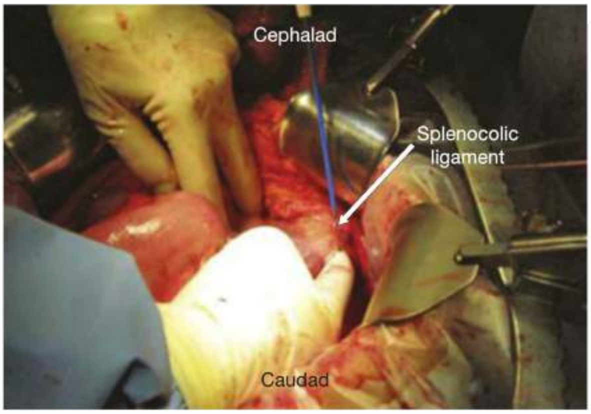

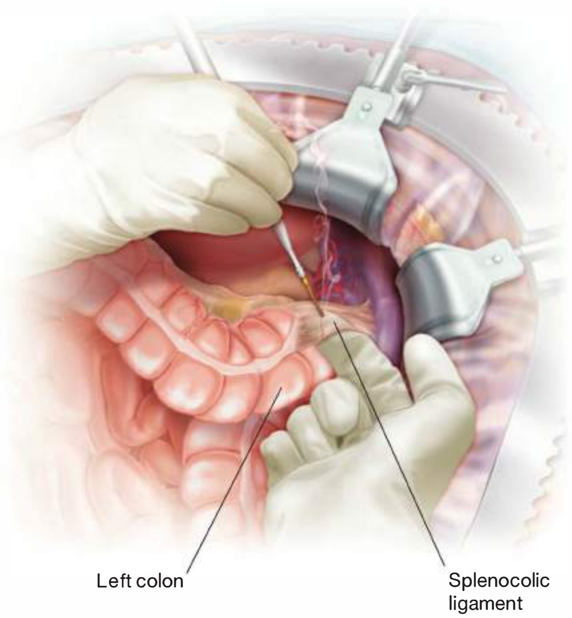

FIG 3 ● Splenic flexure mobilization. After medial and lateral mobilization of the splenic flexure attachments, the surgeon hooks his or her right index finger under the splenocolic ligament, providing good exposure and allowing for a safe transection of this ligament.

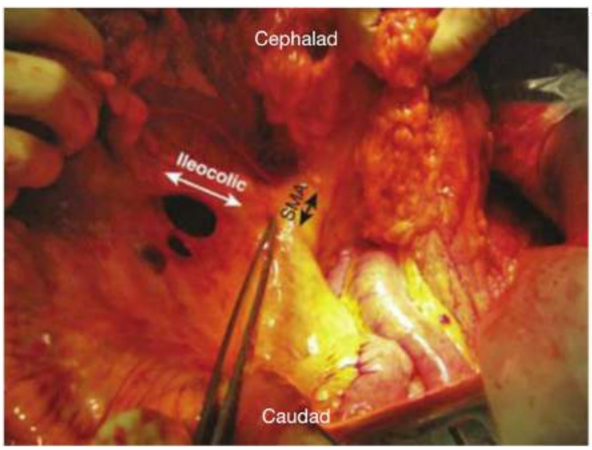
attachments allows for mobilization of the splenic flexure. At this point and from the right side of the table, the surgeon hooks the splenocolic ligament anteriorly with his or her right index finger, exposing the ligament adequately for the assistant to transect it using electrocautery (**FIG 3**).

PROXIMAL DIVISION

- The terminal ileum is mobilized by division of surrounding adhesions proceeding with the dissection toward the root of the mesentery.
- The ileocolic pedicle (and right colic pedicle, if present) is identified and clamped with heavy artery forceps by creating windows on either side with diathermy (**FIG 4**).
- The pedicle is divided between the artery forceps and ligated proximally and distally with absorbable braided, size 0 ties.



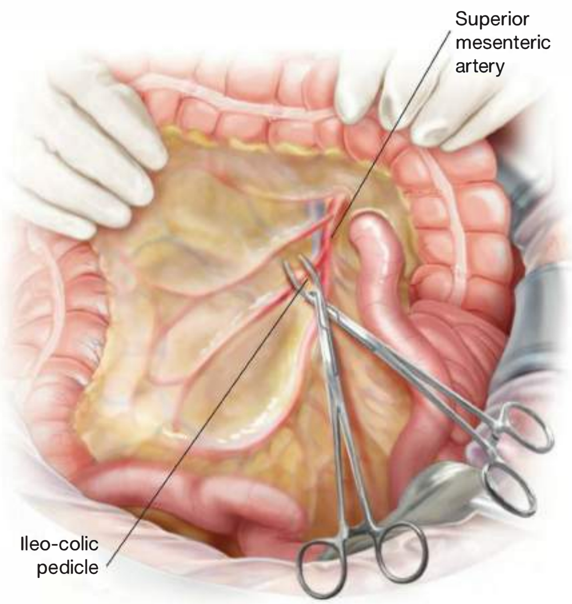


FIG 4 ● Ileocolic pedicle division. The ileocolic vessels are transected between clamps and will be subsequently ligated with heavy silk sutures. SMA, superior mesenteric artery.

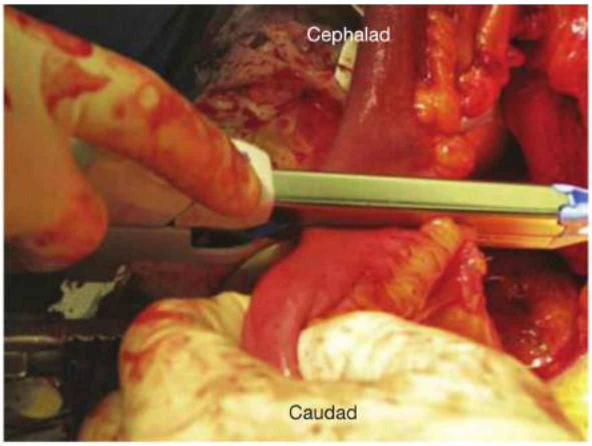
- Alternatively, if the surgeon is certain of the absence of malignancy, then the mesenteric blood supply to the proximal segment can be taken close to the bowel wall.
- The terminal ileum is transected with a single firing of a linear stapler, such as gastrointestinal anastomosis (GIA) 60-3.5 stapler or GIA 60-4.8 if the ileum is thickened or inflamed (**FIG 5**).
- The ascending colon mesentery is divided, proceeding from proximal to distal until the middle colic pedicle is encountered.
- The middle colic pedicle is clamped with heavy artery forceps by creating windows on either side with diathermy.
- The pedicle is divided between the artery forceps and ligated proximally and distally with absorbable braided, size 0 ties.



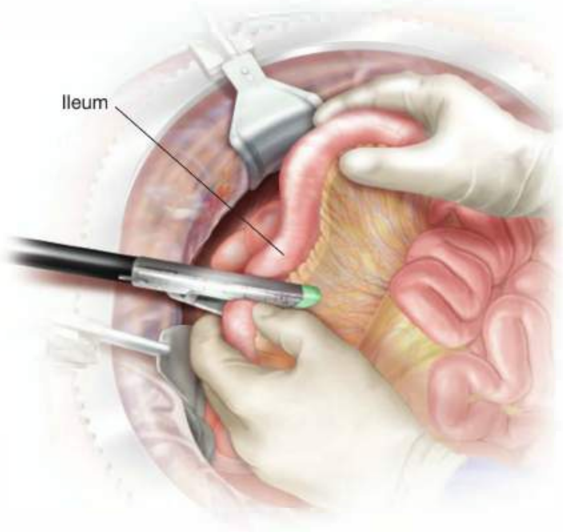


FIG 5 ● Proximal division. The terminal ileum is transected with a linear stapler.

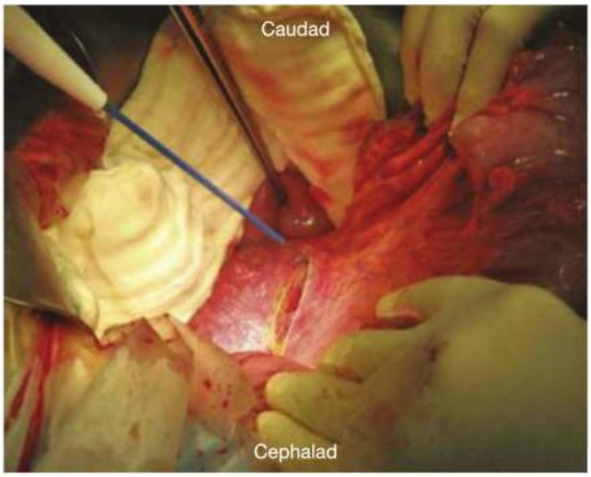
DESCENDING COLON MOBILIZATION

- The descending colon is mobilized by medial traction and dissection along the left paracolic gutter using diathermy (**FIG 6**).
- Care is taken to identify, and avoid damage to, the left gonadal vessels and left ureter (**FIG 7**).
- Dissection is stopped at the rectosigmoid junction.



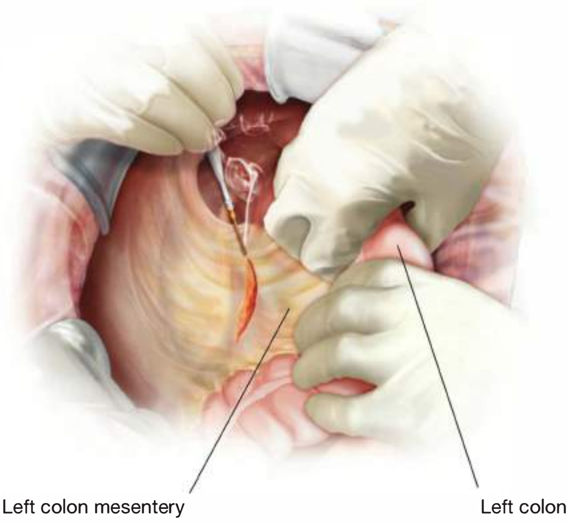


FIG 6 ● Descending colon mobilization. With the descending colon retracted medially, the lateral peritoneal attachments are transected with electrocautery along the left paracolic gutter.

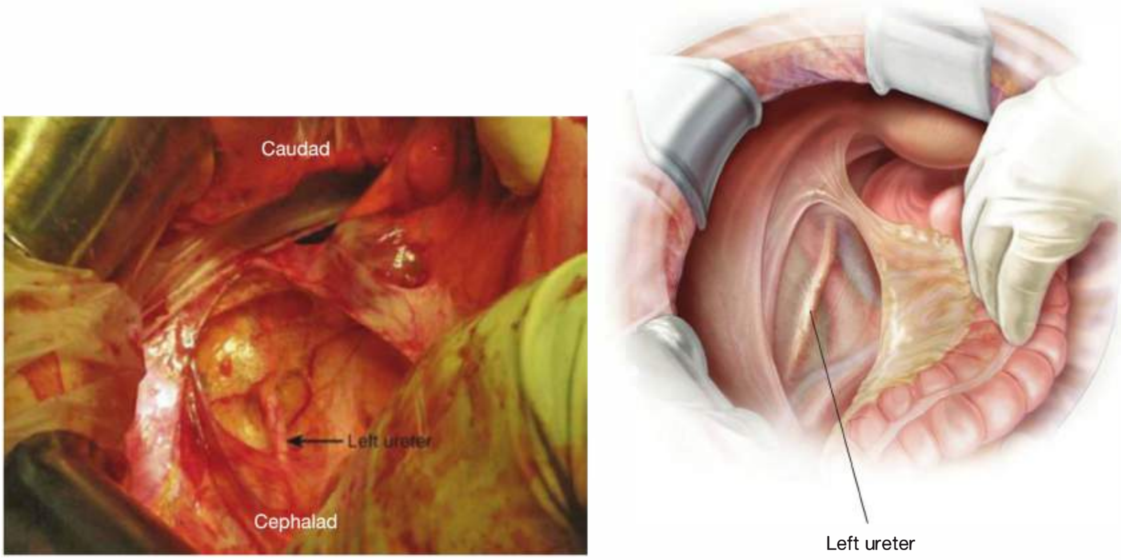

FIG 7 ● Identification of left ureter. After full mobilization of the descending colon, the left ureter is exposed in the retroperitoneum. The surgeon is retracting the descending colon medially.

DISTAL DIVISION

- The inferior mesenteric pedicle is identified and clamped with heavy artery forceps by creating windows on either side with diathermy.
- The pedicle is divided between the artery forceps and ligated proximally and distally with absorbable braided, size 0 ties (**FIG 8**).
- Alternatively, if the surgeon is certain of the absence of malignancy, then the mesenteric blood supply to the distal segment can be taken close to the bowel wall.
- The rectosigmoid junction is then divided with a linear stapler (such as a thoracoabdominal [TA] 60-4.8 stapler; **FIG 9**).
- The specimen is removed and sent to the laboratory in formalin.

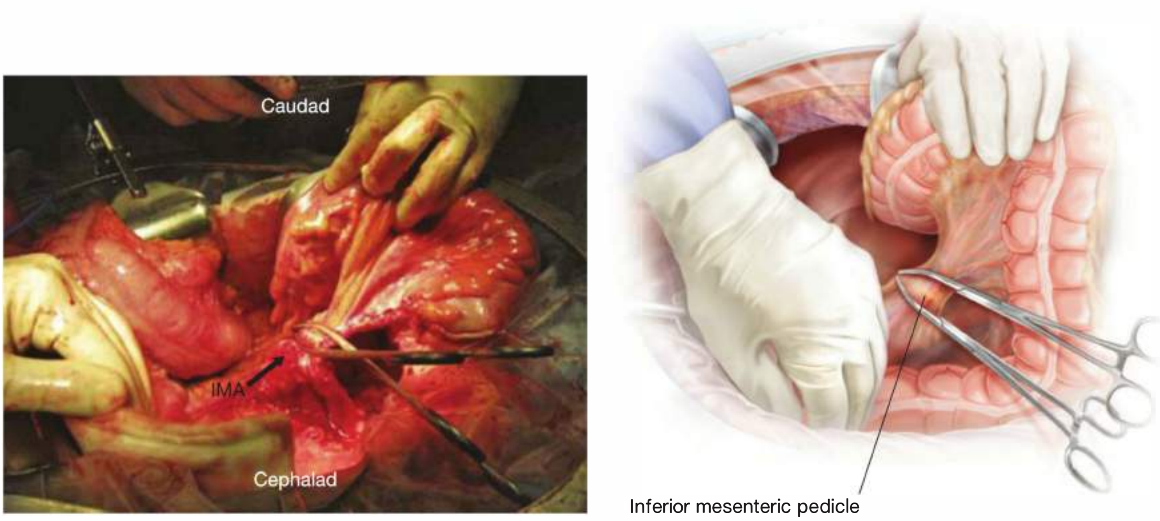

FIG 8 ● Inferior mesenteric artery (IMA) division. The IMA is transected between clamps and will subsequently be ligated with heavy silk sutures.

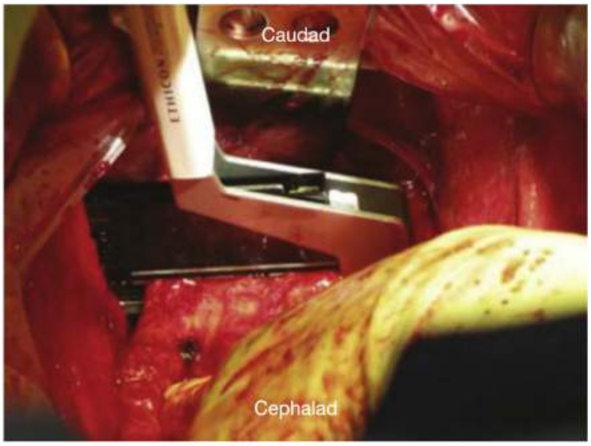

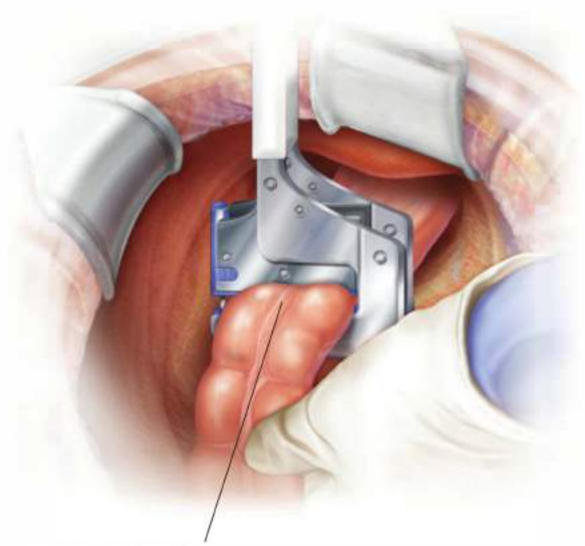

FIG 9 ● Distal division. Distal transection, at the level of the rectosigmoid junction, is performed with a linear TA stapler device.

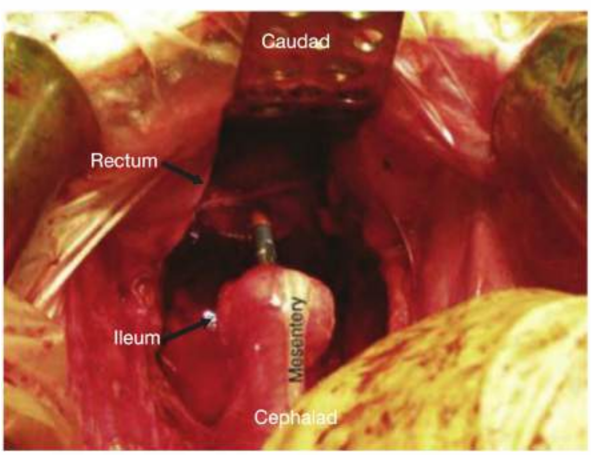
ILEORECTAL ANASTOMOSIS

- The distal ileum is inspected to ensure adequate blood supply and length for a tension-free ileorectal anastomosis.
- An enterotomy is made with diathermy on the antemesenteric border of the distal ileum, 2 cm proximal to the division staple line.
- The anvil of a circular stapler (e.g., end-to-end anastomosis [EEA] 4.8 stapler), the size of which can be established with anal sizers, is inserted into the enterotomy and secured with a purse-string suture (nonabsorbable, monofilament size 0).
- The circular stapler is inserted through the anus, and the trocar is pushed out through the rectum anterior to the staple line.
- The trocar and anvil are joined, ensuring that the small bowel mesentery is not twisted and the anastomosis is tension-free (**FIG 10**). The stapler is then fired, creating a side-to-end ileorectal anastomosis.
- An underwater air leak test is performed by pouring warm water into the pelvis and insufflating air from the below with a proctoscope.
- Consideration is given to a protecting, diverting loop ileostomy if the air leak test is positive, if the patient is malnourished or acutely unwell, or if there are any technical issues with the anastomosis. In more extreme cases, where an anastomosis is undesirable or not possible, an end ileostomy can be fashioned, leaving a closed rectal stump in the pelvis.



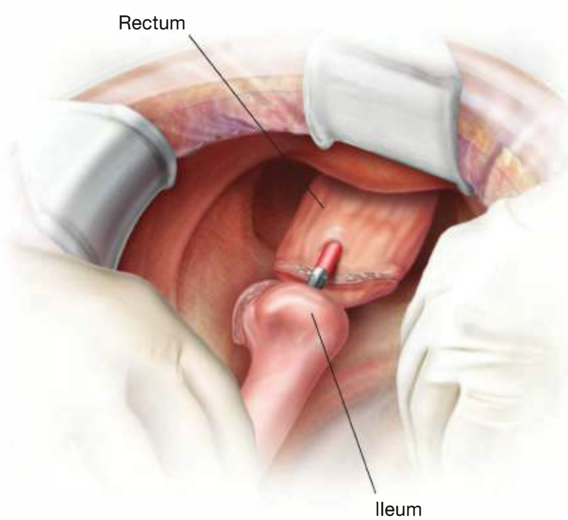


FIG 10 ● Ileorectal anastomosis.

TECHNIQUES

CLOSURE

- Mass fascial closure is performed with size 1 absorbable, monofilament suture.
- The skin incision is closed with staples.
- No intraabdominal or rectal drains are used.

PEARLS AND PITFALLS

Bleeding from the spleen	■ Minimizing traction on the splenic flexure is critical to reducing the incidence of splenic tears. If the spleen is torn, hemostatic agents (such as cellulose sheets or fibrin powders) can be used in the first instance with a swab applying pressure for 5 min in an attempt to achieve hemostasis. Ultimately, however, if bleeding cannot be stopped, then a splenectomy may be required.
Difficult splenic flexure mobilization	■ It may be easier to mobilize the splenic flexure by standing between the patient's legs rather than on the patient's right side. Approaching the splenic flexure proximally and distally repeatedly until it is freed further helps the dissection.
Identification of the ureters	■ On both sides, the ureters are identified by direct visualization to avoid injury. In their normal anatomic position, they are located in front of the psoas muscle just lateral to the transverse spinous processes, and then they pass over the bifurcation of the common iliac arteries to lie anterior to the sacroiliac joints, turning underneath the vas deferens (uterine arteries in females) to enter the bladder. The right colic, ileocolic, and gonadal vessels cross the right ureter. The left colic, gonadal, and sigmoid vessels cross the left ureter. With local invasion or severe inflammation, the ureters can be in a nonanatomic location and be more difficult to identify, in which case, preemptive ureteric stents (with or without lighting) can help avoid injury.
Management of the rectal stump	■ In the event that an anastomosis cannot be performed and an end ileostomy and closed rectal stump are fashioned, it may be desirable to suture the rectal stump to the inferior aspect of the midline wound fascia. This is because if the rectal stump leaks, a mucous fistula (rather than frank intraperitoneal contamination) will be the result.

POSTOPERATIVE CARE

- ERAS perioperative care protocols is applied.[1,2]

COMPLICATIONS

- Anastomotic leak (4.4%)[6]
- Pelvic abscess
- Intraabdominal bleeding
- Adhesive small bowel obstruction (30 %)[7]
- Postoperative ileus
- Wound infection
- Cardiopulmonary complications
- Urinary tract infection
- Failure of treatment in IBD (17% to 26%)[6]
- Overall reduced quality of life compared to general population[8]

Chapter 25

Total Abdominal Colectomy: Laparoscopic Technique

Matthew G. Mutch

DEFINITION

- Total abdominal colectomy (TAC) is the removal of the abdominal colon, which extends from the cecum to the top of the rectum. The upper rectum is an intraperitoneal structure and the top of the rectum can be identified as the point where the teniae coli splay out. After resection, an end ileostomy or ileorectal anastomosis can be created. The determination to perform an ileostomy versus an anastomosis is based on the diagnosis and indication for the resection.

PATIENT HISTORY AND PHYSICAL FINDINGS

- There are several indications for a laparoscopic TAC:
  - Ulcerative colitis or Crohn's colitis
    - Refractory to medical management
    - Complications
      - Acute colitis
      - Stricture
      - Perforation
      - Dysplasia
      - Neoplasm
  - Colon cancer
    - Synchronous cancers
    - Colon cancer in a patient younger than age 40 years
  - Familial adenomatous polyposis (FAP) with rectal sparing
  - Colonic inertia
- A thorough history and physical examination are necessary prior to surgery. Prior abdominal surgery is not an absolute contraindication for the laparoscopic approach.
- In colitis patients, the extent of medical management is dependent on previous regimens with immunomodulators and response to intravenous steroids. Typically, failure to respond after 7 days of intravenous steroids is considered failure of medical management.
- Patients with acute colitis can be safely approached laparoscopically. However, if they have peritonitis or are showing signs of hemodynamic instability, the laparoscopic approach should not be attempted.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Each indication for surgery has unique or specific evaluations that are necessary to determine the optimal treatment.
  - Acute colitis
    - Endoscopic examination of the colon is necessary to confirm the diagnosis.
    - For patients that are hospitalized for acute colitis, stool cultures to rule out *Clostridium difficile* and cytomegalovirus (CMV) infections are very helpful.
  - Colon cancer
    - Pathologic confirmation of adenocarcinoma is necessary.
    - Review of the colonoscopy report to confirm the number and locations of the lesions. Ideally, the lesion(s) are tattooed with a vital dye to mark the location. It is best to inject the ink distal to the most distal lesion and in at least three different locations around the circumference of the lumen.
    - Preoperative staging is completed with a computed tomography scan of the chest, abdomen, and pelvis and a serum carcinoembryonic antigen (CEA) level.
    - Patients younger than age 50 years and/or with a strong family history of colorectal cancer should be considered for genetic counseling.
  - FAP
    - Endoscopy and pathology: confirming the presence of more than 100 adenomatous polyps
    - Genetic testing confirming the diagnosis of FAP is desirable, but not all patients with endoscopic findings consistent with FAP will have an identifiable mutation.
    - If the patient is going to be considered for a rectal sparing procedure, the rectum needs to be examined and cleared of all polyps. If there are 10 or fewer polyps in the rectum that can be removed or destroyed, rectal sparing can be considered.
  - Colonic inertia
    - Normal bowel function ranges from three bowel movements a day to one bowel movement every 3 days. These patients give a long history of constipation that is no longer responsive to laxatives. When the patient gets to the point where his or her abdominal complaints and bowel function are not responsive to laxatives and their symptoms become intolerable, surgery management should be considered.
    - A total colon exam is necessary to rule out a mechanical cause of the patient's constipation.
    - A colonic transit study is necessary to confirm the diagnosis of colonic inertia. The patient ingests a capsule with 25 radiopaque markers and the patient is not allowed to use laxatives during examination period. Plain abdominal x-rays are obtained 3 and 5 days after ingestion. An abnormal exam is when five or more markers are retained in the colon after 5 days. The distribution of the markers is the diagnostic key: Markers scattered throughout the colon are consistent with colonic inertia, whereas accumulation of the markers in the rectum or distal sigmoid colon are suggestive of obstructed defecation.
    - Patients should also be evaluated with either a video defecography or dynamic magnetic resonance imaging (MRI) to evaluate for obstructive defecation. If a patient demonstrates evidence of obstructive defecation, they should undergo biofeedback prior to discussing surgery as a definitive treatment option.

SURGICAL MANAGEMENT

Preoperative Planning

- Depending on the operative plan, patients should be marked for a diverting or end ileostomy. The patient needs to be assessed in the supine, sitting, and standing positions. The stoma should rest on the apex of skin fold and be of adequate distance from bony prominences, skin creases, and the waistline of their pants. The stoma should be brought through the rectus muscle to minimize the risk of developing a parastomal hernia.
- The use of ureteral stents is left to the discretion of the surgeon.

Positioning

- A mechanical bed that is able to place the patient in the extremes of position is necessary.
- The patient is secured to the bed with either a beanbag, a nonslip pad, shoulder braces, or foam pads.
- The patient should be placed in the modified lithotomy position with Allen or Yellofin stirrups (**FIG 1**). This allows access between the legs to assist with mobilization of the left colon and to the perineum for the anastomosis.
- Both arms are tucked to the patient's side with the thumbs facing up. This allows the surgeon, assistant, and camera driver plenty of room to maneuver during the case.

FIG 1 ● Patient positioning. The patient is placed on a lithotomy position with the hips slightly flexed and the legs in Yellofin stirrups. The thighs are placed parallel to the ground to avoid interference with the surgeon's arms and instruments.

- A monitor should be placed off the patient's right shoulder during the mobilization of the right and transverse colon.
- A monitor should be placed off the patients left shoulder for the mobilization of the left colon and splenic flexure.

PORT PLACEMENT AND TEAM SETUP

- There are several options for port placement and they depend on whether a total laparoscopic surgery or hand-assisted laparoscopic surgery (HALS) is going to be used.
  - Straight laparoscopic approach
    - Camera port—The port is placed in the peri-umbilical area in equal distance between the xiphoid process and the pubic symphysis (**FIG 2A**). The camera should be placed at the apex of the pneumoperitoneum so the widest field of view can be obtained.
    - Working ports—There are two working ports on the right side and two ports on the left side. They should be centered on the camera port,

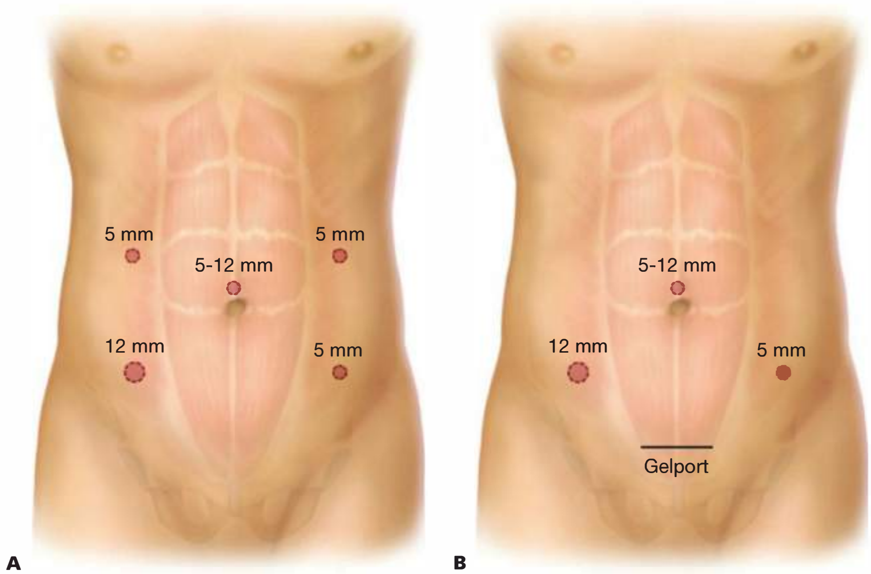

FIG 2 ● Port placement. **A.** Port placement for a conventional laparoscopic total colectomy. **B.** Port placement for a hand-assisted laparoscopic total colectomy.

lateral to the rectum muscle, and greater than a hand's width apart.

- HALS approach
  - Hand port—The hand port is placed in the suprapubic position via either a midline or Pfannenstiel incision (FIG 2B).
  - Camera port—The camera is placed in the supraumbilical position so that the port does not interfere with skirt of the hand port.
  - Working ports—There is one working port placed on the right and left sides. They are placed in equal distance between the hand port and the camera and lateral to the rectum muscle.
- Team setup
  - For the HALS approach to the right and transverse colon, the surgeon stands on the patient's left side with his or her left hand placed in the hand port and with his or her right hand on the energy source.
  - During the mobilization of the left colon, the surgeon stands on the patient's right side, right hand in the abdomen and left hand on the energy source (FIG 3). The camera operator stands to the head side of the surgeon.
  - The operative steps described in the chapter are the same whether the procedure is being performed straight laparoscopically or as HALS. For the purpose of this chapter, the HALS approach to the total colectomy operation will be described.

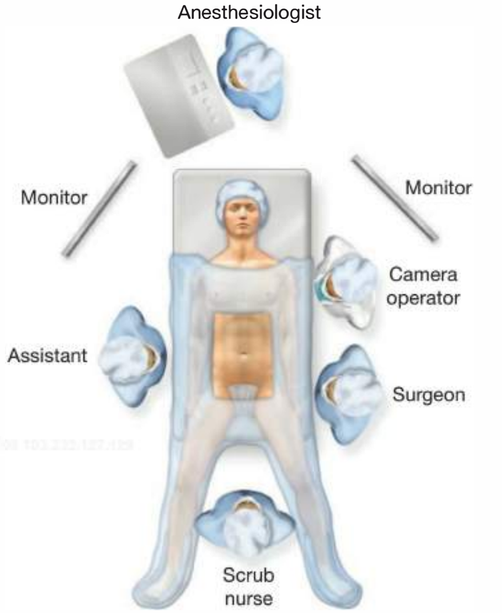

FIG 3 ● Operating team setup. For the HALS approach to the right and transverse colon, the surgeon stands on the patient's left side with his or her left hand placed in the hand port and with his or her right hand on the energy source. During the mobilization of the left colon, the surgeon will stand on the patient's right side, right hand in the abdomen and left hand on the energy source. The camera operator stands to the head side of the surgeon.

MOBILIZATION OF THE RIGHT COLON

- Once the abdomen has been accessed and inspected, the patient is placed in steep Trendelenburg position to pack the small bowel in the right upper quadrant (RUQ). The posterior approach will be described for the mobilization of the right colon. The specific steps of operation are the same for medial to lateral, lateral to medial, and superior to inferior, but the order of the steps is different depending on the approach.
- The goals of the operation are to access the retroperitoneal plane, identify and sweep the duodenum out of the way, mobilize the right colon mesentery, divide the lateral attachments and omentum, and ligate the vasculature.
- For the posterior approach, the small bowel is placed in the RUQ and the base of the ascending colon mesentery is exposed from the third portion of the duodenum to the cecum (FIG 4). The ileocolic vessels (ICV) are seen as they cross over the third portion of the duodenum. The patient is not tilted so that the small bowel will stay in the RUQ.
- The middle finger and thumb grasp the ICV off the retroperitoneum. The index finger then sweeps under the mesentery to expose the third portion of the duodenum (FIG 5). The peritoneum is then scored dorsal to the ICV from the duodenum all the way down to the cecum.

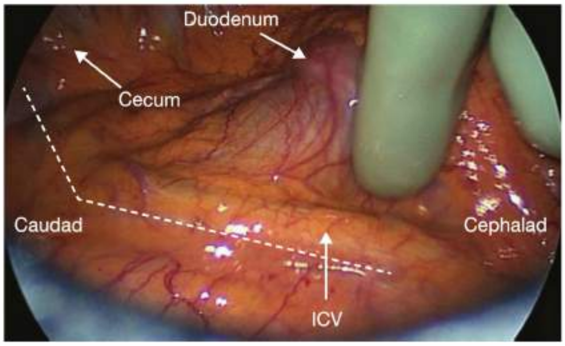

FIG 4 ● Root of the ascending colon mesentery: key anatomy. The base of the ascending colon mesentery is exposed from the third portion of the duodenum to the cecum. The ICV are seen as they cross over the third portion of the duodenum. The dissection plane will be initiated along the dorsal aspect of the ICV *(dotted line)*.

- Once the retroperitoneum is accessed, the duodenum is identified and swept posteriorly. After the retroperitoneum has been accessed, the hand is placed under

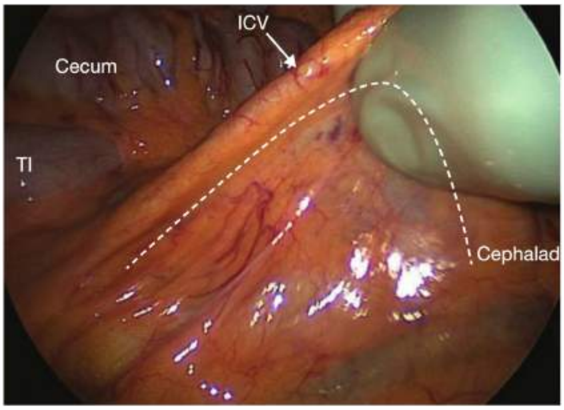

FIG 5 ● Initiation of the medial to lateral mobilization. With the surgeon holding the ICV anteriorly, the peritoneum is scored dorsal to the ICV from the duodenum all the way down to the cecum *(dotted line)*. TI, terminal ileum.

the mesentery, palm down, and the ascending colon mesentery is elevated off the retroperitoneum (**FIG 6**) through a medial to lateral dissection approach. The retroperitoneum is bluntly swept down with an energy device.

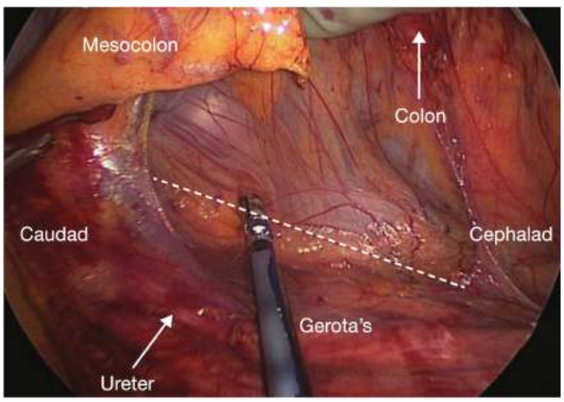

FIG 6 ● Medial to lateral mobilization of the ascending colon. With the surgeon's hand retracting the colon anteriorly, the ascending mesocolon is separated from the retroperitoneum (Gerota's fascia) by sweeping the retroperitoneal tissues dorsally with a 5-mm energy device. This dissection is carried along the transition between the two distinctive fat planes of the mesocolon and Gerota's fascia *(dotted line)*.

- This medial to lateral dissection is carried out beyond the colon from the midtransverse colon, out to the hepatic flexure, and down the ascending colon to the cecum. The more extensively the dissection can be carried laterally, the easier the lateral dissection will be.
- Tension is the key to facilitating an easy dissection as this is an avascular plane than can be effortlessly dissected with adequate tension. The motion should almost be a swimming-type motion in which tension is created, the tissue is swept down, tension is recreated, and the tissue is swept down, over and over.
- Now all that remains is the lateral attachments, which are transected with an energy device up along the right gutter (**FIG 7**). At this point, the patient is in airplane position with the right side up so the small bowel will fall to the left upper quadrant (LUQ). This exposes the lateral attachments of the right colon and the hepatic flexure.
- At this point, the hand may get in the way so it can be removed and instruments can be passed through the hand port. With a grasper in the right hand, the cecum is grasped and retracted medially, and the energy source in the left hand is passed through the hand port.
- Once the cecum is adequately mobilized, the hand is placed back into the abdomen. The left hand is placed under the right colon mesentery and lateral to the colon to expose the lateral attachments, which are divided under tension by the first assistant.
- The right colon and its mesentery are elevated to expose the retroperitoneum and dissect any remaining retroperitoneal attachments. This dissection is carried all the way up to the hepatic flexure.

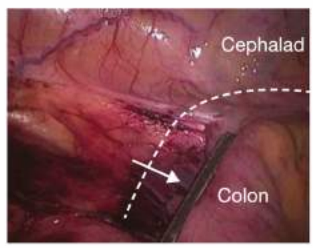

FIG 7 ● Lateral mobilization of the ascending colon. The white line of Toldt is transected along the right paracolic gutter *(dotted line)*. The medial to lateral dissection plane previously dissected is readily entered, greatly facilitating this step of the operation.

MOBILIZATION OF THE TRANSVERSE COLON

- The key to mobilizing the transverse colon is accessing the lesser sac. This is accomplished by either dividing the lesser omentum and taking the omentum with the specimen or preserving the omentum by separating it from the transverse colon and its mesentery.
- To resect the omentum, the lateral dissection of the right colon is continued up to the hepatic flexure. The colon is rolled medially and the lateral cut edge of the lesser omentum or hepatocolic attachments are elevated with a laparoscopic instrument. The hepatocolic ligament is then transected with an energy device (**FIG 8**). This plane between the omentum, mesentery, and duodenum/stomach is developed, ensuring the duodenum and

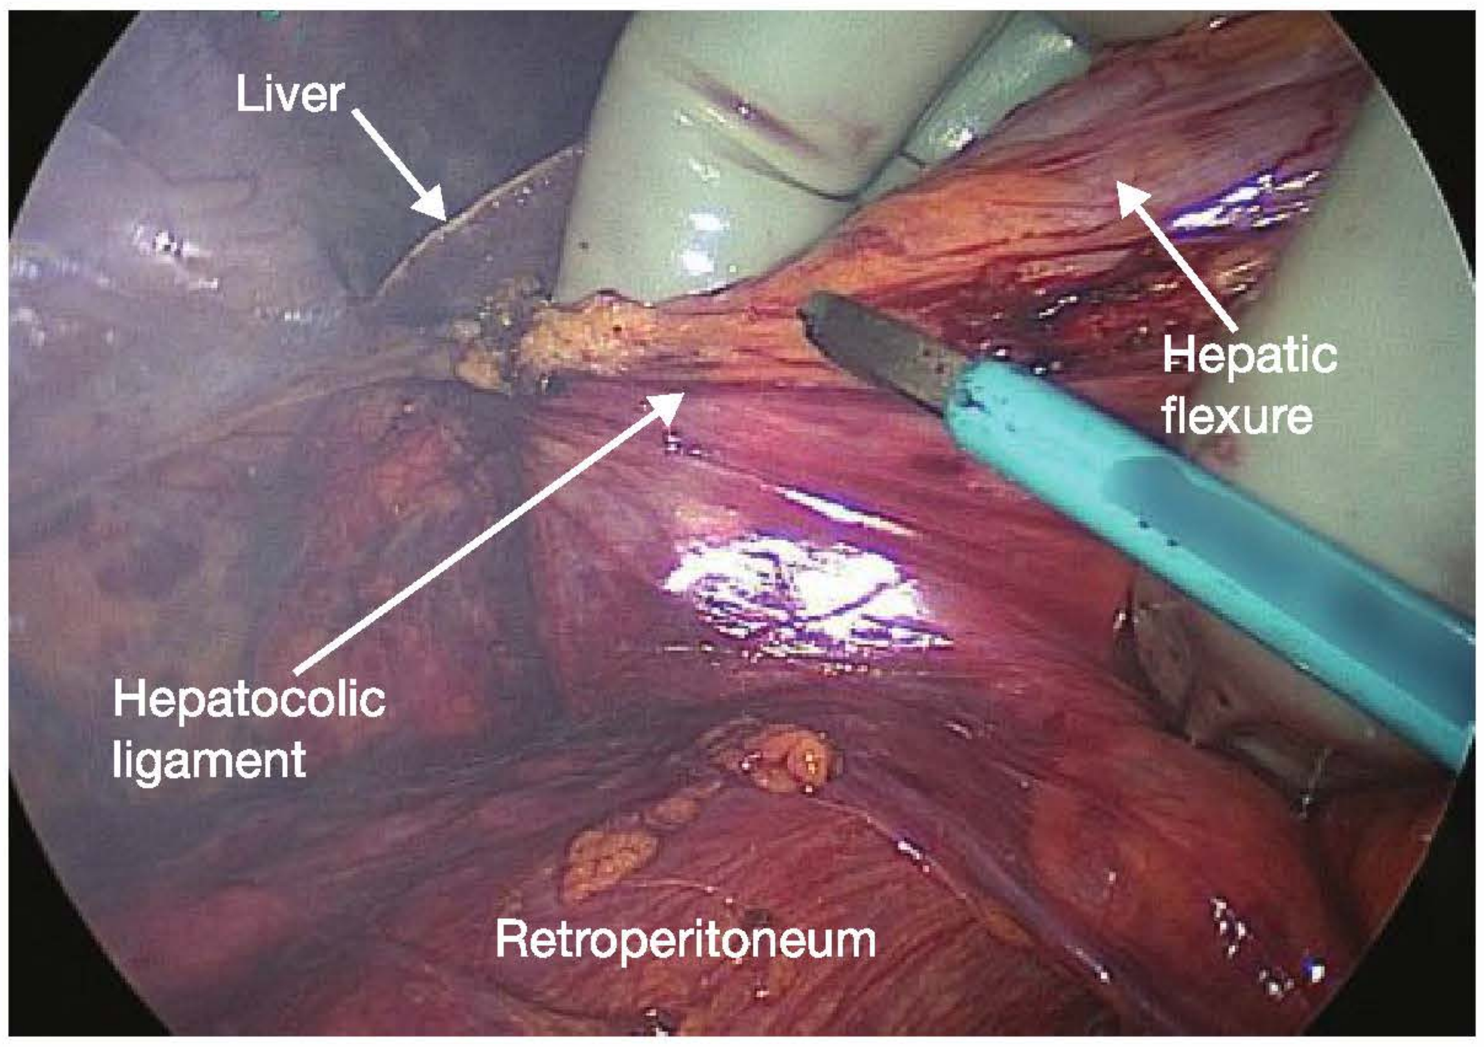

FIG 8 ● Mobilization of the hepatic flexure. The hepatocolic ligament is transected with an energy device.

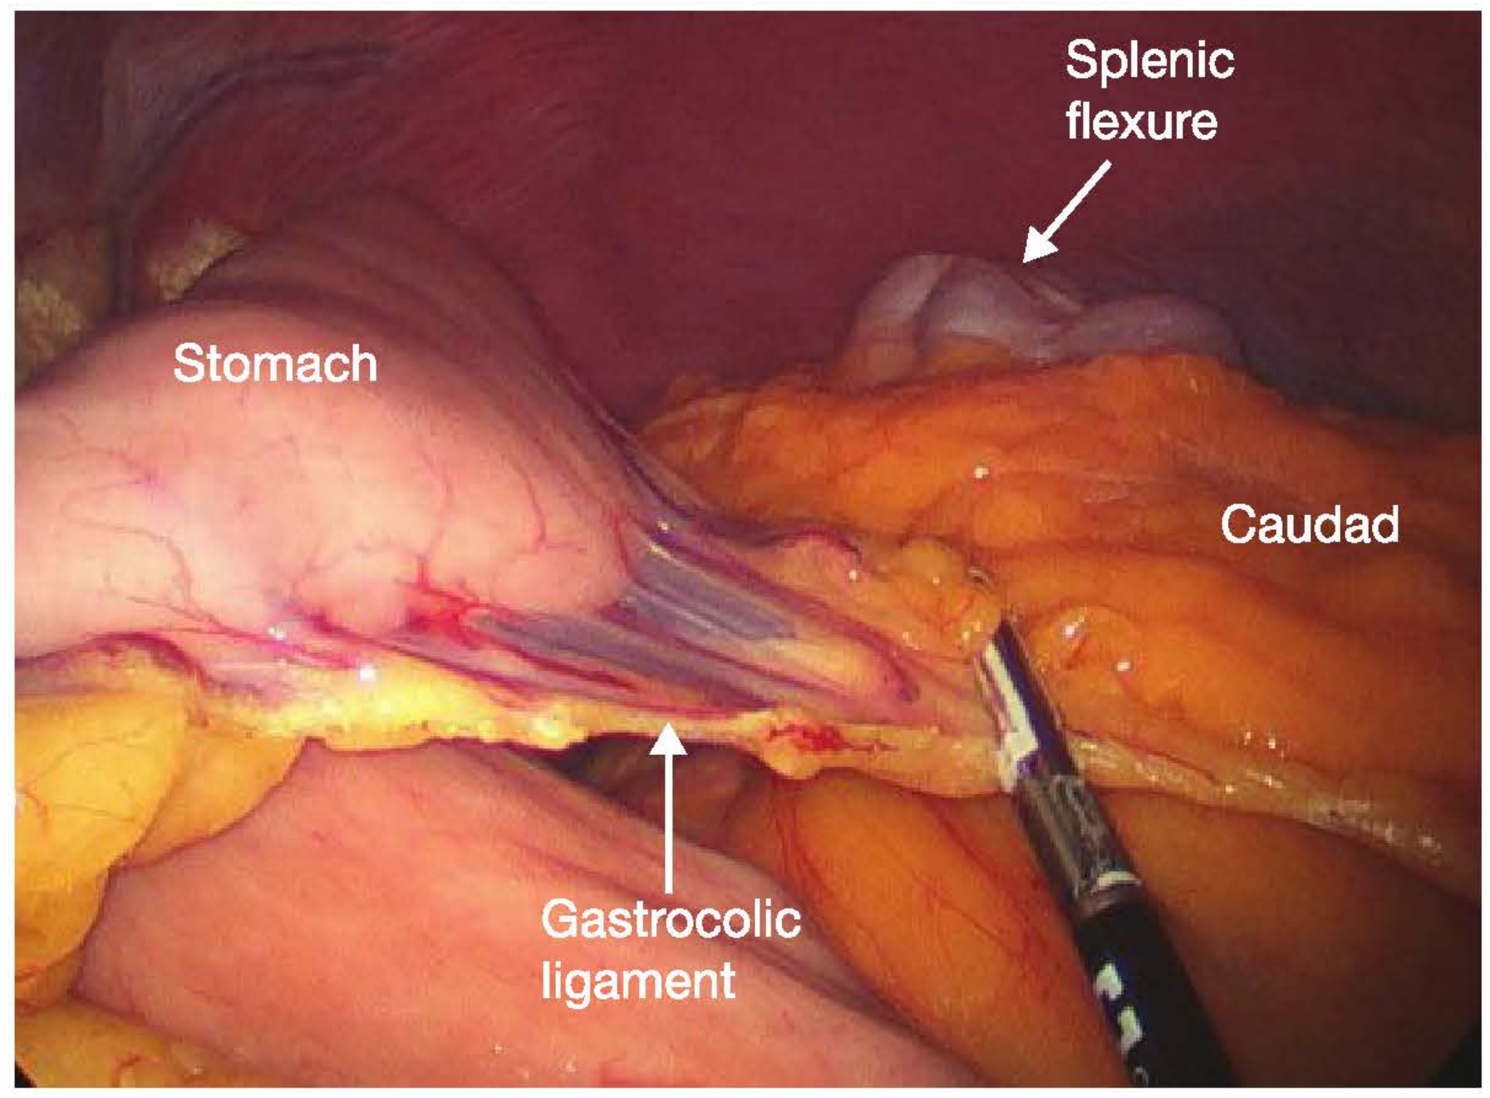

FIG 9 ● Mobilization of the transverse colon. The gastrocolic ligament is transected from right to left, toward the splenic flexure of the colon, with an energy device.

stomach are swept free; this step is greatly facilitated by the previous medial to lateral dissection step, which already separated the hepatic flexure from the duodenum and the head of the pancreas.

- The gastrocolic ligament is then divided from right to left with an energy device (**FIG 9**). This can be a very tedious dissection, as the entire plane tends to be fused, but with good exposure, tension, and patience, the lesser sac is entered. The lesser sac opens up toward the middle of stomach. Care must be taken to not dissect into the transverse colon mesentery. Once in the lesser sac, the dissection should be carried as far toward the splenic flexure as possible.
- There may be residual attachments of the mesentery to the antrum of the stomach that are taken down by elevating the stomach and pushing the mesentery down.
- With the lesser omentum divided and the lesser sac completely open, the ICV and right colic and middle colic vessels will be easily isolated when it comes time for them to be transected.

TRANSECTION OF THE MESENTERIC VASCULATURE

- The ICV pedicle is first isolated. The ileocolic pedicle, easily identified because it has been dissected off the retroperitoneum already, is lifted anteriorly. With the ICV pedicle adequately isolated, it can be transected with an energy device (**FIG 10**). Transection of the ICV as they cross the third portion of the duodenum ensures that the ICV are transected at their origin without compromising the superior mesenteric vessels, which are located medially at the root of the mesentery.

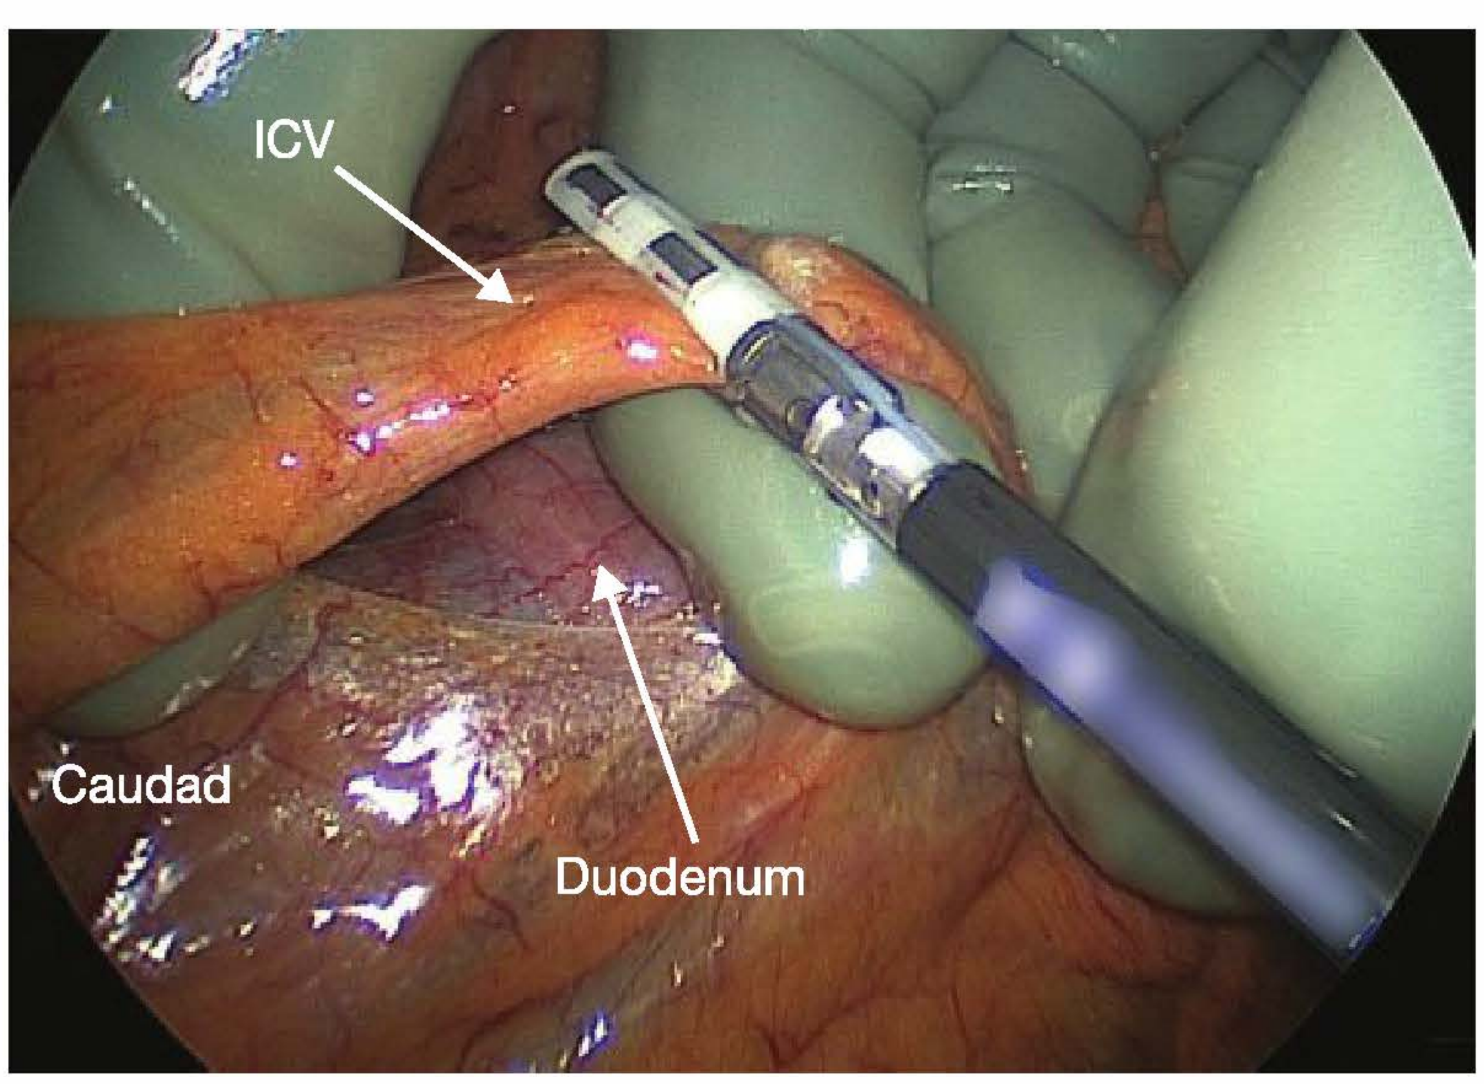

FIG 10 ● Transection of the ICV. The ICV are transected with the energy device at their origin as they cross over the third portion of the duodenum.

- Next, the transverse colon is elevated to expose the medial or inferior aspect of the mesentery (**FIG 11A**). The surgeon elevates the proximal transverse colon and passes his or her left hand through the mesenteric defect of the ileocolic pedicle, into the lesser sac, anterior to the pancreas, and encircles the middle colic vessels. The first assistant stands between the legs and via the right left quadrant (RLQ) port elevates the distal transverse colon and its mesentery. With the middle colic vessels elevated, the base of the mesentery and a bare area should be seen near the ligament of Treitz (**FIG 11B**).
- With the transverse colon mesentery elevated, the peritoneum is incised from the bare area on the left (by the ligament of Treitz) to the previously cut edge of the mesentery on the right (**FIG 11B**). This allows the individual middle colic vessels to be safely isolated and transected with an energy device. Because of the mobilization and separation of the omentum from the transverse colon mesentery, the vessels can be safely transected without fear of injury to the omentum or stomach.

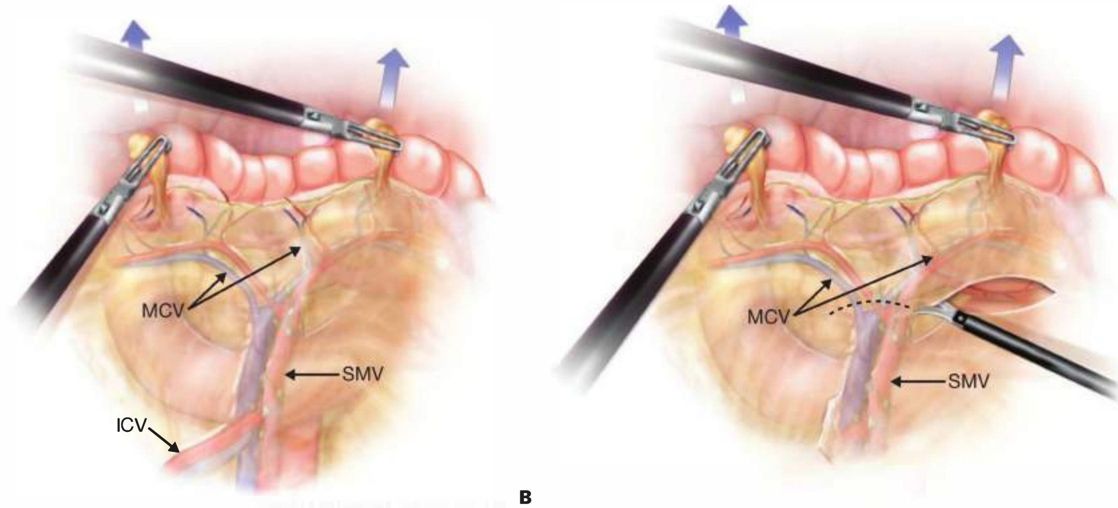

FIG 11 ● Transection of the middle colic vessels. **A.** With the transverse colon tented upward, the vascular anatomy at the root of the mesentery is identified. The middle colic vessels (MCV) are seen as they originate from the superior mesenteric vessels (SMV). **B.** Transection of the MCV. The root of the mesentery is incised from the bare area on the left (by the ligament of Treitz) to the previously cut edge of the mesentery on the right. This allows the individual middle colic vessels to be safely isolated and transected with an energy device. The *dash line* represents the line for incising the peritoneum over the middle colic vessels.

MOBILIZATION OF THE LEFT COLON

- The surgeon now moves to the patient's right side, places his or her right hand in the hand port, and with his or her left hand, he or she wields the energy device.

TRANSECTION OF THE INFERIOR MESENTERIC ARTERY

- The patient is placed in a steep Trendelenburg position and in airplane position with the left side up to use gravity to place the small bowel in the RUQ and the omentum in the upper abdomen to expose the transverse colon and splenic flexure. This helps to expose the inferior mesenteric artery (IMA) at its origin off the aorta and the inferior mesenteric vein (IMV) at the level of the ligament of Treitz.
- The surgeon's right hand is placed through the hand port and an energy source is placed through the RLQ working port.
- The retroperitoneum is accessed at the level of the sacral promontory. The superior hemorrhoidal artery (SHA) is grasped and elevated (**FIG 12A**), exposing the IMA and its terminal branches, the SHA, and left colic artery. A wide incision is made in the peritoneum dorsal to this artery (**FIG 12B**); the wider the incision, the more the artery can be more elevated to obtain better exposure. Because of the curve of the pelvis at this point, the sigmoid mesentery curves up and away from the visual field. Therefore, the retroperitoneal plane is higher than expected, so the more mobile the arterial pedicle is, the easier it is to visualize the correct plane.
- Identification of the left ureter is necessary before the IMA can be ligated (**FIG 13**). The following text is a four-step algorithm to identify the left ureter.
  - Mobilization of the superior rectal artery is as described earlier and the ureter is identified.
  - At the level of the IMV: The IMV is grasped and elevated. The peritoneum is incised dorsal to the IMV and the retroperitoneum is accessed. The retroperitoneum is flat in this area and is often more easily accessed. Once in the correct plane, the dissection is carried in a caudad fashion to meet up with the initial plane under the superior rectal artery.

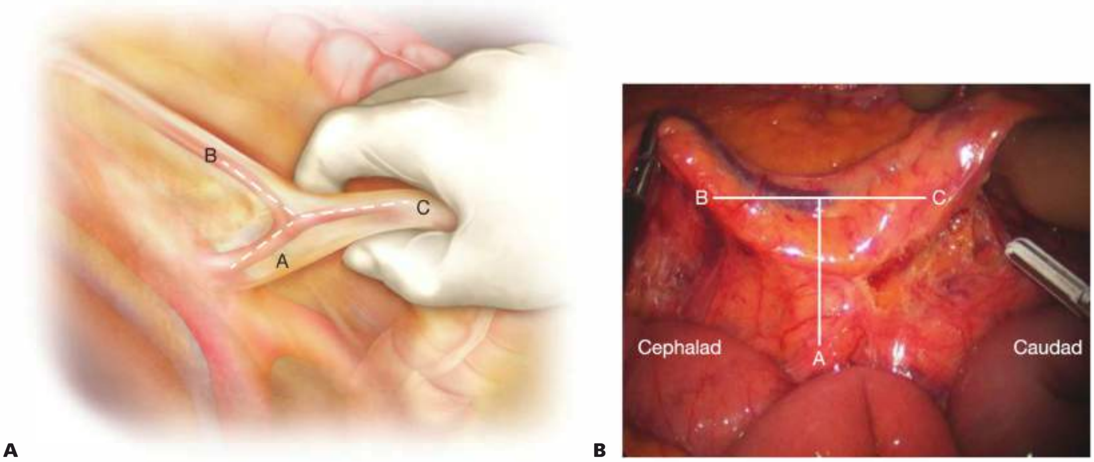

FIG 12 ● Identification of IMA and its branches. **A.** Grasping the SHA anteriorly helps identify the "letter T" formed between the IMA *(A)* and its left colic artery *(B)* and SHA *(C)* terminal branches. The IMA takeoff is just cephalad from the aortic bifurcation. The thumb and index finger are lifting the SHA off the groove located anterior to the right common iliac artery. **B.** Incision along the dorsal aspect of both the left colic vessels *(B)* and the SHA *(C)* allows for safe entry into the retroperitoneal space, helping isolate the IMA *(A)* at its origin.

   - If the ureter is still not identified, the sigmoid and left colon is mobilized in a lateral to medial fashion.
   - Finally, the top of the hand port can be removed and the left ureter can be located via an open fashion.
- After the left ureter is identified and swept into the retroperitoneum, the IMA can be isolated at its origin. The index finger elevates the superior rectal artery and the middle finger is used to sweep down the retroperitoneum along the course of the IMA. This motion continues until the bare area is exposed cephalad to the IMA and medial to the IMV.
- It is important to sweep down the retroperitoneal tissue in this area to help preserve the sympathetic plexus around the IMA. Once the IMA is safely isolated and the left ureter is clearly out of harm's way, the IMA can be transected at its origin from the aorta with a linear vascular stapler (**FIG 14**) or with an energy device.

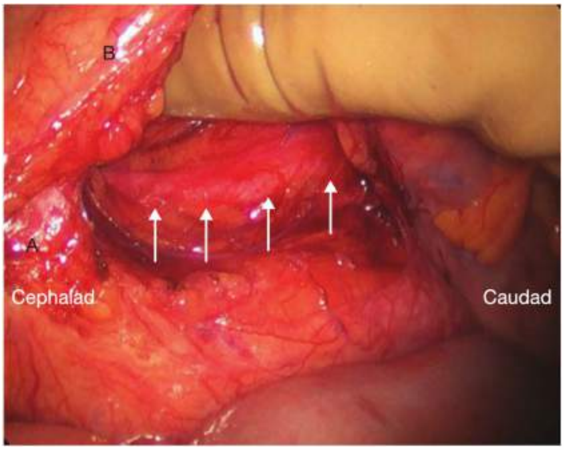

FIG 13 ● Identification of the left ureter. After the IMA *(A)* and SHA *(B)* have been lifted off the retroperitoneum, the left ureter *(arrows)* can be identified and preserved intact. Identification of the left ureter at this stage is critical in order to avoid injuring the ureter during the IMA transection.

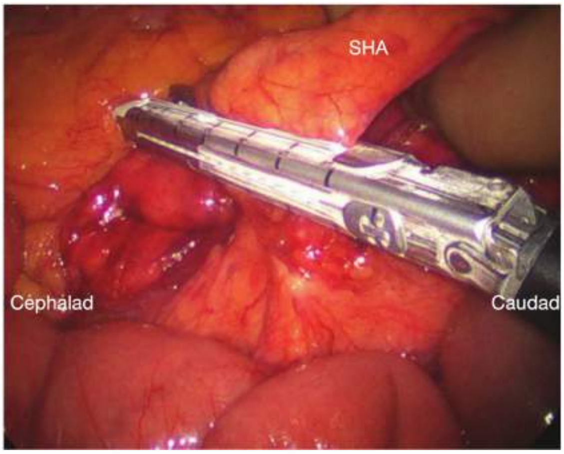

FIG 14 ● Transection of the IMA. With the left ureter safely dissected away into the retroperitoneum, the IMA is transected with a linear vascular stapler at its origin of the aorta. The surgeon's hand is holding the SHA anteriorly.

TRANSECTION OF THE INFERIOR MESENTERIC VEIN

- The IMV courses parallel to the left colic artery. The previous IMA dissection plane is carried cephalad with Endo Shears and 5-mm energy device (sweeping the retroperitoneal tissues dorsally) until the left colic artery separates from the IMV as it courses toward the splenic flexure at the level of the ligament of Treitz.
- Now that the IMV is elevated off the retroperitoneum, it is isolated at the inferior border of the pancreas and near the ligament of Treitz (**FIG 15**). It can be isolated with the same technique used for the IMA: The index finger and thumb elevate and create tension on the IMV, and the middle finger and/or dissecting instrument sweeps the retroperitoneum dorsally along the course of the vein.
- A bare area is then created near the inferior border of the pancreas that allows the IMV to be safely isolated.
- Once isolated, it can be safely transected with an energy device (**FIG 16**).

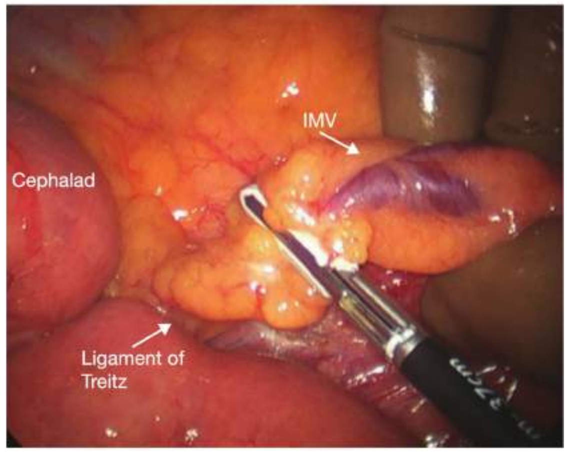

FIG 16 ● IMV transection. The IMV is transected at the level of the ligament of Treitz with an energy device.

Mobilization of the Left Colon

- The left colon mesentery is now dissected off the retroperitoneum using a medial to lateral dissection approach (**FIG 17**) all the way out to the lateral abdominal wall.
- The hand is placed palm down under the mesentery to elevate it as a fan-type retractor. The plane is dissected bluntly with an energy device from the sigmoid colon up to the splenic flexure. The further laterally and superiorly the dissection is carried, the easier the lateral dissection and splenic flexure mobilization will be later during the case. Care must be taken during mobilization near the inferior border of the pancreas, as it is very easy to carry the dissection deep to the pancreas.
- All that remains at this point are the lateral attachments. The hand is used to depress the sigmoid colon and lateral peritoneum is incised (**FIG 18**). It is not uncommon for the hand to get in that way at this point, so it may be necessary to pass the energy source through the surgeon's fingers or the hand may be taken out and an instrument can be passed through the hand port to begin the dissection.
- Once the medial plane of dissection is accessed, the hand can be passed in the opening and the lateral attachments are elevated and exposed. At this point, the surgeon uses a grasper for exposure and the first assistant uses the energy source through the left lower quadrant (LLQ) port to transect the rest of the lateral colon attachments, moving toward the splenic flexure.

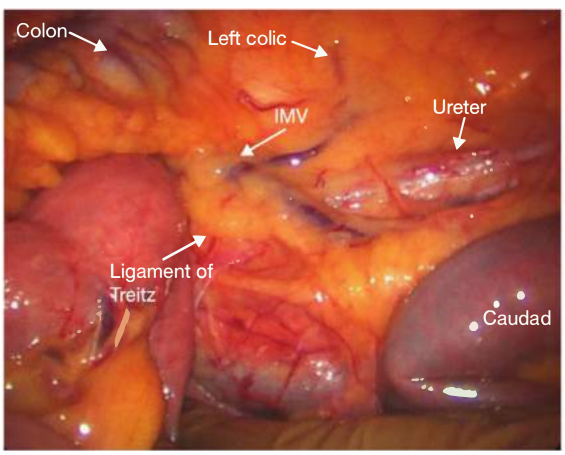

FIG 15 ● Identification of the IMV. The IMV can be identified at the root of the mesotransverse colon at the level of the ligament of Treitz. At this level, the IMV has separated from the left colic artery (which courses away from the IMV and toward the splenic flexure of the colon) and from the left ureter.

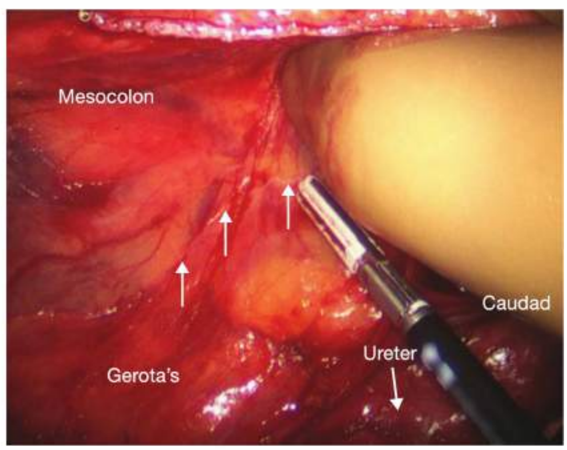

FIG 17 ● Medial to lateral dissection. With the surgeon holding the mesocolon anteriorly (notice the stapled transected IMA stump in between the surgeon's fingers), the retroperitoneal tissues are swept downward (dorsally) with an energy device. The dissection progresses along the transition of the two fat planes: mesocolon and Gerota's *(arrows)*.

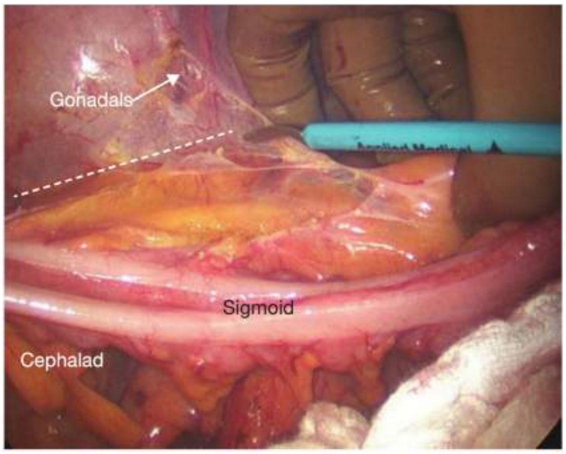

FIG 18 ● Lateral mobilization of the sigmoid and descending colon. The white line of Toldt *(dotted line)* is transected with an energy device. The medial to lateral dissection plane is readily entered, greatly facilitating the lateral mobilization of the descending colon.

MOBILIZATION OF THE SPLENIC FLEXURE

- The mobilization of the splenic flexure is greatly facilitated by the previous transection of the gastrocolic ligament and the previous medial to lateral mobilization of the descending colon.
- The splenic flexure is grasped laterally with the hand and medially with a grasper. The colon is put on stretched and pulled down and medial to identify the next level of attachment between the splenic flexure of the colon and the diaphragm and spleen. The splenodiaphragmatic and splenocolic ligaments are then transected with an energy device (**FIG 19**).
- All that remains are the posterior attachments to the inferior border of the pancreas. Division of these attachments to the midline allows for a full mobilization of the splenic flexure. This ensures adequate reach of the proximal colon for a tension-free anastomosis.

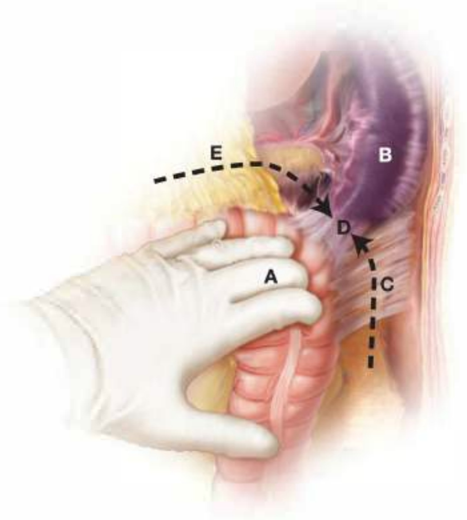

FIG 19 ● Mobilization of the splenic flexure. The surgeon retracts the splenic flexure of the colon *(A)* downward and medially, exposing the attachments of the splenic flexure to the spleen *(B)*. The phrenocolic *(C)* and splenocolic *(D)* ligaments are transected in an inferior to superior and lateral to medial direction, meeting the previously transected gastrocolic ligament *(E)* dissection plane around the splenic flexure.

RECTAL TRANSECTION

- Depending on the approach, the rectum can now be prepared for division.
  - HALS
    - Once the colon is completely mobilized and free, it can be extracted through the hand port and the rectum can be divided in an open fashion.
    - The colon is extracted by passing the small bowel underneath the colon and its mesentery. The surgeon stays on the patient's right side and the left colon is elevated while the proximal small bowel is fed under the colon and its mesentery. The patient is then placed in airplane position left side down to facilitate migration of the small bowel into the LUQ. Once the entire small bowel is passed under the colon, the cecum is grasped and brought out through the hand port. This allows the small bowel to be positioned in the left side of the abdomen, with the cut edge of the small bowel straight and facing to the patient's right side. It is in the correct orientation for an ileostomy or ileorectal anastomosis.

- Straight laparoscopic approach
  - The top of the rectum is identified by the splaying out of the teniae coli.
  - The mesorectum is scored at a right angle at the point of distal transection. A window is created between the posterior wall of the rectum and the mesorectum. The rectum is divided with an endoscopic stapler.
  - The mesorectum is then ligated with the energy source of choice.
  - The colon is then extracted via an LLQ or suprapubic extraction port.

ILEORECTAL ANASTOMOSIS/END ILEOSTOMY

- The site of the specimen extraction will depend on whether an anastomosis or an end ileostomy is going to be created.
- Ileorectal anastomosis
  - HALS
    - The colon can be extracted via the hand port and the rectum and terminal ileum can be divided in an open fashion.
    - Once the anvil has been placed in the terminal ileum, a side-to-end, or an end-to-end anastomosis (EEA), ileorectal anastomosis is created in an open fashion by direct visualization through the hand port or laparoscopically (**FIG 20**).
    - The entire cut edge of the small bowel mesentery must be visualized to face the patient's right side to ensure there is no twisting.

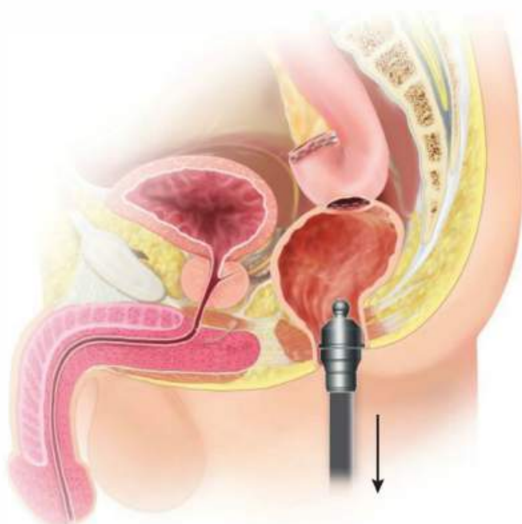

FIG 20 ● Stapled ileorectal anastomosis. A side-to-end EEA stapled ileorectal anastomosis is constructed.

    - The anastomosis is tested under water (air leak test) in standard fashion via the open hand port site.
  - Straight laparoscopic approach
    - A Pfannenstiel or an LLQ incision can be used as the extraction site. If the rectum has been divided, the extraction incision is made and the colon is extracted, starting with the distal transected end.
    - The terminal ileal mesentery is divided.
    - The terminal ileum is divided and a purse string is placed so an EEA can be created.
    - The ileum is dropped back into the abdomen and the extraction site is closed.
    - Laparoscopically, the stapling cartridge is passed transanally up to the top of the rectal stump.
    - The anvil is reassembled ensuring the small bowel mesentery is not twisted.
    - The anastomosis can be tested with either an air leak test or endoscopic visualization.
- End ileostomy
  - HALS approach
    - The colon is resected and the stoma is created via the open incision of the hand port as described elsewhere in this textbook.
  - Straight laparoscopic approach
    - The colon can be extracted through the ileostomy site, but care must be taken when this approach is used.
      - If the colon is dilated, full of stool, or significantly inflamed, avoid using the stoma site as an extraction site.
      - If the stoma is going to be permanent, realize that in order to get the specimen out, the stoma site may need to be made bigger than usual. This may increase the risk of the patient developing a parastomal hernia.
    - The colon can be extracted via an LLQ or a periumbilical position. Once the colon is extracted and the terminal ileum is divided, it can be dropped back into the abdomen and brought out of the stoma site.
- The ileostomy is then matured in a Brooke ileostomy fashion with absorbable sutures as described elsewhere in this textbook.

CLOSURE OF THE ABDOMEN

- All 10-mm ports should be closed. The 5-mm ports do not need to be closed.
- The hand port or extraction site can be closed with either interrupted or running stitch of no. 1 suture.

PEARLS AND PITFALLS

Options for right colon/mesocolon mobilization	■ Posterior approach: under the small bowel mesentery ■ Medial to lateral: through the right colon mesentery, caudad to the ileocolic pedicle ■ Lateral to medial: incise laterally at the cecum and roll it medially ■ Superior to inferior: enter the retroperitoneum by first dividing the lesser omentum along hepatocolic ligament
Right colon mobilization: posterior approach	■ If it is difficult to elevate the right colon mesentery and expose the fourth portion of the duodenum, start the dissection at the level of the cecum and work in an inferior to superior direction to mobilize the right colon mesentery.
Right colon mobilization: medial to lateral approach	■ The further the mobilization of the right colon can be carried out laterally, the easier the lateral and hepatic flexure mobilization will be.
Right colon mobilization: superior to inferior approach	■ When trying to enter the lesser sac, roll the right colon medially and elevate the lateral cut edge of the lesser omentum with the grasper. This will allow for direct visualization of this avascular plane, which can be easily dissected in a blunt fashion.
Transection of the middle colic vessels	■ With the lesser sac completely opened and the stomach free of the transverse colon mesentery, the middle colic vessels are free to be safely ligated. ■ When encircling the middle colic vessels, confirm that your hand is on top of the pancreas and ensure that the line of division of the middle colic vessels starts above the ileocolic pedicle, as this ensures that the superior mesenteric artery will not be injured.
Options for mobilization of the left colon/mesocolon	■ Medial approach: This can be done at the level of the sacral promontory or at the level of the IMV. ■ Lateral approach
Four ways of identifying the left ureter	■ A four-step technique was described earlier. Do not spend a lot of time with one approach if you are having difficulty, as the other steps described are necessary to complete the case. Therefore, alternating your approach to identifying the ureter also helps to complete the other steps of the procedure.
Mobilization of the splenic flexure	■ Completing the medial to lateral dissection makes it easier to mobilize the splenic flexure. ■ Be patient when entering the lesser sac. Incise the peritoneum fusing the omentum to the transverse colon and dissect the omentum off the backside of the mesentery one layer at a time.

POSTOPERATIVE CARE

- The patient can begin a liquid diet on the day of surgery. The diet can be advanced as tolerated. Solid food can be safely provided before the resumption of bowel function.
- A urinary catheter should be removed within 24 hours of surgery unless it is needed to assess patient volume status.
- Patients can begin ambulation as early as the day of surgery and by postoperative day 1; they are to be encouraged to spend more time out of bed than in bed.
- Venous thromboembolism (VTE) prophylaxis is important because of the magnitude of the operation. Low-molecular-weight heparin (LMWH), subcutaneous heparin, or pneumatic compression boots are all acceptable methods. There is data supporting the use of LMWH for 21 days postoperatively to decrease the risk of VTE.
- For patients with ileostomies, it is important to provide extensive stoma teaching. Points that need to be covered are diet, expected output, measuring of output, and pouching issues.

OUTCOMES

- Laparoscopic TAC for acute colitis is safe, with improved short-term outcomes and no increase in morbidity.
- For patients with hereditary nonpolyposis colorectal cancer (HNPCC), the risk of a developing a metachronous cancer is 25%. This high risk is also found in patients younger than age 40 years without a documented mutation in a mismatch repair gene. Therefore, treatment options include segmental resection with annual colonoscopy versus TAC with annual proctoscopy.
- Patients with a strong family history of colorectal cancer or documented HNPCC have a significantly lower risk of developing a metachronous colorectal cancer after a more extensive resection compared to those patients who underwent a segmental resection.
- HALS and straight laparoscopy have equivalent short-term outcomes for patients undergoing TAC. There was no difference in pain scores, length of stay, return of bowel function, and narcotic usage, but the operative time for the HALS approach was 57 minutes shorter.
- TAC with ileorectal anastomosis provides an excellent functional outcome and improved quality of life for patients with medically refractory constipation due to colonic inertia.

COMPLICATIONS

- Bleeding
- Anastomotic leak
- Rectal stump leak
- Parastomal hernia
- Pelvic abscess

- Wound infection
- Postoperative ileus
- VTE

Chapter **26**

Total Abdominal Colectomy: Hand-Assisted Technique

Daniel Albo

DEFINITION

- Total abdominal colectomy (TAC) is the removal of the abdominal colon, which extends from the cecum to the top of the rectum, following which the distal ileum is anastomosed to the rectum or an end ileostomy is created.
- Hand-assisted laparoscopic surgery (HALS) is a minimally invasive surgical approach that uses conventional laparoscopic-assisted (LA) surgery techniques with the addition of a hand-assist device (placed in the projected specimen extraction site), which allows for the introduction of a hand into the surgical field. HALS in colorectal surgery retains all of the same advantages of conventional LA surgery over open surgery, including less pain, faster recovery, lower incidence of wound complications, and reduction of cardiopulmonary complications, especially in the obese and in the elderly.
- Advantages of HALS over conventional LA colorectal surgery include the following:
  - Reintroduces tactile feedback into the field
  - Shorter learning curves; easier to teach
  - Shorter operative times and lower conversion to open rates
  - Higher usage rates of minimally invasive surgery

DIFFERENTIAL DIAGNOSIS

- Indications for HALS TAC are as follows:
  - Inflammatory bowel disease (IBD)
  - Severe acute colitis (various etiologies)
  - Polyposis syndromes, including familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer (HNPCC)
  - Slow-transit constipation
  - Malignancy

PATIENT HISTORY AND PHYSICAL FINDINGS

- Most patients with colon tumors generally present after an incidental finding during screening colonoscopy or with occult bleeding and iron deficiency anemia.
- A thorough history and physical examination should include the following:
  - Previous surgeries (does not preclude a laparoscopic approach)
  - Presence of obstructive symptoms
  - A detailed personal and family history of colorectal cancer, polyps, and/or other malignancies
  - In IBD, the extent of previous medical management, including use of immunomodulators and steroids and response to therapy, is important.
  - Routine abdominal examination, noting any scars

IMAGING AND OTHER DIAGNOSTIC STUDIES

- A colonoscopy with documentation of all polyps should be performed. Suspicious lesions should be tattooed to facilitate localization during surgery.
- A computed tomography (CT) of the chest, abdomen, and pelvis evaluates for potential metastases in cancer patients. In IBD, a CT of the abdomen/pelvis allows evaluation for possible strictures, abscesses, fistulae, and/or active inflammation.
- In IBD, CT or magnetic resonance (MR) enterography and push enteroscopy may help evaluate the extent of small bowel disease.
- Patients with severe constipation require a colonic transit study to confirm functional colonic disease.
- A preoperative carcinoembryonic antigen level should be obtained in cancer patients.

SURGICAL MANAGEMENT

Preoperative Preparation

- Patients in which an ileostomy is possible should undergo stoma marking by an enterostomal therapist.
- Clinical trials have shown no need for mechanical bowel preparation.
- Intravenous cefoxitin is administered within 1 hour of skin incision.
- Use hair clippers if needed and chlorhexidine gluconate skin preparation is used.
- A preoperative time-out and briefing is performed.
- Ultrasound-guided bilateral transversus abdominis plane (TAP) block reduces the need for postoperative narcotics.

Equipment and Instrumentation

- 5-mm camera with high-resolution monitors
- 5-mm and 12-mm clear ports with balloon tips—they hold ports in the abdomen and minimize their intraabdominal profile during surgery.
- Laparoscopic endoscopic scissors and a blunt-tip 5-mm energy device
- 60-mm linear reticulating laparoscopic staplers with vascular and tan cartridges
- We use the GelPort hand-assist device due to its versatility and ease of use. This device allows for the introduction/removal of the hand without losing pneumoperitoneum and allows for insertion of multiple ports through the hand-assist device if necessary. It also allows for the introduction of laparotomy pads into the field and is very useful in retracting bowel/omentum in obese patients.

Patient Positioning and Surgical Team Setup

- Place the patient on a modified lithotomy position (**FIG 1**), with the arms tucked and padded (to avoid nerve/tendon injuries). The patient is taped over a towel across the chest, without compromising chest expansion.

- Place the legs on Allen stirrup with the heels firmly planted on the stirrups to avoid pressure on the calves and the lateral peroneal nerves.
- Keep the thighs parallel to the ground to avoid conflict between the thighs and the surgeon's arms/instruments.
- The coccyx should be readily palpable off the edge of the table.
- The surgeon starts at the patient's right lower side, with the assistant to his or her left side and with the scrub nurse to his or her right or in between the patient's legs (**FIG 2**).
- Align the surgeon, ports, targets, and monitors in straight lines. Place monitors in front of the surgeon and at eye level to prevent lower neck stress injuries.
- Avoid unnecessary restrictions to potential team movement around the table. All energy device cables exit by the patient's upper left side. All laparoscopic (gas, light cord, and camera) elements exit by the patient's upper right side.
- The energy instruments are placed in a plastic pouch in front of the surgeon to avoid unnecessary instrument transfer during the operation (**FIG 2**).

FIG 1 • Patient positioning. The patient is on a modified lithotomy position, with the thighs parallel to the ground to avoid conflict with the surgeon's elbows/instruments. The arms are tucked. The patient is secured to the table by taping across the chest over a towel. All pressure points are padded to avoid neurovascular injuries.

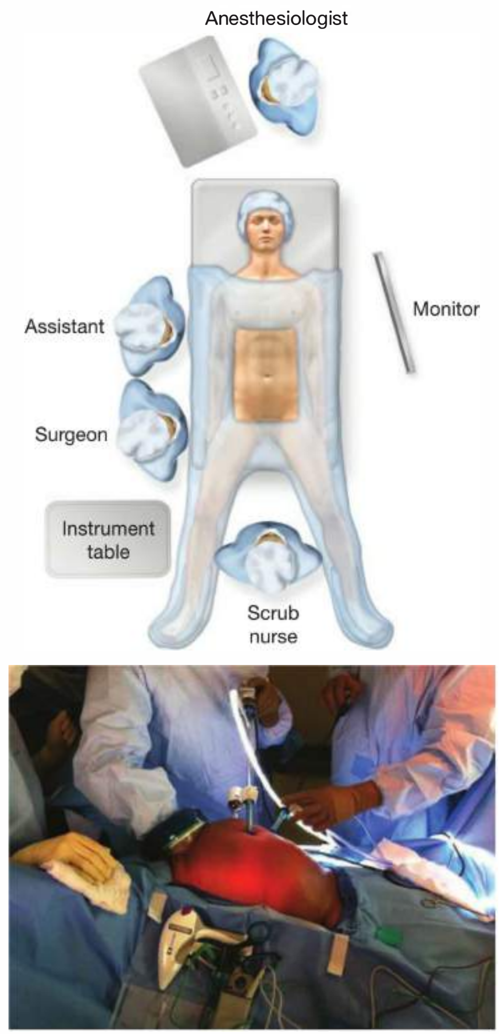

FIG 2 • Team setup. The surgeon stands to the patient's right side, with the assistant to his or her left, and the scrub nurse to his or her right or in between the patient's legs. The team, ports, targets, and monitors are aligned. Notice the energy devices placed in a pouch in front of the surgeon to minimize instrument transfer.

PORT PLACEMENT AND OPERATIVE FIELD SETUP

- Insert the GelPort through a 5- to 6-cm Pfannenstiel incision (**FIG 3**). This incision will be also used for specimen extraction. It provides a better cosmetic result and lowers the incidence of wound infections and incisional hernias. It also allows for more working space between the hand and the instruments. Alternatively, the GelPort can also be inserted in the epigastrium, if access to the middle colic vessels is of concern.
- Ports: Insert a 5-mm working port in the right upper quadrant (RUQ), a 12-mm working port in the right lower quadrant, and a 5-mm camera port above the umbilicus. These three ports are triangulated, with the camera port at the apex of the triangle. This setup avoids conflict between the instruments and the camera and prevents disorientation (avoids "working on a mirror"). A third 5-mm working port is inserted in the left anterior flank of the abdomen for the mobilization of the right colon; it can also be valuable for the mobilization of the splenic flexure in patients with deep left upper quadrants.

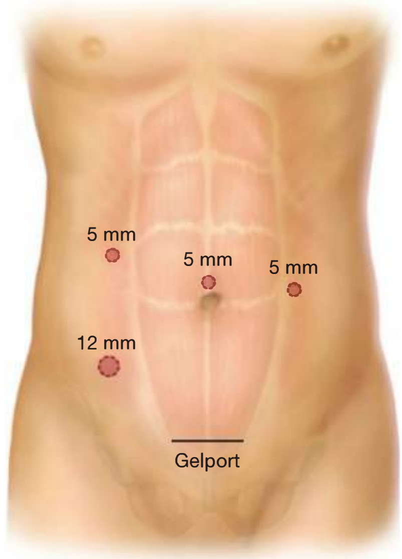

FIG 3 ● Port placement. The GelPort is placed through a 5- to 6-cm Pfannenstiel incision. Alternatively, the GelPort can be placed on an epigastric location. A 5-mm periumbilical camera port site is inserted. Working ports are inserted in the RUQ, right lower quadrant (RLQ), and left anterior flank of the abdomen. All ports are triangulated.

OPERATIVE STEPS

- Our HALS TAC operation is highly standardized and consists of 13 steps. After the initial point of entry, every step will expose the necessary planes of dissection for the following steps, ensuring that no truly virgin tissue planes are encountered anymore, thus greatly reducing the complexity of this operation. These steps, in order, are as follows:
  - Transection of the inferior mesenteric vein (IMV)
  - Transection of the inferior mesenteric artery (IMA)
  - Medial to lateral dissection of the descending mesocolon
  - Lateral mobilization of the sigmoid and descending colon
  - Mobilization of the splenic flexure and transverse colon
  - Mobilization of the hepatic flexure
  - Supramesocolic transection of the middle colic vessels
  - Transection of the ileocolic pedicle
  - Medial to lateral mobilization of the ascending colon
  - Lateral mobilization of the ascending colon
  - Intracorporeal distal transection
  - Extracorporeal mobilization and proximal transection
  - Intracorporeal ileorectal anastomosis

Step 1. Transection of the Inferior Mesenteric Vein

- This is the critical "point of entry" in this operation. We favor it over starting dissection at the IMA level due to the IMV's constancy in location, the ease of its visualization by the ligament of Treitz, and the absence of structures that can be injured around it (no iliac vessels or left ureter nearby). This will be the only time during the operation when a virgin tissue plane is entered. Every step will set up the following ones, opening the tissue planes sequentially.
- The patient is placed on a steep Trendelenburg position with the left side up. Using the right hand, move the small bowel into the RUQ and the transverse colon and omentum into the upper abdomen. If necessary, place a laparotomy pad to hold the bowel out of the field of view, especially in obese patients. This pad can also be used to dry up the field and to clean the scope tip intracorporeally. Make sure that the circulating nurse notes the laparotomy pad in the abdomen on the white board.
- Identify the critical anatomy: IMV, ligament of Treitz, and left colic artery (**FIG 4**).
- If there are attachments between the duodenum/root of mesentery and mesocolon, transect them with laparoscopic scissors. This will allow for adequate exposure of midline structures
- Pick up the IMV with the right hand. Dissect under (dorsal) the IMV and in front of Gerota's fascia with endoscopic scissors, starting at the level of the ligament of Treitz and proceeding with the dissection caudally toward the IMA. The assistant provides upward countertraction with a grasper.
- Transect the IMV (**FIG 5**) cephalad of left colic artery, which moves away from the IMV and toward the splenic flexure of the colon, with the 5-mm energy device.

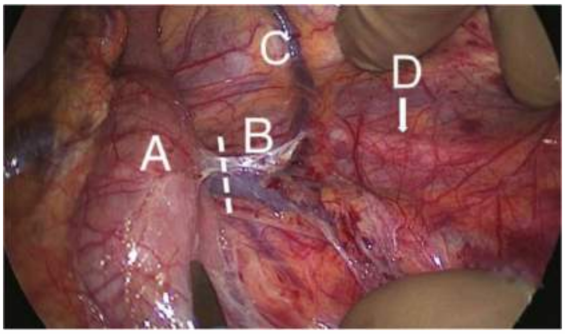

FIG 4 ● Step 1: transection of the IMV. Key anatomy. Ligament of Treitz *(A)*. IMV *(B)*. Left colic artery *(C)* as it separates from the IMV and goes toward the splenic flexure of the colon. The left ureter *(D)* is located far from the IMV projected transection *(dotted lines)*.

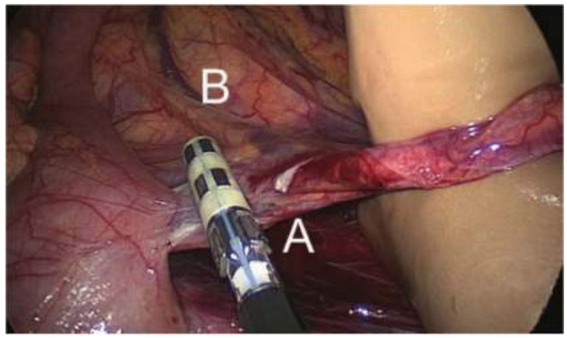

FIG 5 ● Step 1: transection of the IMV. The surgeon holds the IMV *(A)* anteriorly with his or her right hand and transects it cephalad of the left colic artery *(B)* with a 5-mm energy device.

Step 2. Transection of the Inferior Mesenteric Artery

- Identify the critical anatomy: the "letter T" formed between the IMA and its left colic and superior hemorrhoidal artery (SHA) terminal branches (**FIG 6**).
- Using the right hand, the aorta is identified and tracked down to the level of its bifurcation. The IMA will originate 1 to 2 cm proximal to this level.
- Holding the SHA up with the right hand, dissect the plane along the palpable groove between the SHA and the left iliac artery using laparoscopic scissors. A wide incision is made in the peritoneum dorsal to the SHA; the wider the incision, the easier the SHA can be elevated to obtain better exposure. After scoring the peritoneum under the SHA, use a 5-mm energy device to dissect by gently pushing the retroperitoneal tissues downward (dorsally) along the avascular plane located between the mesodescending colon, anteriorly, and the retroperitoneum, posteriorly. This avascular plane can be identified by the transition between the two distinctive fat planes of the mesocolon and Gerota's fascia.
- Preserve the sympathetic nerve trunk intact in the retroperitoneum. This avoids autonomic dysfunction postoperatively.
- Identify the left ureter (**FIG 7**), located in front of the left iliac artery and psoas muscle and medial to the gonadal vessels, before transecting anything. If you are directly on the psoas muscle, chances are that you left the left ureter attached to the dorsal surface of the mesocolon; bring it down into the retroperitoneum gently using blunt dissection with the energy device.
- If you cannot identify the ureter, try dissecting superior to inferior, starting from the IMV plane of dissection and moving caudally behind the IMA. If you still cannot find it, perform a lateral to medial mobilization of the sigmoid colon toward the midline. In this latter scenario, you will encounter the left gonadal vessels first, lateral to the left ureter.

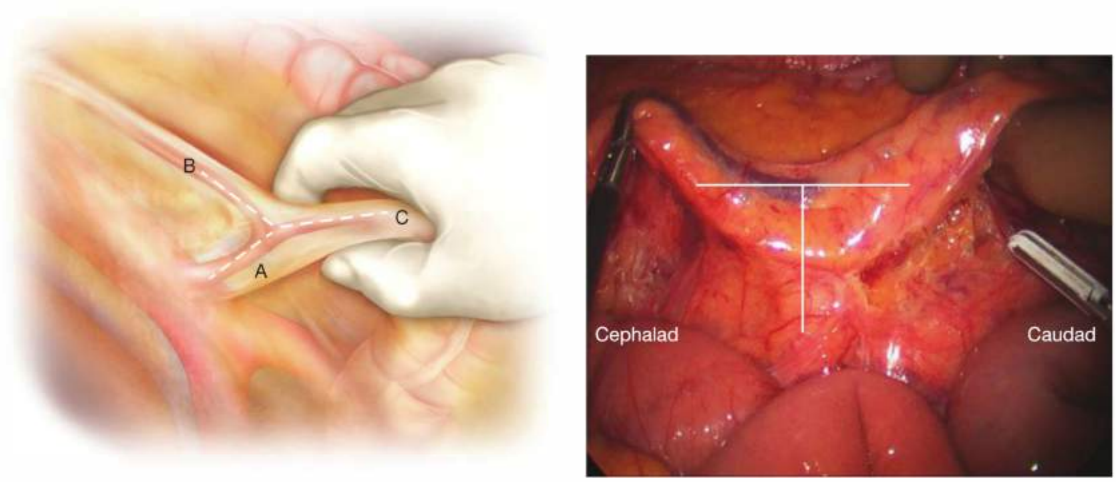

FIG 6 ● Step 2: critical anatomy. Identify the "letter T" formed between the IMA *(A)* and its left colic artery *(B)* and SHA *(C)* terminal branches. The IMA takeoff is just cephalad from the aortic bifurcation. The thumb and index finger are lifting the SHA off the groove located anterior to the right common iliac artery.

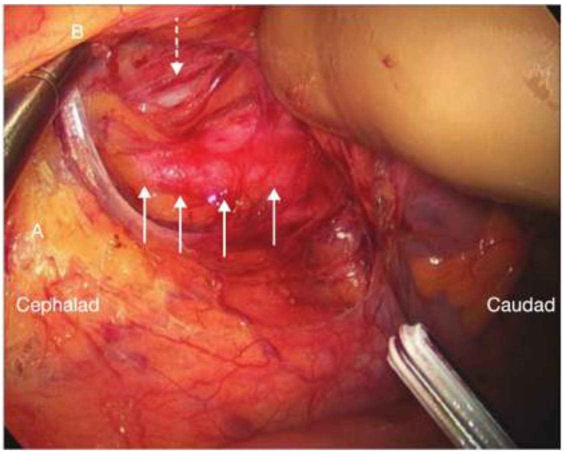

FIG 7 ● Step 2: identification of the left ureter and gonadal vessels. After the IMA *(A)* and SHA *(B)* have been lifted off the retroperitoneum, the left ureter *(solid arrows)* can be identified and preserved intact. Identification of the left ureter at this stage is critical in order to avoid injuring it during the IMA transection. Distal to the takeoff of the IMA, the left gonadal vessels can be identified lateral to the left ureter *(dotted arrow)*.

- Dissect with your thumb and index finger around and behind the IMA and again visualize the letter "T" formed between the IMA, the left colic artery, and the SHA (**FIG 8**).
- With the left ureter safely preserved in the retroperitoneum, transect the IMA at its origin with a vascular load stapler (**FIG 9**) or energy device. This ensures excellent lymph node harvest and allows great exposure for the following step.

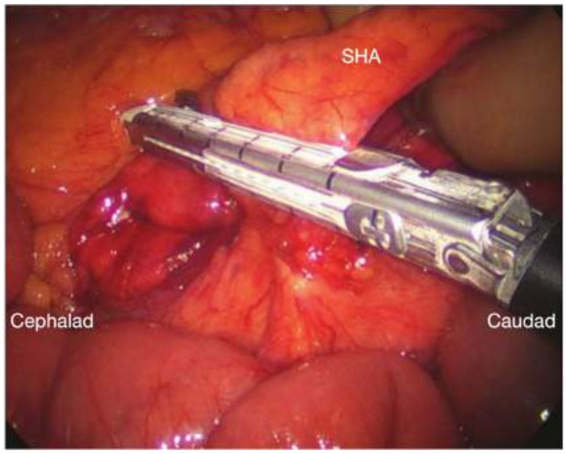

FIG 9 ● Step 2: transection of the IMA. With the left ureter safely dissected away into the retroperitoneum, the IMA is transected with a linear vascular stapler at its origin of the aorta. The surgeon's hand is holding the SHA anteriorly.

Step 3. Medial to Lateral Dissection of the Descending Mesocolon

- The surgeon's right hand and the assistant's grasper hold the descending mesocolon up, creating a working space between the mesocolon and the retroperitoneum (**FIG 10**). The plane between the mesocolon and Gerota's fascia, readily identified by the transition between the two fat planes, is dissected bluntly in a downward direction toward the retroperitoneum with the 5-mm energy device.
- Dissect laterally until you reach the lateral abdominal wall, caudally toward the pelvic inlet, and cephalad until

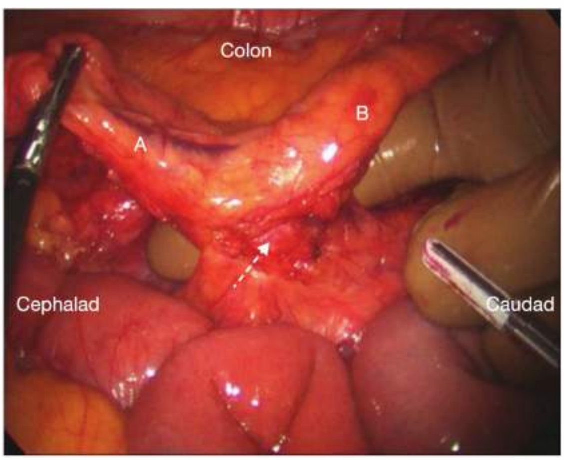

FIG 8 ● Step 2: circumferential dissection of the IMA. After the left ureter has been identified, the IMA *(arrow)* is circumferentially dissected at its origin of the aorta. Again, the "letter T" formed between the IMA and its terminal branches, the left colic artery *(A)*, and the SHA *(B)* can be clearly identified.

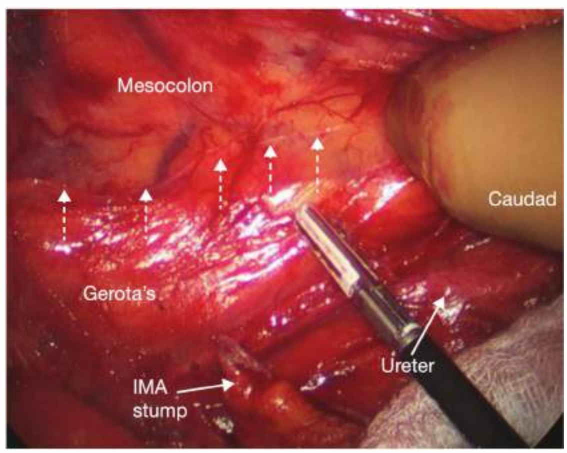

FIG 10 ● Step 3: medial to lateral mobilization of the mesocolon. With the surgeon holding the mesocolon anteriorly, the retroperitoneal tissues are swept downward (dorsally) with an energy device. The dissection progresses along the transition of the two fat planes *(dotted arrows)*: mesocolon (anteriorly) and Gerota's fascia (posteriorly). Notice the stapled IMA stump and left ureter in the retroperitoneum.

you separate the splenic flexure from the tail of the pancreas. Completing this step will greatly facilitate performance of steps 4 and 5.

Step 4. Lateral Mobilization of the Sigmoid and Descending Colon

- The surgeon pulls the sigmoid colon medially, exposing the lateral sigmoid colon attachments (**FIG 11A**). Transect the attachments between the sigmoid and the pelvic inlet with laparoscopic scissors in your left hand, staying medially, close to the sigmoid and mesosigmoid, to avoid injuring the ureter/gonadal vessels.
- Dissect caudally until reaching the entrance to the left pelvic inlet.
- Retract the descending colon medially with your hand to expose the white line of Toldt. The assistant holds the omentum/bowel out of way.
- Transect the white line of Toldt up to the splenic flexure using endoscopic scissors or energy device (**FIG 11B**). You should readily enter the medial to lateral dissection plane dissected during step 2, greatly facilitating this lateral mobilization of the descending colon.
- Dissect in a cephalad direction until reaching the splenic flexure of the colon.

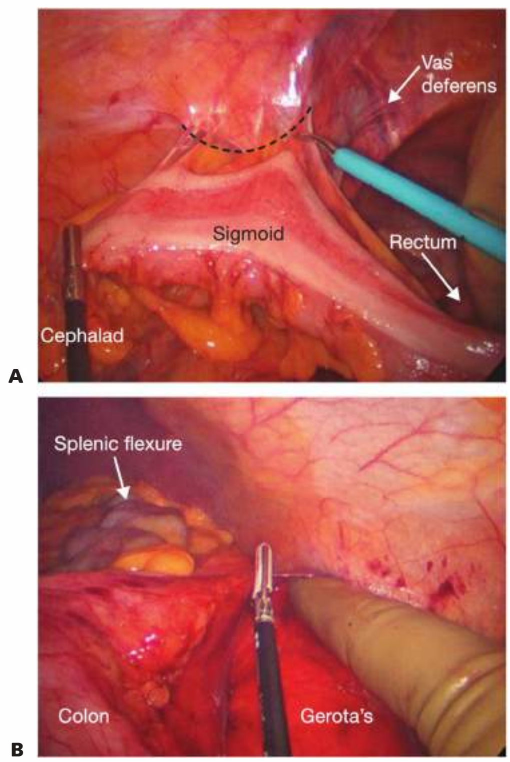

FIG 11 ● Step 4: lateral mobilization of the sigmoid and descending colon. **A.** The white line of Toldt *(dotted line)* is transected with an energy device. **B.** The medial to lateral dissection plane is readily entered, greatly facilitating the lateral mobilization of the descending colon.

- The left ureter and gonadal vessels, dissected in step 3, should be readily visible in the retroperitoneum.

Step 5. Mobilization of the Splenic Flexure and Transverse Colon

- The patient is now placed on a reverse Trendelenburg position with the left side up to allow the splenic flexure of the colon to come down into the surgical field.
- The mobilization of the splenic flexure is best accomplished by a combination medial to lateral and lateral to medial dissection approaches. The key to an easy splenic flexure mobilization is to have completed the separation of the splenic flexure off the retroperitoneum during the medial to lateral mobilization (step 3).
- The medial to lateral phase of the splenic flexure mobilization is started by entering the lesser sac at the midline. The transverse colon is retracted downward and the stomach is retracted superiorly, exposing the gastrocolic ligament. The gastrocolic ligament is then transected medially with an energy device until the lesser sac is entered.
- Transection of the gastrocolic ligament then proceeds along the transverse colon in a medial to lateral direction until the splenic flexure is reached (**FIG 12A**). Care must be taken to avoid inadvertent injury to the colon.
- At this point, a superior to inferior and lateral to medial dissection around the splenic flexure is performed (**FIG 12B**). The surgeon inserts his or her right hand behind the splenic flexure (possible due to the previous medial to lateral mobilization step) and hooks his or her index finger under the splenocolic ligament, gently pulling the splenic flexure down and exposing the splenocolic ligament fully, which is then transected with an energy device (**FIG 12C**).
- Attachments of the splenic flexure to the pancreas are transected and the splenic flexure is now fully mobilized to the midline.

Step 6. Mobilization of the Hepatic Flexure

- The patient is kept in a reverse Trendelenburg position but with the table now rotated with the right side up to allow the hepatic flexure to come down into the field.
- Standing at the left side of the table, the surgeon retracts the transverse colon downward with his or her left hand and completes the transection of the gastrocolic ligament until reaching the hepatic flexure of the colon using a 5-mm energy device.
- At this point, the hepatocolic ligament is readily visible. Slide your left index finger under it, hold it upward, and transect it with a 5-mm energy device (**FIG 13**).
- Proceeding on a superior to inferior dissection, and retracting the hepatic flexure downward with your hand, separate the hepatic flexure form the second portion of the duodenum and the head of the pancreas with the 5-mm energy device by gently teasing the retroperitoneal tissues down. Take care to avoid avulsing the gastrocolic venous trunk of Henle and its tributaries, which can lead to severe bleeding that is difficult to control.

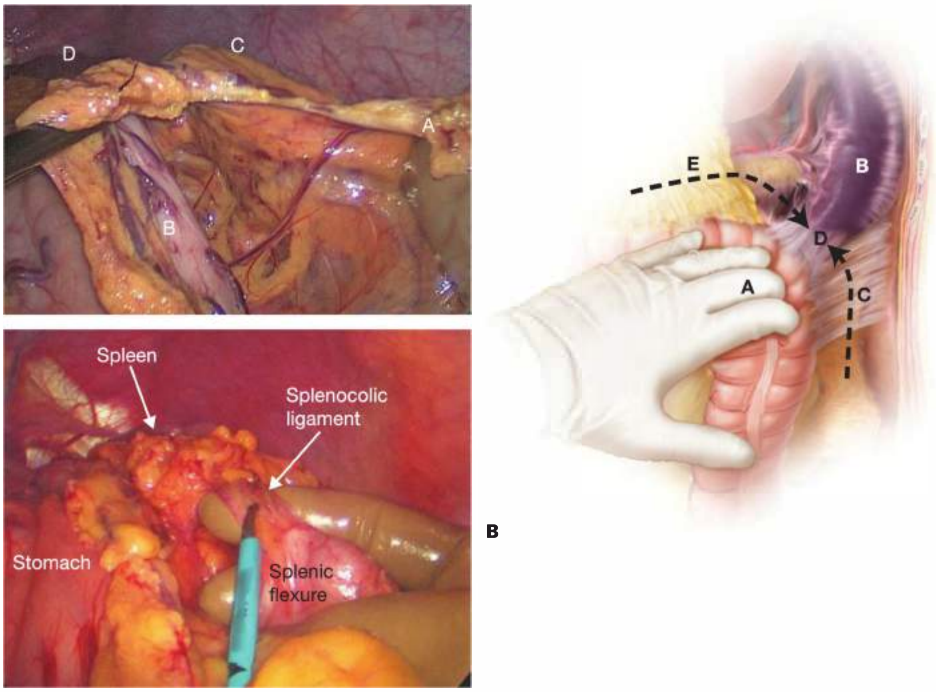

FIG 12 ● Step 5: mobilization of the splenic flexure. **A.** The lesser sac, between the transverse colon *(A)* and the stomach *(B)*, is entered. The gastrocolic ligament is transected with an energy device from right to left, toward the splenic flexure of the colon *(C)* until the spleen *(D)* is reached. **B.** The surgeon retracts the splenic flexure of the colon *(A)* downward and medially, exposing the attachments to the spleen *(B)*. The phrenocolic *(C)* and splenocolic *(D)* ligaments are transected in an inferior to superior and lateral to medial direction, meeting the previously transected gastrocolic ligament *(E)* dissection plane around the splenic flexure. **C.** With the surgeon "hugging" the splenic flexure with his or her right hand, the index finger is hooked under the splenocolic ligament, which is then transected with an energy device.

Step 7. Transection of the Middle Colic Vessels (Supramesocolic Approach)

- Dissection and transection of the middle colic vessels can be one of the most daunting maneuvers in colorectal surgery. Traditionally, these vessels are approached inframesocolically by dissecting the root of the mesotransverse colon at the intersection with the root of the mesentery, where the venous anatomy is extremely variable and complex. The superior mesenteric vein and its branches and the gastrocolic venous trunk of Henle and its branches surround the middle colic vessels. Venous tears tend to travel distally to the next major tributary. In terms of the SMV and the gastrocolic trunk of Henle, this next "tributary" is the portal vein confluence, which lies in a retroperitoneal plane for which you do not have control at this time.

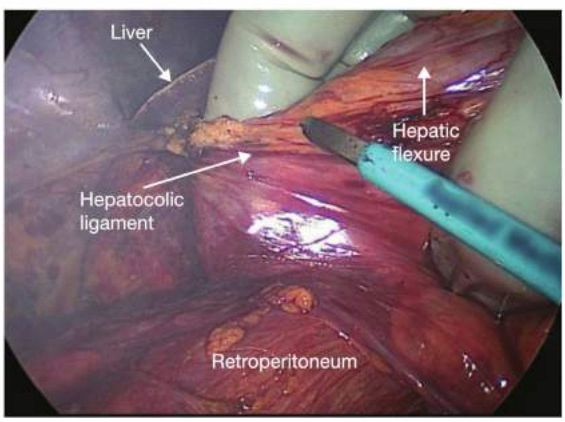

FIG 13 ● Step 6: mobilization of the hepatic flexure. Slide your left index finger under the hepatocolic ligament, hold it upward, and transect it with an energy device.

- In order to prevent potentially devastating bleeding complications during the dissection and transection of the middle colic vessels, we have developed a supramesocolic approach to these vessels. The hand-assisted technique greatly facilitates the performance of this technique and makes it very safe.
- The superior aspect of the transverse mesocolon is now readily visible, with the middle colic vessels easily palpable as they cross the third portion of the duodenum in the midtransverse colon (**FIG 14**). With the assistant pulling down on the transverse colon downward with a grasper, the surgeon "picks up" the middle colic vessels supramesocolically with his or her left thumb and index finger. Using his or her right hand, the surgeon now dissects under the middle colic vessels with the 5-mm

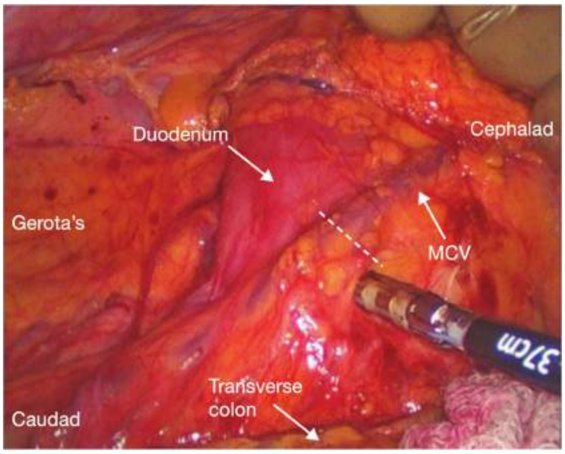

FIG 14 ● Step 7: supramesocolic transection of the middle colic vessels (MCV). With the transverse colon retracted caudally, the MCV are readily visualized at this point through a supramesocolic approach as they cross over the third portion of the duodenum. This allows for a safe dissection and high transection *(dotted line)* with a 5-mm energy device without risking injury to the SMV and gastrocolic venous trunk of Henle.

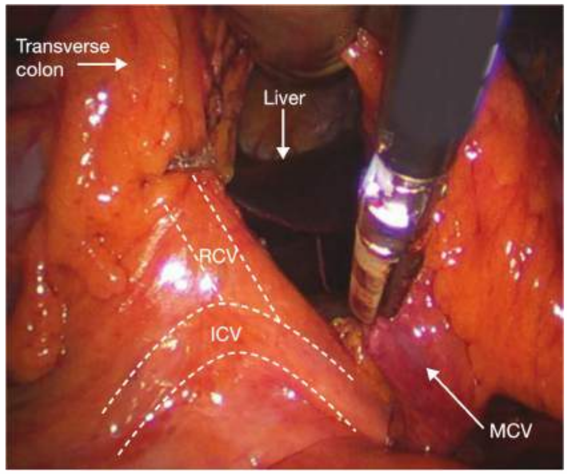

FIG 15 ● Vascular anatomy after transection of the middle colic vessels (MCV). While pulling upward on the transverse colon, the transected stump of the MCV is observed. The ICV, with its right colic vessels (RCV) branch, can be readily identified as they cross over the third portion of the duodenum.

energy device, completely encircling the middle colic vessels with the thumb and index finger. With great exposure and control, now the surgeon transects the middle colic vessels with the 5-mm energy device (FIG 14).

- During this approach, the transverse mesocolon separates the middle colic vessels from the SMV and the gastrocolic venous trunk of Henle from shielding them and thus greatly reducing the potential risk of serious venous injuries. It also allows for a very high transection of the middle colic vessels and therefore a great lymphatic nodal capture.
- After transection of the middle colic vessels, the ileocolic vessels (ICV) can now be readily identified as they cross over the third portion of the duodenum (FIG 15).

Step 8: Transection of the Ileocolic Pedicle

- Place the patient on a Trendelenburg position with the right side up to facilitate exposure to the ICV. Place the hepatic flexure back in the RUQ. Move the transverse colon and the omentum into the upper abdomen. Move the small bowel into the left lower quadrant (LLQ) to expose the duodenum and the root of the mesoascending colon. In obese patients, a laparotomy pad may greatly assist in retracting the bowel.
- Grab the ICV as they cross over the third portion of the duodenum with your thumb and index finger and pull them up anteriorly (FIG 16A).
- With the ICV on stretch, a parallel incision is made with hot scissors on the peritoneal layer underneath (dorsal) the pedicle (FIG 16B) extending to the root of the mesentery and the superior mesenteric vein, using hot scissors.
- A window is created under the ileocolic pedicle in the avascular plane that separates the pedicle from the retroperitoneum.
- The ileocolic pedicle is isolated and divided close to its origin off the superior mesenteric vessels using an energy device (FIG 16C).

Step 9: Medial to Lateral Mobilization of the Ascending Colon

- The retroperitoneum is now exposed by the surgeon pulling upward (anteriorly) on the distal transected ICV stump while the assistant retracts the mesoascending colon upward (anteriorly) with a grasper.
- Using blunt dissection with a 5-mm energy device, the ascending mesocolon is mobilized off the retroperitoneum by gently sweeping the duodenum and Gerota's fascia down (dorsally), using a medial to lateral dissection approach.
- As the dissection proceeds from medial to lateral, and to facilitate exposure, the surgeon's left hand should be pronated and placed underneath the mesocolon, giving upward traction for the retroperitoneal dissection (FIG 17).
- Mobilization of the right mesocolon is carried out laterally to the abdominal wall, superiorly to the hepatorenal recess and medially exposing the third portion of the duodenum and the head of the pancreas.
- At this point, critical structures including the right ureter, the right gonadal vein, and the duodenum are identified and preserved intact in the retroperitoneum.

A B C

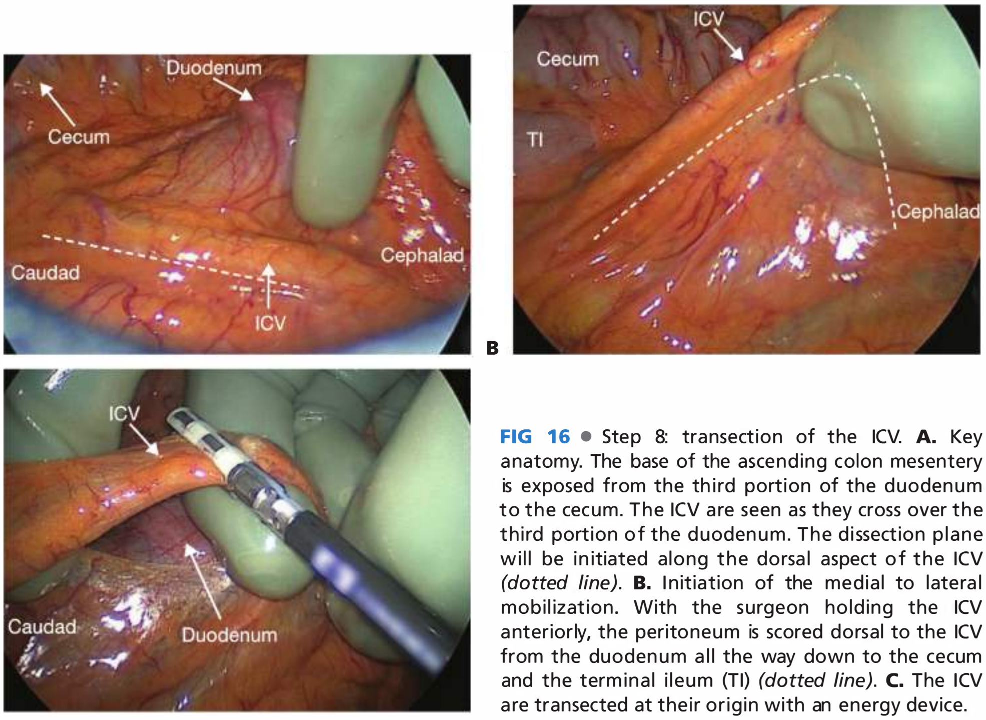

FIG 16 ● Step 8: transection of the ICV. **A.** Key anatomy. The base of the ascending colon mesentery is exposed from the third portion of the duodenum to the cecum. The ICV are seen as they cross over the third portion of the duodenum. The dissection plane will be initiated along the dorsal aspect of the ICV *(dotted line)*. **B.** Initiation of the medial to lateral mobilization. With the surgeon holding the ICV anteriorly, the peritoneum is scored dorsal to the ICV from the duodenum all the way down to the cecum and the terminal ileum (TI) *(dotted line)*. **C.** The ICV are transected at their origin with an energy device.

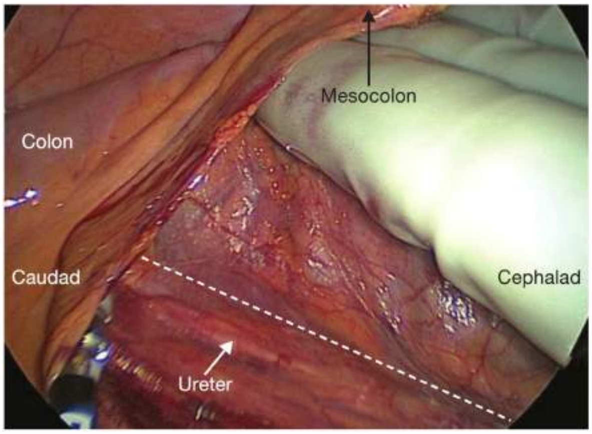

FIG 17 ● Step 9: medial to lateral mobilization of the ascending mesocolon. The surgeon, while retracting the ascending mesocolon upward (anterior) with the hand fully pronated and facing upward, separates the ascending mesocolon from the retroperitoneum by dissecting along the transition of the two distinct fat planes *(dotted line)*. The right ureter can be readily identified in the retroperitoneum and is preserved intact.

STEP 10: LATERAL MOBILIZATION OF THE ASCENDING COLON

- The base of cecum is grasped and retracted anteriorly toward the abdominal wall.
- With the ileum on stretch by the assistant, a peritoneal incision is created from the cecum medially along the root of the terminal ileum mesentery (**FIG 18A**). You should readily enter the retrocolic space previously created by the medial to lateral mobilization of the ascending mesocolon.
- The right ureter and the right gonadal vein are most easily identified at this phase of the operation coursing over the right iliac vessels and into the pelvis (**FIG 18B**). Lateral and anterior to the psoas muscle, the lateral femoral cutaneous nerve is also frequently identified.

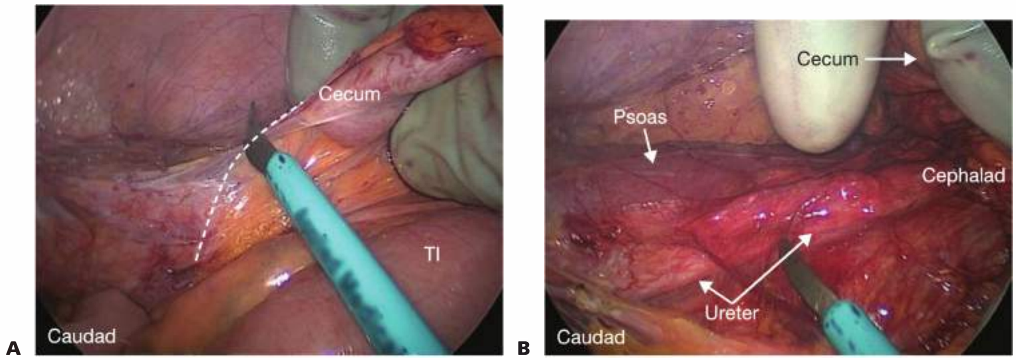

FIG 18 ● Step 10: lateral mobilization of the ascending colon. **A.** With the surgeon pulling on the cecum medially and superiorly, a peritoneal incision is created from the cecum medially along the root of the terminal ileal mesentery. **B.** After mobilization of the cecum, the right ureter is readily identified in the retroperitoneum. *TI*, terminal ileum

- The white line of Toldt is incised, dividing the only remaining attachments of the ascending colon if the medial to lateral dissection was carried out adequately during the previous step.
- The entire colon is now fully mobilized and ready for transection.

Step 11: Intracorporeal Distal Transection

- Dissect the rectosigmoid junction circumferentially. The rectosigmoid junction can be identified by the splaying of the teniae coli. Transect the upper mesorectum with the 5-mm energy device at the level of the projected distal bowel transection.
- While pulling on the sigmoid upward with the left hand, transect the bowel intracorporeally just distal to the rectosigmoid junction with a linear Endo GIA stapler device (**FIG 19**).

Step 12: Extracorporeal Mobilization and Proximal Transection

- The entire colon and the terminal ileum are delivered extracorporeally through the Pfannenstiel incision site with the Alexis wound protector in place to prevent infectious and/or oncologic soilage of the wound (**FIG 20**). There should be absolutely no tension during the extraction of the specimen.
- The terminal ileum is transected at a suitable site between Kocher clamps. The specimen is sent to the pathologist.

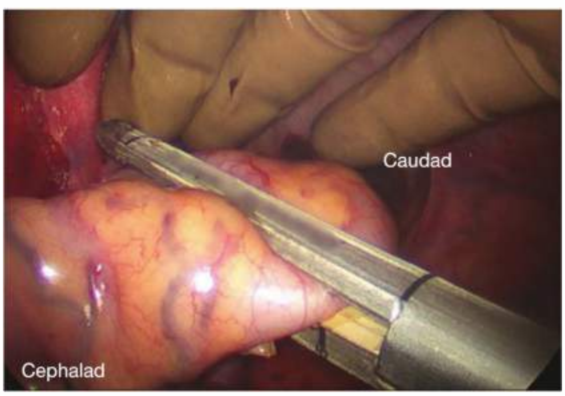

FIG 19 ● Step 11: intracorporeal distal transection. The specimen is transected with a linear stapler just distal to rectosigmoid junction, which can be identified by the splaying of the teniae coli.

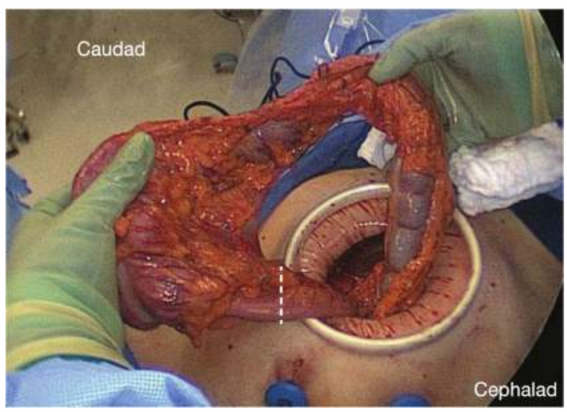

FIG 20 ● Step 12: extracorporeal mobilization and transection. The entire colon is extracted without any tension. The distal ileum will be transected along the *dotted line* between Kocher clamps.

STEP 13: INTRACORPOREAL ILEORECTAL ANASTOMOSIS

- At this point, the anvil of a 28-Fr end-to-end anastomosis (EEA) stapler device is placed through the open end of the terminal ileum and is exteriorized with a spear through the antimesenteric border approximately 5 cm from the open end of the ileum. The open end of the terminal ileum is then closed with an endoscopic linear stapler with a 60-mm vascular stapler.
- The terminal ileum, with the anvil in place, is reintroduced into the abdominal cavity, the Gelcap is reapplied, and the pneumoperitoneum is reinsufflated.
- The surgeon stands to the patient's right side, with the left hand through the GelPort and with the camera in his or her right hand through one of the right lateral port sites. The patient is placed on a slight Trendelenburg position.
- An experienced assistant introduces the 28-Fr EEA stapler into the rectum and delivers the spear anterior to the rectal stump staple line. The EEA stapler and the anvil are mated (by the surgeon's left hand); the EEA stapler is closed and then fired, creating a side-to-end ileorectal anastomosis (**FIG 21**).
- Two intact doughnuts should be obtained. The distal doughnut is sent for evaluation as the distal margin. The anastomosis is inspected to ensure that it is tension-free and that it has excellent blood supply.
- Finally, the anastomosis is insufflated under water to ensure that it is airtight. The presence of air bubbles would indicate an anastomotic disruption and should prompt a revision of the anastomosis.
- Alternatively, the distal transection and ileorectal anastomosis can be constructed extracorporeally through the open Pfannenstiel incision site. We find it easier to perform the anastomosis intracorporeally, due to the superior visualization and exposure that laparoscopy provides.

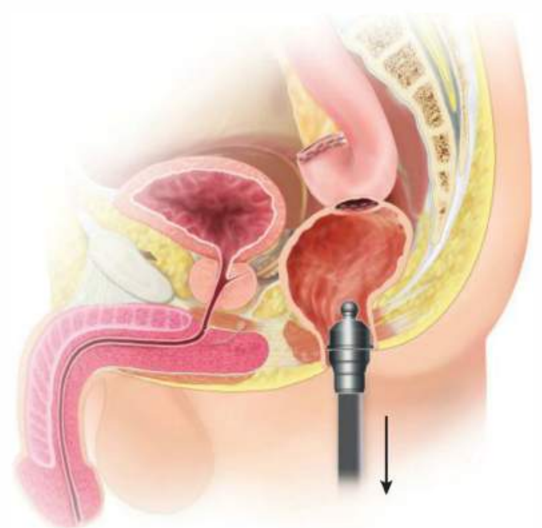

FIG 21 ● Step 13: intracorporeal anastomosis. A side-to-end ileorectal anastomosis is constructed with a 28-Fr EEA stapler device.

PEARLS AND PITFALLS

Setup	■ Proper patient, team, port, and instrumentation setup is critical.
Operative technique	■ Point of entry: IMV at the ligament of Treitz. Ideal due to its ease of localization and the absence of critical nearby structures that can be injured. ■ The medial to lateral dissection steps set up all other steps. ■ Visualize the "letter T" and high IMA ligation in malignancy; identify the left ureter prior to IMA transection. ■ The supramesocolic approach allows for a much easier and safer transection of the middle colic vessels. ■ The ICV can be readily identified by the third portion of the duodenum. ■ Distal transection and anastomosis: Although possible to perform extracorporeally, it is easier to do it intracorporeally (better visualization).
Pitfall: dissecting anterior to the SHA	■ Solution: Identify "groove" between left common iliac artery and SHA and dissect in between the two vessels.
Pitfall: floppy sigmoid difficult to handle	■ Use the back of the hand as a "shelf" to hold the sigmoid up while picking up the SHA with thumb and index finger.
Pitfall: cannot identify the left ureter during SHA/IMA dissection	■ Extend the IMV dissection plane on a superior to inferior direction behind the IMA. ■ If still unable to locate left ureter, mobilize the sigmoid lateral to medial. Distally, the left ureter is located medial to the gonadal vessels.

POSTOPERATIVE CARE

- Postoperative care is driven by a clinical pathway that includes the following:
  - Pain control: intravenous acetaminophen for 24 hours (start in the operating room) followed by intravenous ketorolac for 72 hours (if creatinine is normal). The TAP nerve block greatly reduces the need for narcotics.
  - Deep vein thrombosis (DVT) prophylaxis with enoxaparin, starting within 24 hours of surgery
  - No additional antibiotics; judicious use of intravenous fluids
  - No nasogastric tube. Remove Foley catheter on postoperative day 1.
  - Early ambulation, diet ad lib, aggressive pulmonary toilet
  - Targeted discharge: postoperative days 3 to 4

OUTCOMES

- HALS leads to improvements in short-term outcomes, including less pain, faster recovery, shorter hospital stay, and lower incidence of cardiac/pulmonary complications when compared to open surgery.
- When compared to conventional laparoscopy, HALS results in higher usage rates of minimally invasive surgery, shorter learning curves, lower conversion rates, shorter operative times, and shorter hospital stays.
- For cancer resection, minimally invasive surgery oncologic outcomes are at least comparable to those of open surgery.

COMPLICATIONS

- Wound infections and incisional hernias are markedly reduced with the use of a Pfannenstiel extraction site.
- Urinary/sexual dysfunction: important to preserve hypogastric nerves intact
- Ureteral injury: critical to identify the ureters prior to vascular transection
- DVT: low risk with use of DVT prophylaxis
- Cardiac and pulmonary complications: significantly reduced compared to the open surgery approach

Chapter 27

Low Anterior Resection and Total Mesorectal Excision/ Coloanal Anastomosis: Open Technique

Konstantinos I. Votanopoulos Jaime L. Bohl

DEFINITION

- Low anterior rectal resection (LAR) with total mesorectal excision (TME) is defined as the removal of the rectum en bloc with an intact perirectal fascial envelope distal to the cancer-bearing rectal wall. The visceral endopelvic fascia, also known as fascia propria or investing fascia of the mesorectum, is identified by a thin, loose areolar tissue that circumferentially separates the rectum and mesorectum from surrounding pelvic structures. Removal of the rectum with an intact mesorectum ensures complete removal of all lymph nodes and lymphatics that drain the diseased rectum without oncologic contamination of the pelvis at the time of surgery.
- Coloanal anastomosis is the attachment of a mobilized proximal colon segment to the anal canal while preserving the anal sphincter musculature with a negative distal margin.
- This operation is performed primarily for distal rectal cancer, when tumor location mandates rectal transection at the level of the pelvic floor (levator ani and puborectalis).

PATIENT HISTORY AND PHYSICAL FINDINGS

- A detailed history should identify locally advanced rectal lesions that are causing bowel obstruction, bleeding, pseudodiarrhea, fecal incontinence, or excessive pelvic or anal pain. Nearly obstructed patients may require a temporary laparoscopic loop sigmoid colostomy prior to neoadjuvant chemoradiation. Patients with pain due to fixed tumors in the anal canal and sphincter are not candidates for coloanal anastomosis.
- Prior colon and anorectal surgery, vascular surgery, or sphincter trauma during childbirth may have compromised the vascular supply to the planned colonic conduit or reduce the anal sphincter function.
- Patients with poor functional status or poor fecal control prior to surgery are likely to have reduced quality of life and fecal soiling after surgery. These patients may be best served with a permanent colostomy rather than a sphincter-sparing coloanal anastomosis.
- Digital rectal exam and rigid proctoscopy should be performed by the lead surgeon prior to the administration of neoadjuvant therapy. Anal sphincter, pelvic floor function, topography of rectal wall involvement, and distance of the distal aspect of the tumor from the dentate line determine the likelihood of sphincter salvage and method of reanastomosis. Submucosal tattooing distal to the rectal tumor identifies the location of clinically regressed tumors after neoadjuvant chemoradiation and is helpful for determining tumor clearance during pelvic dissection.
- A detailed family history is necessary to identify risk of an inherited colon and rectal cancer syndrome as well as risk for metachronous colorectal cancer. We currently screen all young patients (<60 years of age) for Lynch syndrome and refer patients to genetic counseling when they have a positive screen or if they have multiple affected relatives.
- Past medical history should identify patients with cardiopulmonary, liver, or kidney disease not medically suitable for a physiologically demanding operation.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- A complete colonoscopy is obtained.
- Preoperative staging with endorectal ultrasound (ERUS) or magnetic resonance imaging (MRI) determines the need for neoadjuvant chemoradiation. ERUS has a higher sensitivity and specificity for tumor depth rather than lymph node involvement as compared to MRI. MRI allows for assessment of the circumferential margin at the mesorectal envelope.[1]
- Tumors located at the distal two-thirds of the rectum with greater than or equal to T3 wall invasion or greater than or equal to N1 nodal status will be referred for neoadjuvant treatment to decrease the risk of locoregional recurrence.[2] Additionally, neoadjuvant therapy may lead to tumor shrinkage, increasing the likelihood of sphincter preservation while avoiding exposure of the small bowel, colonic conduit, and anastomosis to postoperative radiation. Postoperative radiation is associated with increased risk of anastomotic stricture and radiation enteritis.[3]
- We routinely order a contrast-enhanced computed tomography (CT) scan of the chest, abdomen, and pelvis to evaluate for distant metastatic disease. Selected patients with liver metastases will be treated with a combination of staged resections and chemotherapy, whereas patients with synchronous peritoneal carcinomatosis will be evaluated for cytoreductive surgery with hyperthermic intraperitoneal chemotherapy. Positron emission tomography (PET) for the initial staging of rectal cancer rarely alters disease management.[4]
- Carcinoembryonic antigen (CEA) levels are checked prior to the initiation of neoadjuvant chemoradiation, prior to resection and prior to initiation of adjuvant chemotherapy.

SURGICAL MANAGEMENT

Preoperative Planning

- Patients undergo preoperative counseling and stoma marking by an enterostomal therapist. Counseling allows the patient to understand ostomy care, optimizes stoma placement, and reduces stoma-related complications.[5]

- Placement of ureteral stents can facilitate ureteral identification in the setting of large rectal tumors, inflammation, previous surgery and pelvic radiation, and also contributes to intraoperative identification of ureteral injuries.
- Bowel preparation or enema removes the mechanical obstacle of bowel contents in a narrow pelvis and reduces the tension on an infraperitoneal anastomosis.
- Parenteral antibiotic prophylaxis covering bowel flora is given prior to surgical incision.
- Deep venous thrombosis prophylaxis via sequential compression devices (SCDs) and subcutaneous (SC) heparin or low-molecular-weight heparin (LMWH) prior to surgical incision is administered.
- The surgical tray should include a lighted St. Mark's retractor with the longest available blades, a big bite surgical energy device, and laparoscopic cautery and suction.

Positioning

- LAR with coloanal anastomosis requires access to both the pelvis and the perineum. Therefore, patients are placed in a lithotomy position with the hips slightly flexed and the knees completely flexed in Yellofin stirrups. Extra padding is applied on the fibular head and heels to prevent nerve injury and pressure ulcers. The buttocks are at the edge of the table with the tip of the coccyx accessible. The legs remain adducted during the pelvic dissection but will need to be abducted to allow perineal access during creation of the coloanal anastomosis (**FIG 1**).

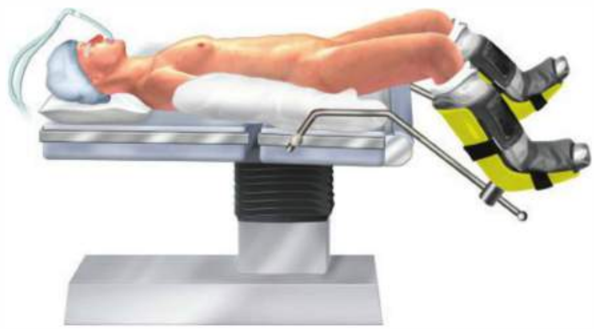

FIG 1 ● The patient is on a lithotomy position with the patient's hips slightly flexed and the legs completely flexed in Yellofin stirrups.

TECHNIQUES

LOW ANTERIOR RECTAL RESECTION WITH TOTAL MESORECTAL EXCISION

Incision, Abdominal Exploration, and Retraction of the Small Bowel

- A laparotomy incision is made from the supraumbilical midline to the pubic bone. The fascia is opened between the rectus muscles. As the incision is opened to the level of the pubic bone, the bladder is mobilized to the left of the incision.
- A careful exploration of the abdominal and pelvic cavity is undertaken to assess for distant metastatic disease and/or unresectable local disease. Attention should be given to the liver, retroperitoneum, aortic and external iliac lymph nodes, as well as peritoneal surfaces. Locally advanced disease may require a diverting colostomy followed by chemotherapy and radiation prior to resection.
- A fixed abdominal retractor, such as a Bookwalter or Thompson retractor, is used for exposure. A laparotomy pad wrapped around the small intestine from the ligament of Treitz to the terminal ileum will prevent loops of small intestine from migrating into the operative field. A midline incision that barely extends above the umbilicus allows for tacking the small bowel under the right abdominal wall.

Mobilization of the Left and Sigmoid Colon, Colonic Mesentery, and Splenic Flexure

- The left colon lateral attachments are incised with a cephalad direction. The areolar plane between the left colonic mesentery and the retroperitoneum is identified and opened. This plane is a few millimeters medial from the peritoneal reflection or white line of Toldt. Developing a plane at the exact edge of the white line of Toldt has the potential of lifting the retroperitoneal structures with subsequent ureteral and nerve injury.
- The splenocolic, phrenocolic, and renocolic attachments are divided at the splenic flexure. In patients with difficult visualization, the transverse colon is retracted downward and the lesser sac is entered over the midtransverse colon by incising the gastrocolic ligament. Development of this plane in a medial to left lateral direction detaches the omentum from the distal transverse colon so that the medial and lateral planes of dissection can be joined to complete the splenic flexure mobilization (**FIG 2**).
- The splenic flexure and proximal left colon mesentery are separated from the Gerota's fascia. Incomplete mobilization of the splenic flexure results in a short colonic conduit and tension on the colorectal anastomosis, which could then lead to a postoperative anastomotic leak.

Vessel Ligation and Left Ureter Identification

- The separation of the left and sigmoid colon from the retroperitoneum is continued by reversing direction toward the pelvis. The left ureter is identified as it crosses over the left iliac artery and into the pelvis in a way that preserves the retroperitoneal location of the ureter but also identifies the areolar plane that medially extends to the superior hemorrhoidal vessels (SHV) arch (**FIG 3**). Lifting the mesosigmoid and placing the index finger behind the SHV arch allows the surgeon to incise with electrocautery the right surface of the peritoneum just under the dorsal surface of the SHV. This plane of dissection along the dorsal aspect of the SHV, as it is carried over the promontory, leads into the presacral tissue plane that will be later developed during the TME. At this

FIG 2 ● Mobilization of the splenic flexure. The splenic flexure of the colon *(A)* is retracted medially to identify and release the lateral peritoneal attachments. Care is taken to avoid injury to the spleen *(B)*. The phrenocolic ligament *(C)*, the splenocolic ligament *(D)*, and the gastrocolic ligament *(E)* are identified and subsequently divided. This dissection can be carried from medial to lateral as well as lateral to medial, until both planes of dissection meet around the spleen.

point, the mesentery is divided in between the sigmoid and descending colon, starting from the antimesenteric border. The SHV are ligated at the level of their origin from the inferior mesenteric artery (IMA) in order to preserve the left colic pedicle intact. The colon itself is not divided. This prevents the colon from dropping into the dissection field during the operation and also allowing for any blood supply deficiencies in the proximal colon to manifest by the end of the dissection and prior to the anastomosis.

- In cases of coloanal anastomosis, a high IMA transection at its takeoff from the aorta is usually performed, in an effort to prevent anastomotic tension (**FIG 4**). The collateral marginal artery that connects the middle colic artery and the IMA and runs close to the colon provides blood supply to the distal descending colon in these cases.
- Reidentification of the ureter prior to IMA or SHV pedicle ligation ensures the left ureter is safe from injury.
- Additional length of the colonic conduit can be achieved by ligating the inferior mesenteric vein just lateral to the ligament of Treitz.

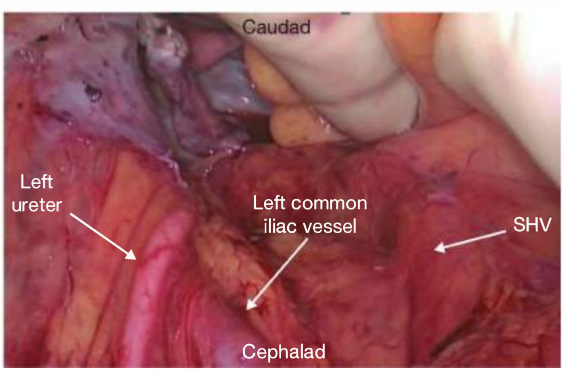

FIG 3 ● The sigmoid colon and its mesentery have been separated from the retroperitoneum to reveal the left ureter as it crosses the left common iliac vessels. The peritoneal reflection over the left side of the rectum and mesorectum has been incised dorsal to the SHV to allow encircling these vessels prior to ligation.

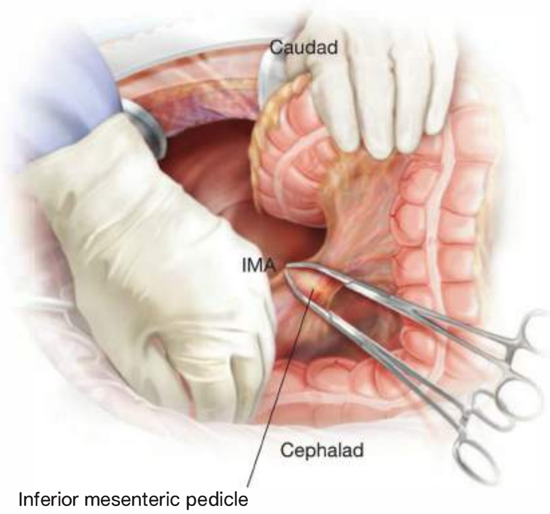

FIG 4 ● High IMA transection. In coloanal anastomosis cases, the IMA is transected at its origin between clamps in order to obtain maximal mobilization of the colonic conduit.

Posterior Mobilization of the Rectum and Hypogastric Nerve Identification

- A lighted St. Mark's retractor is placed posteriorly to the ligated SHV. By retracting the rectum anteriorly, the presacral areolar space is exposed and divided with electrocautery. The hypogastric nerves are identifiable at this location prior to dissecting the presacral space (**FIG 5**). These nerves should be swept posteriorly and preserved as they course in a medial to lateral direction along the presacral fascia.
- The presacral dissection plane is bloodless. Proper retraction with the St. Mark's retractor assists the surgeon in following the areolar plane between the fascia propria anteriorly and the presacral fascia posteriorly, down to the levator muscles and pelvic floor (**FIG 6**).
- Failure to properly expose the presacral space with the lighted St. Mark's retractor risks dissecting to far posteriorly and into the presacral venous plexus. Staying on the anterior surface of the areolar plane close to the mesorectal boundary will allow the surgeon to stay in the presacral space, thus avoiding catastrophic bleeding from injured presacral veins.
- Blunt dissection should be avoided at all cause, because it can lead to violation of the mesorectum with the attendant increased risk of locoregional tumor recurrence. It is imperative to adhere to a sharp dissection technique when dissecting around the mesorectum.

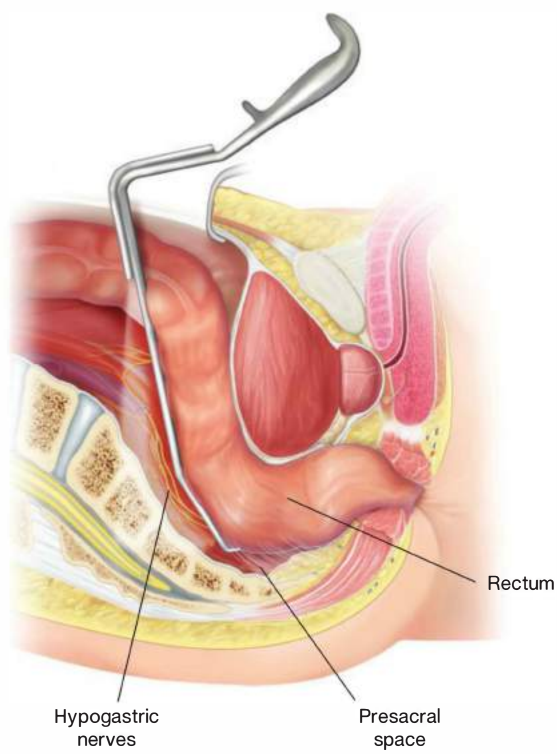

FIG 5 ● Using a lighted St. Mark's retractor, the rectum is retracted anteriorly, exposing the presacral space posteriorly. The hypogastric nerves are exposed and should be swept posteriorly and away from the mesorectum. This begins the superior and posterior portion of the TME.

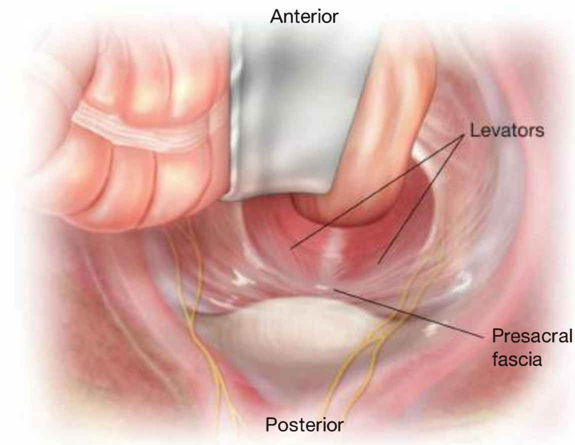

FIG 6 ● Exposed with the aid of a lighted St. Mark's retractor, the presacral plane of dissection should be followed down to the levator muscles and the pelvic floor.

- As the posterior dissection continues laterally, the surgeon must proceed on an anterolateral direction, or in a semicircular fashion, to open the lateral planes. This helps avoiding penetrating through the endopelvic fascia, which holds the hypogastric vein and its branches as well as the parasympathetic plexus attached to the lateral pelvic walls. In this fashion, potentially catastrophic bleeding and severe autonomic dysfunction can be averted.

Division of Lateral Ligaments

- The lateral rectal ligaments can be taken with cautery or with an energy device. It is not usually necessary to ligate vessels within the lateral stalks with the exception of the middle rectal vessel variants. Identification of the lateral rectal ligaments is achieved by placing the rectum on posterolateral traction between the index and middle fingers in the direction opposite of the lateral rectal ligament to be transected (**FIG 7**).

Anterior Mobilization of the Rectum and Proximal Colonic Transection

- Following the areolar tissue circumferentially around the rectum and incising the anterior peritoneal reflection connects the right and left lateral dissections. Once the peritoneal reflection is incised, the dissection continues behind Denonvilliers' fascia, which covers the seminal vesicles and prostate (**FIG 7**). Dissection anterior to Denonvilliers' fascia is associated with annoying bleeding and with an increased risk of parasympathetic nerve damage. This plane is intentionally violated only in anterior tumors that invade into the seminal vesicles or prostate. In these cases, the seminal

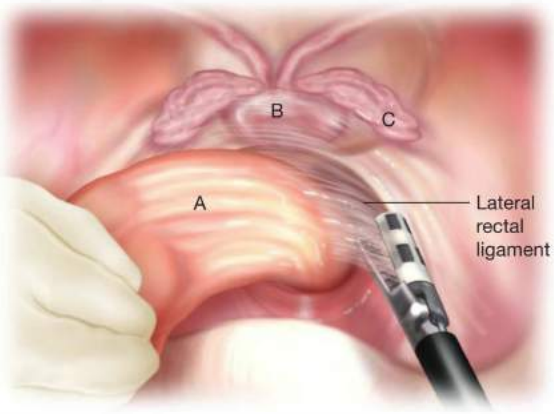

FIG 7 ● Transection of the lateral rectal ligaments and anterior pelvic dissection. Posterolateral retraction of the rectum allows for good exposure of the lateral rectal ligament (the right one is shown here), which can then be transected with cautery or with an energy device. The anterior dissection will then proceed behind Denonvilliers' fascia, in the space between the rectum, posteriorly, and the prostate and seminal vesicles (*B* and *C*, respectively), anteriorly.

vesicles and/or part of the prostate have to be resected en bloc with the rectum in order to achieve a clear radial margin.

- In women, the rectovaginal septum is more easily separated from the rectum anteriorly.
- At this point, the colon is transected proximally between the sigmoid and descending colon lymphovascular distribution in between Kocher clamps. The transected end of the colon should reach the pubis with ease, ensuring adequate mobilization of the colon conduit for a tension-free anastomosis.

COLOANAL ANASTOMOSIS: STAPLED TECHNIQUE

- This method is feasible when there is at least 2 cm of rectal stump above the dentate line.
- The rectum is divided above the levators with a contoured stapler. The specimen, including the entire rectum and mesorectum as well as the sigmoid colon, is now fully disconnected and is sent to the pathologist. The pelvis is now empty with good visualization of the pelvic floor (**FIG 8**).
- The anvil of a 29mm end-to-end anastomosis (EEA) is placed in the open end of the descending colon and a purse string is placed around its shaft.
- A 29-mm EEA stapling device is introduced gently into the rectal stump.
- The trocar is brought out through the rectal stump. The elected site of the rectal drum penetration depends solely on creating an exit angle suitable to accept the anvil without the need for further maneuvering of the stapling device itself. Any repositioning of the stapler post exodus of the trocar runs the risk of lateral tear and incomplete rectal stump donut. A long packing forceps is used to push the rectal stump around the trocar penetration point to avoid lateral tearing of the rectal stump (**FIG 9**), which could lead to an anastomotic leak.

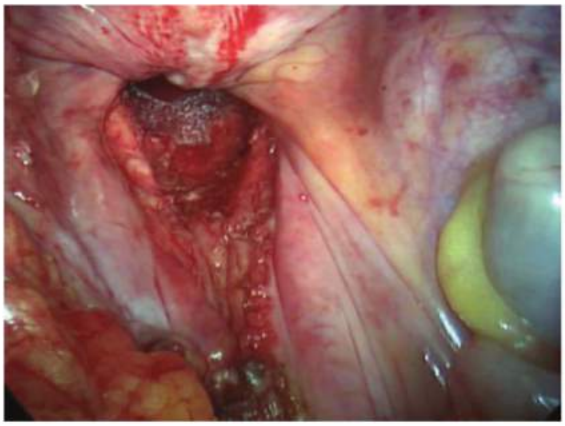

FIG 8 ● After resection of the rectum, the pelvis is empty, with good visualization of the pelvic floor.

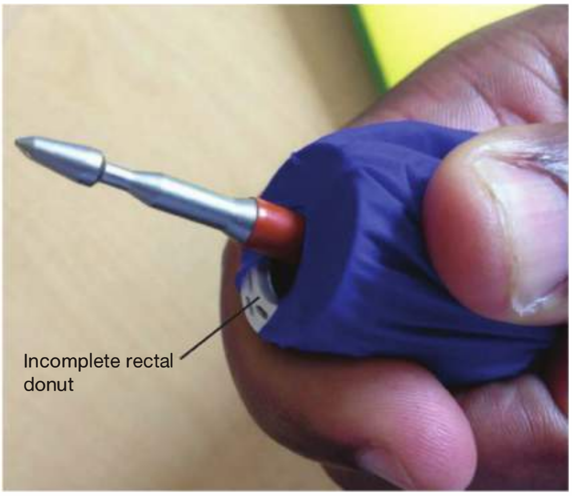

FIG 9 ● Once the trocar is deployed, it is critical to avoid any movement on the EEA stapling device to avoid lateral tearing of the rectal stump, which could lead to an anastomotic leak.

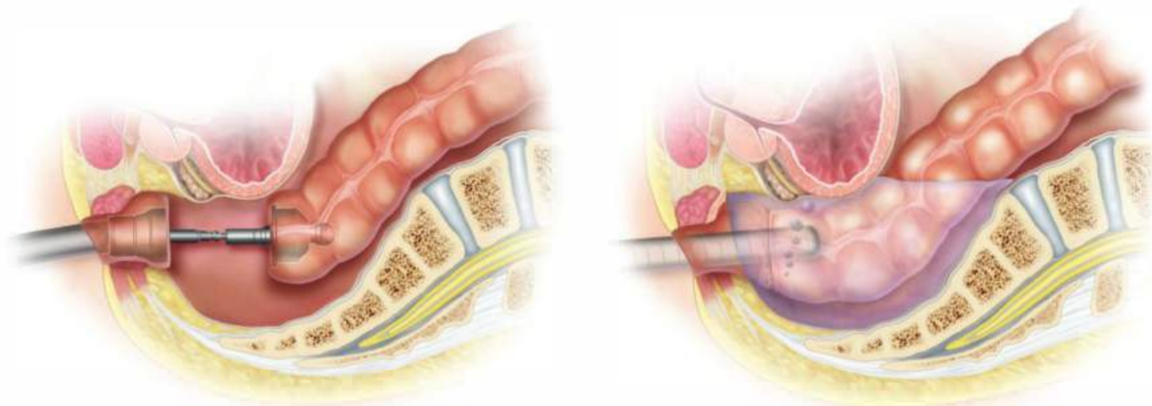
- The anvil and the EEA stapler are then mated and fired, creating a tension-free coloanal anastomosis (FIG 10A). Two complete doughnuts should be obtained; the distal doughnut should be sent to the pathologist for a frozen section evaluation to ensure the distal margin is negative for cancer. A positive margin may necessitate conversion to an abdominoperineal resection (APR). The integrity of the anastomosis is tested by insufflation under water (FIG 10B). Air bubbles would indicate an anastomotic leak, necessitating either a revision of the anastomosis, in addition to a proximal diverting loop ileostomy (depending on the magnitude of the leak).
- The patient is always diverted with a loop ileostomy to protect the anastomosis, and a 19-Fr round drain is placed in the pelvis for no more than 2 to 3 days.



A B

FIG 10 ● Stapled coloanal anastomosis. **A.** An EEA is created with a 29mm EEA stapler. **B.** The completed colorectal anastomosis is tested under water. Air bubbles identified during insufflation of the anastomosis indicate an anastomotic leak.

COLOANAL ANASTOMOSIS: HAND-SEWN TECHNIQUE

Placement of Self-Retaining Anal Retractor

- Eversion of the anal canal with a self-retaining Lone Star anal retractor (FIG 11), or with two Gelpis, can facilitate surgeon visualization.

Injection of Local Anesthetic with Epinephrine

- The dentate line is identified and the submucosal plane is injected circumferentially with a local anesthetic containing epinephrine. This decreases bleeding and loss of visualization. The distal rectum is divided full thickness sharply transendoanally above the dentate line (FIG 11). The distal margin should be sent to the pathologist for a frozen section evaluation to ensure that it is negative for cancer. A positive margin may necessitate conversion to an APR.

Anal Verge Sutures Placed in Four Quadrants

- The 3-0 Vicryl sutures are placed in all four quadrants through the anal mucosa and a small portion of the internal sphincter (outside-in placement). The needles are kept in place and the sutures are tacked down to the Lone Star retractor to keep them secured. These sutures will eventually be placed through the distal colon segment to complete the coloanal anastomosis.

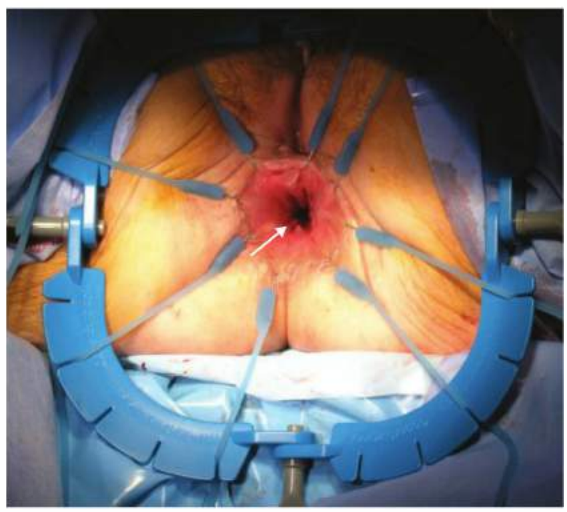


FIG 11 ● A Lone Star retractor is used to evert the anal canal and to expose the dentate line *(arrow)*. The rectum will be transected transendoanally above the dentate line.

Colonic Conduit Delivery

- A purse-string suture is placed in the open end of the descending colon around an insufflated Foley catheter. The descending colon stump is lubricated and is then delivered to the perineum by slowly pulling the Foley catheter

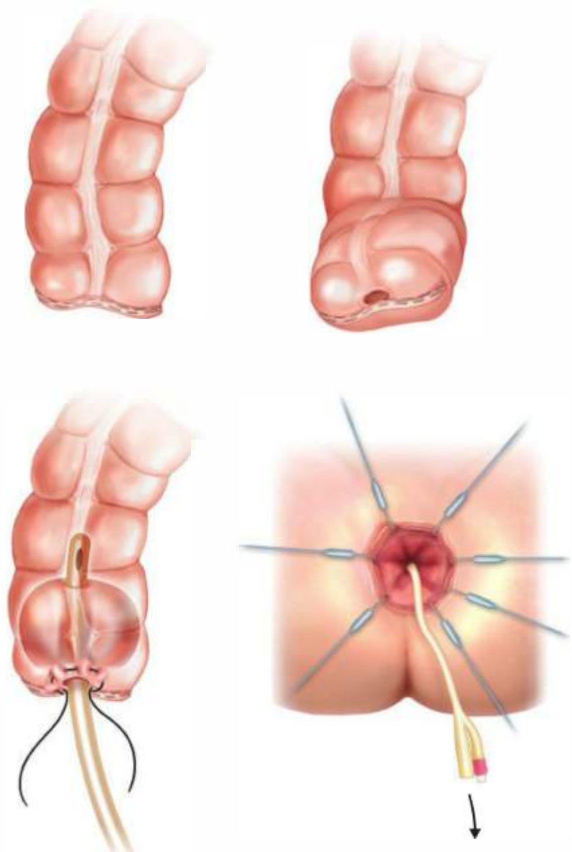

FIG 12 ● A purse-string suture is placed in the open end of the descending colon around an insufflated Foley catheter. The descending colon stump is lubricated and is then delivered to the perineum by slowly pulling the Foley catheter through the open distal rectal stump.

through the open distal rectal stump (FIG 12). The assistant guides the colonic conduit through the pelvis ensuring adequate colon length, lack of tension on the colonic conduit's blood supply, and orientation without twisting.

- The colonic conduit should easily emerge from the anal canal so the surgeon can see the purse string. This ensures there will be a tension-free anastomosis at the level of the dentate line and allows the surgeon to assess the blood supply of the colonic conduit as it passes through the anal canal. Occasionally, it is necessary to clean a portion of mesenteric fat and appendix epiploicae to prevent its inclusion in the coloanal anastomosis and to debulk a large conduit as it passes through the anal canal.

Colon Anchored with Anal Canal Sutures

- The purse string in the distal colon is amputated, the Foley catheter is removed, and the previously placed four-quadrant distal sutures are now placed full thickness through the open distal colon wall (outside-in placement). The colonic conduit is pushed back up into the anal canal when surgical knots are placed to secure the anchoring sutures (FIG 13). The anchored sutures are kept long and secured with a hemostat outside the anal canal to maintain orientation of the colonic conduit and to guide completion of the coloanal anastomosis.

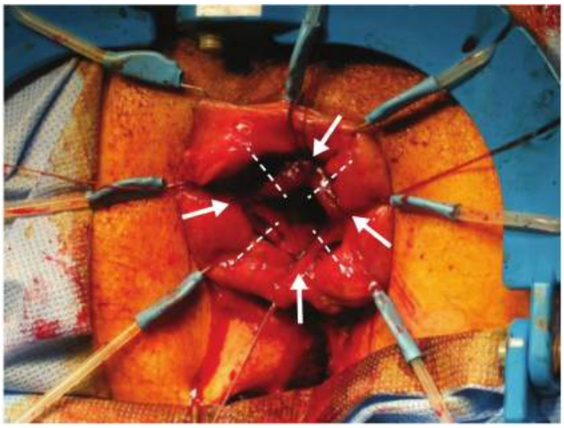

FIG 13 ● The proximal colon is opened and anchored to the anal canal. The previously placed four-quadrant distal sutures have now been placed full thickness through the open distal colon wall *(arrows)*. Placing full-thickness sutures in between these four-quadrant sutures (along the *dotted lines*) will complete the anastomosis.

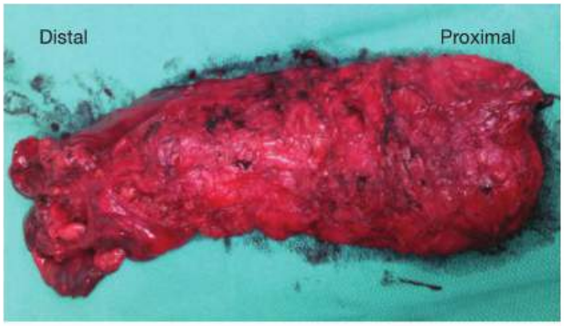
Completion of Circumferential Anastomosis

- An anal retractor such as a Hill Ferguson or standard Fansler retractor can then be placed through the anal canal and distal colon. Placing interrupted 3-0 Vicryl full-thickness sutures through the colon and anus (inside-out placement) completes the anastomosis (FIG 13).

En Bloc Removal of the Rectal Specimen

- If a more distal resection is required or if the surgeon prefers to perform a perineal anorectal resection en bloc with the rectal dissection, the surgeon can begin the perineal dissection in the intersphincteric plane, located between the internal and external anal sphincters. This dissection can begin at the dentate line or within the intersphincteric groove at the anal verge. The intersphincteric dissection proceeds proximally to the level of the puborectalis sling of the levators. An abdominal assistant can guide the perineal surgeon to then dissect into the pelvis and connect the two dissection planes. The en bloc rectal and internal anal sphincter dissection can then be passed off the field. The coloanal anastomosis is fashioned as previously described at the level where the intersphincteric dissection began. In cases where the internal anal sphincter is excised, the distal anastomosis should include anal mucosa and parts of the external anal sphincter.[6] The resected specimen should show an intact mesorectum with no tapering on the distal end (FIG 14).



Loop Ileostomy Creation and Pelvic Drain Placement

- Creation of a loop ileostomy through a previously marked right lower quadrant location diverts stool from the coloanal anastomosis and protects the anastomosis. A 19-Fr round drain is placed behind the anastomosis.

FIG 14 ● The excised rectum has a smooth posterior surface when the mesorectum is excised intact, with no distal tapering of the mesorectum observed.

PEARLS AND PITFALLS

Mobilizing the left colon	■ Dissect the plane a few millimeters medial to the white line of Toldt.
Left ureter identification	■ Complete mobilization of the sigmoid colon mesentery from the retroperitoneum allows identification of the left ureter during proximal IMA ligation.
Mobilization of colonic conduit	■ High transection of the IMA and transection of the IMV lateral to the ligament of Treitz elongate the colonic conduit for a tension-free anastomosis.
Posterior mesorectal dissection	■ Dissecting the areolar plane behind the mesorectum requires the surgeon to lift the rectum anteriorly with a lighted St. Mark's retractor. Dissection posterior to this plane risks entry into the presacral venous plexus, which can lead to exsanguinating hemorrhage.
Anterior rectal dissection	■ Keep dissection behind Denonvilliers' fascia unless an anteriorly located tumor necessitates excision to obtain a negative radial margin.
Colonic conduit delivery for anastomosis	■ Properly orient the colonic conduit so there is no mesenteric twisting or undue tension as it is delivered though the anal canal. Mesenteric fat can be removed from the distal colon to facilitate placement through the canal, but too much dissection can compromise the blood supply of colon and the proximal portion of the anastomosis.
Stapled anastomosis	■ Avoid maneuvering of the circular stapler after deployment of the trocar. A lateral rectal drum tear extending to the stapler rim will result into an incomplete distal donut and an anastomotic leak.

POSTOPERATIVE CARE

- Prophylactic LMWH is initiated the day of the operation.
- Physical therapy for ambulation is involved on postoperative day (POD) 1.
- Early feeding with clear liquids can increase patient comfort and stimulate return of gastrointestinal motility.
- Bladder dysfunction following deep pelvic dissection is common. We routinely keep a Foley catheter in place for 5 days.
- Although patients wait for return of intestinal function, they can be taught the basics of ileostomy care.
- Patients should be advised that drainage from the rectum could occur despite fecal diversion. A single episode of bloody rectal discharge while the patient is ambulating between PODs 5 and 7 is often an indicator of evacuation of a pelvic fluid collection through the stapler line and does not require further imaging unless the patient shows signs of infection. Persistent rectal drainage that is purulent or bloody should prompt workup for a postoperative complication.

OUTCOMES

- Survival from rectal cancer after multimodality treatment is dependent on disease stage. Overall, 5-year survival is approximately 90% for stage I, 74% to 65% for stage II, and 81% to 33% for stage III of disease. Development of distant metastasis occurs in less than 10% in patients with stage I disease but increases up to 28% and 50% in patients with stages II and III rectal cancer, respectively.[7]
- Local pelvic recurrence of rectal cancer is also dependent on tumor and nodal stage. Local recurrence is less than or equal to 5% for patients with stage I rectal cancer but increases to 15% for stage II disease and 22% for stage III disease.[7] If a pelvic recurrence can be treated with a margin-negative surgical resection, 5-year survival can approach 40%. Often, this requires a pelvic exenteration which demands a multispecialty surgical approach.[8]

COMPLICATIONS

- Complications can occur in up to one-third of patients undergoing TME and coloanal anastomosis with 15% of patients experiencing major complications.[9]
- Rectal cancer patients who have received neoadjuvant chemoradiation and who undergo a coloanal anastomosis with a colonic conduit that depends on collateral blood flow, have multiple risk factors for anastomotic leak. Fecal diversion with loop ileostomy after coloanal anastomosis

reduces the clinical consequences of an anastomotic leak.[10,11]

- Most patients have defecatory dysfunction after removal of the rectum. In the native state, the rectum functions as a distensible organ to store stool until the patient initiates evacuation. Proctectomy patients loose this storage capacity and have more frequent bowel movements. They typically complain of a defecation pattern termed "low anterior syndrome," in which the patient senses a frequent defecation urge. Treatment includes fiber supplementation to bulk up the stool, use of Imodium or Lomotil to slow intestinal transit, and enemas to assist with evacuation. Patients with a severe decrease in quality of life may elect to undergo conversion to a permanent end colostomy.

Chapter 28

Low Anterior Rectal Resection: Laparoscopic Technique

Joël Leroy   Didier Mutter   Jacques Marescaux

DEFINITION

- Low anterior resection (LAR) is the full mobilization and resection of the rectum at the level of the levators, leaving behind only a short or no rectal stump.
- LAR for rectal cancer requires a total mesorectal excision (TME) to ensure a radical resection with adequate radial and distal margin. The goal is to achieve an en bloc resection of the cancer with complete dissection of the pararectal lymph nodes contained within the mesorectum.
- Laparoscopic LAR is a minimally invasive approach to TME with significant short-term advantages when compared to open LAR, including less pain, faster recovery, lower morbidity, and shorter hospital stays, without compromising the oncologic safety of the operation.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A full history and physical examination will allow the surgeon to determine if a sphincter-sparing operation is possible, whether a temporary ileostomy is likely, and will also aid in discussions regarding postoperative functional status.
- History elements elicited should include baseline functional status, bowel incontinence, sexual and urinary dysfunction, as well as pain with defecation or tenesmus. Previous history of pelvic radiation and pelvic surgery should also be noted.
- History of incontinence should prompt discussions regarding postoperative quality of life with a low anastomosis.
- History of pain or tenesmus suggests involvement of the anal sphincter or a larger tumor. This will alter the course of treatment and a sphincter-sparing operation may not be possible in this subgroup of patients.
- Physical examination should include a digital rectal exam (DRE), vaginal exam, anoscopy, and a thorough abdominal exam.
- DRE should assess tumor size, degree of fixation to rectal and pelvic wall, mobility, location (anterior/posterior/lateral), distance from the anorectal ring, and anterior extension into vagina/prostate. Anal sphincter involvement can also be determined by DRE in the majority of patients.
- Anterior rectal tumors in female patients require a vaginal exam to rule out extension into the vagina.
- Anoscopy for low rectal tumors may allow for better visualization of the tumor during the physical exam.
- The abdominal exam should evaluate for liver metastasis. A bilateral groin exam should be performed to evaluate for potential inguinal lymphadenopathy.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- A colonoscopy with documentation of all polyps should be performed. Suspicious lesions should be tattooed to facilitate localization during surgery.
- Staging with endorectal ultrasound or rectal magnetic resonance imaging (MRI) should be performed to determine the need for neoadjuvant therapy and to plan operative strategy. A computed tomography (CT) of the chest, abdomen, and pelvis evaluates for potential metastases.
- A preoperative carcinoembryonic antigen level should be obtained.

SURGICAL MANAGEMENT

Preoperative Planning

- Informed consent is obtained preoperatively. The patient has been informed of the potential necessity to perform a diverting ileostomy or end colostomy.
- Potential ostomy sites are marked the evening before the intervention.
- We follow the Society of American Gastrointestinal and Endoscopic Surgeons' (SAGES) bowel preparation guidelines.
- Appropriate intravenous antibiotics are administered within 1 hour of skin incision.

Equipment and Instrumentation

- 10-mm, 0-degree camera (30-degree camera is optional) with high-resolution monitors
- Laparoscopic endoscopic scissors and a blunt tip, 5-mm energy device (10-mm can be useful in obese patients)
- Laparoscopic linear staplers

Positioning and Port Placement

Patient setup

- Patient setup is a major operative step.
- The patient should be adequately secured to the table.
- Adequate padding is essential to prevent nerve and venous compressions.
- The patient is placed in a supine position with a cushion placed underneath the left flank in order to obtain a moderate lateral decubitus, which will retract bowel loops toward the right part of the abdomen.
- A rotation to the right and a caudal head tilt (Trendelenburg position) will help to retract bowel loops by means of gravity.
- The patient's legs will then be spread apart in a semiflexion using adjustable leg supports to allow for a double abdominal and perineal access.
- One should control the perfect positioning of the buttocks at the distal edge of the table to allow for an easy access to the anal and perineal area.
- The arms are padded and tucked.
- An orogastric tube is inserted; it will be removed at the completion of the surgery.
- A Foley catheter is inserted; it will be left in place for 24 hours.

FIG 1 ● Team setup. Surgeon *(1)*. First assistant *(2)*. Second assistant *(3)*. Scrub nurse *(4)*. Anesthesiologist *(5)*.

Team positioning

- This procedure is performed with two assistants and a scrub technician.
- During the abdominal part of the procedure (**FIG 1**), the surgeon stands on the right flank of the patient, his or her first assistant lateral to the patient's right shoulder, and the second assistant in between the patient's legs. The scrub technician is then located to the right of the surgeon lateral to lower limbs.
- During the perineal part of the procedure, the entire team shifts toward the extremity of the table once the perineum has been exposed.
- The monitors are placed in front of the operating team and at eye level to improve ergonomics.

Port placement

- One 12-mm supraumbilical port (port A) is introduced first using a mini-open technique. It will be used to accommodate the camera (**FIG 2**).
- Two other ports, a 5-mm port in the right flank (port B) and a 12-mm port in the right iliac fossa (port C), are used as operating ports (**FIG 2**).
- The fourth port in the left flank at the level of the umbilicus is inserted through the rectus muscle (port D, 5 mm in diameter), where the colostomy will be performed (**FIG 2**).
- The last port introduced in the suprapubic area (port E, 12 mm in diameter) is used for pelvic retraction and for exposure of the sigmoid colon's root (**FIG 2**).
- Port fixation in the wall should be perfect in order to prevent any risk of parietal injury and to prevent increased operative times due to a loss in abdominal pressure. One should not hesitate to fix ports to the skin.
- Additional ports may be used in case of difficulty in exposure. In this case, a port will be positioned in the right hypochondrium (port F) to retract the ileocecal area. This is particularly useful in obese patients (**FIG 2**).

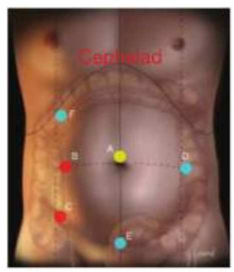

FIG 2 ● Port placement. Optical port *(A)*. Working ports *(B,C)*. Retracting ports *(D,E)*. Additional retracting port *(F)*.

LAPAROSCOPIC LOW ANTERIOR RESECTION

Exploration and Exposure

- The intervention is begun by an exploration of the abdominal cavity to locate the tumor and evaluate for possible metastases. It also allows to expose the pelvis and to evaluate the length and quality of the sigmoid loop, which will allow determining the type of mobilization of the left colon and of the splenic flexure.
- The tumor's identification may be necessary and especially so for tumors located proximally. Combined endoscopy may be required in cases where an effective preoperative marking could not be performed on the day before the intervention.
- Exposure is improved by placing the patient in a Trendelenburg position with the table tilted to the right.
- In women, exposure of the posterior pelvis and of the rectovaginal (Douglas') pouch can be obtained by direct or indirect suspension of the uterus by means of the T'Lift™ (VECTEC, France) tissue retraction device (**FIG 3A,B**) or suprapubic transparietal sutures (**FIG 4A,B**).
- Visceral obesity (in male patients) is more incapacitating than subcutaneous obesity (in female patients). The use of retractors is very helpful.

Primary Vascular Oncologic Approach to the Sigmoid Colon

- As for any oncologic surgical procedure, a primary vascular approach is the rule.

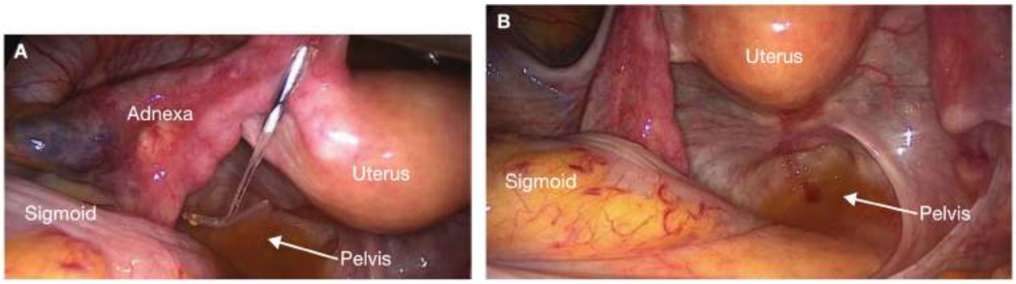

FIG 3 ● T'Lift™ tissue retraction system. **A.** T'Lift™ tissue retraction system passed through the round ligament. **B.** Pelvic exposure in women after bilateral uterine suspension with T'Lift™ tissue retraction system.

- In rectosigmoid cancer, one should approach the inferior mesenteric vessels at their origin in order to perform an "en bloc" removal of all lymph nodes associated with the rectosigmoid junction (D3 resection). It does not preclude the potential preservation of the proximal inferior mesenteric artery (IMA) and of the left colic artery (LCA).
- We always start with a primary approach to the IMA. The inferior mesenteric vein (IMV) is then approached in order to prevent any venous overload related to the late ligation of the IMA.
- Once the root of the sigmoid mesocolon has been exposed, the left retroperitoneal space is opened by incising the posterior peritoneum from the anterior aspect of the promontory up to the left border of the duodenojejunal junction (ligament of Treitz) (**FIG 5A**).
- Once the retroperitoneum has been opened, dissection is initiated opposite the promontory on the posterior aspect of the inferior mesenteric vascular sheath (i.e., the superior rectal artery at this level). This step is facilitated by the anterior traction on the mesocolon, which induces the pneumodissection of the retrovascular space, thanks to intraabdominal carbon dioxide pressure.
- Dissection is carried on in contact with the vascular sheath cranially until the origin of the IMA on the aorta.
- The dissection is continued from caudad to cephalad in contact with the artery, which is skeletonized over approximately 2 cm in order to achieve ligation and division 1 or 2 cm away from the aorta (**FIG 5B**).

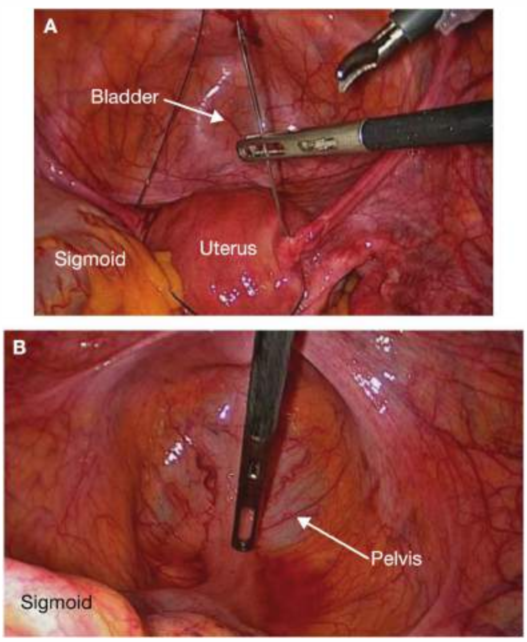

FIG 4 ● **A.** Transparietal suprapubic sutures for uterine suspension. **B.** Exposure of the pelvis in women after transparietal suprapubic suture uterine suspension.

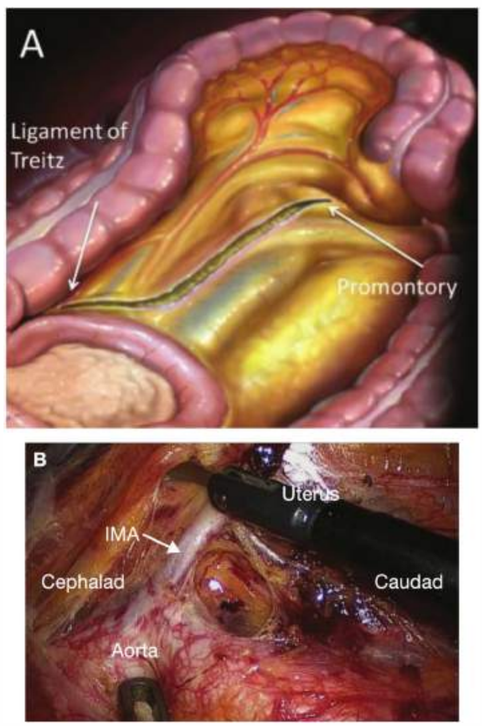

FIG 5 ● Dissection of the IMA. **A.** Opening of the left retroperitoneal space by incising the posterior peritoneum from the anterior aspect of the promontory to the ligament of Treitz. **B.** The IMA has been dissected 1 to 2 cm from the aorta.

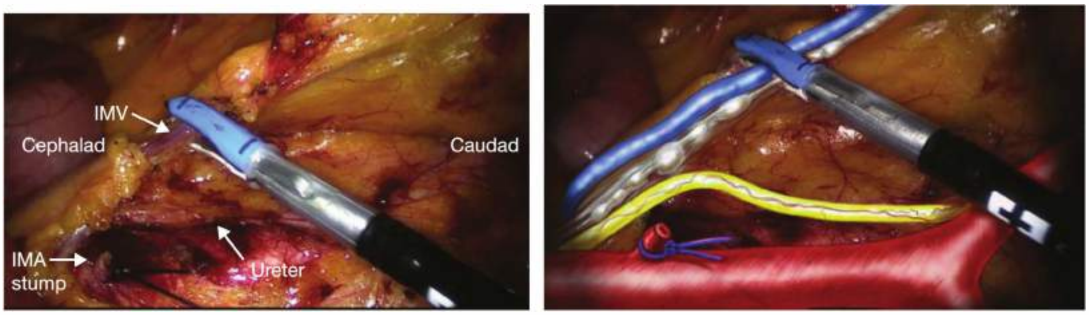

FIG 6 ● IMV transection at the level of the ligament of Treitz. The IMA was previously transected off the aorta. The retroperitoneal structures are exposed.

- This technique allows preserving sympathetic nerve plexuses, which course along the aorta on its right anterior aspect.
- Division of the IMA is performed with the LigaSure™ vessel-sealing device using a ligation with a loop on the IMA stump.
- Once the IMA has been divided, the assistant standing between the patient's legs will grasp the artery using an atraumatic forceps introduced into the suprapubic port (port D) and apply anterior traction to ideally expose dissection planes in contact with the left posterior and lateral aspects of the artery.
- It helps to preserve the nerve plexus in contact with the artery, and notably the left sympathetic trunk of the neurovegetative system that will be progressively freed and parietalized.
- The next operative step will be to identify the IMV lateral to Treitz's flexure underneath the inferior edge of the pancreas.
- The IMV is then transected at the level of the ligament of Treitz with the LigaSure™ vessel-sealing device or in between clips (**FIG 6**).

Mobilization of the Left and Sigmoid Colon

- Many authors prefer to start with the mobilization of the splenic flexure using a medial posterior transverse transmesocolic approach. We prefer to mobilize the splenic flexure at the end of the operation in order to prevent excessive mobilization, which can be a cause of morbidity.
- Our main objective is to perform a medial to lateral mobilization of the mesocolon.
- A medial to lateral mobilization of the sigmoid colon allows for traction on the upper rectum with a perfect exposure of its anterior, posterior, and lateral aspects.
- Mobilization of the mesocolon is performed using a medial to lateral approach (**FIG 7A,B**) by opening the plane between Toldt's fascia anteriorly and Gerota's fascia posteriorly.
- The dissection is carried laterally until the posterior aspect of the descending colon is reached laterally.
- Caudally, the dissection is carried toward the pelvic inlet. One should be cautious when in contact with the aorta as well as with the left iliac vessels where nerve rami of the superior hypogastric sympathetic plexus courses.
- The left ureter is identified during the dissection. It is located between the aorta and the genital vessels, well protected by Gerota's fascia.
- Mobilization of the sigmoid colon is completed with a division of its lateral attachments to the abdominal wall (**FIG 8**).

Dissection of the Rectum According to the Total Mesorectal Excision (Heald's) Technique

- The principle of TME relies on the study of the embryologic development of the pelvis and of organs located within it. A surgical intervention cannot be envisaged without a detailed knowledge of pelvic and fascial

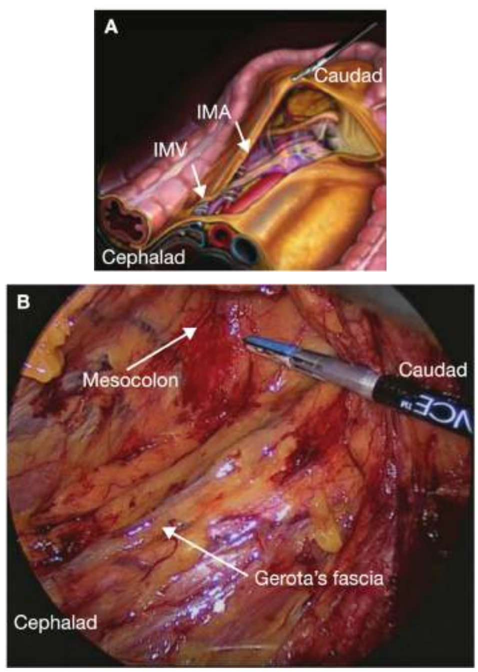

FIG 7 ● **A,B.** Medial to lateral mobilization of the mesocolon. The mesocolon is separated from the retroperitoneum (Gerota's fascia) using a medial to lateral approach. The left ureter and gonadal vessels are visualized in the retroperitoneum. *IMA*, inferior mesenteric artery; *IMV*, inferior mesenteric vein.

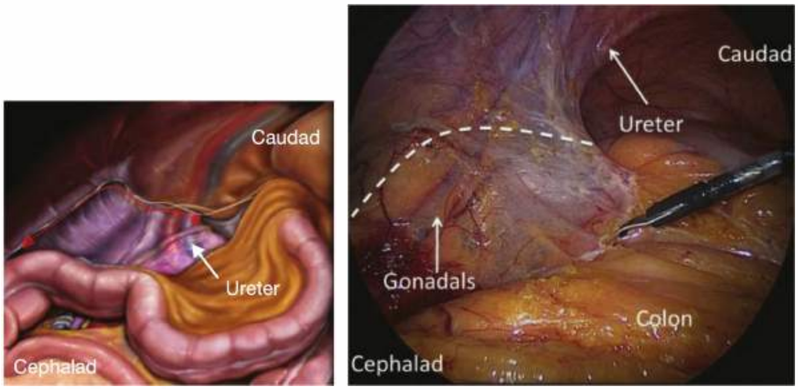

FIG 8 ● Lateral mobilization of the sigmoid loop by dividing the lateral attachments to the abdominal wall *(dotted line)*. The left ureter and gonadal vessels are visualized in the retroperitoneum.

anatomy (**FIG 9A**) that is essential to obtaining appropriate surgical specimens.

- Heald's principles rely on the dissection of the space located between the fascia propria of the rectum and the presacral fascia posteriorly, the lateral pelvic fascia laterally, and Denonvilliers' fascia anteriorly.

Posterior Dissection of the Rectum

- Once the sigmoid colon has been mobilized, a cranial and anterior traction is exerted on the rectum in order to expose the posterior aspect of the upper rectum.
- The presacral space (**FIG 9B,C**) is opened under the effect of traction and of pneumoperitoneum pressure, along with an atraumatic anterior retraction of the posterior rectal wall—a small swab at the tip of an atraumatic grasper is used. The tracts, which cross the space, are divided by means of a 2-mm electrode located at the tip of a LigaSure Advance™ vessel-sealing device.
- Dissection should be continued toward the pelvic floor. When progressing downward, dissection should continue along the presacral fascia until it fuses with the fascia propria (Waldeyer's fascia).
- During this dissection, left and right branches of the inferior hypogastric plexuses can be observed. The lateral pelvic fascia protects them along the pelvic side walls.

Lateral Dissections of the Rectum

- Cranial and medial retraction is maintained on the rectum in order to open the lateral pelvic space. This step is begun on the right side.

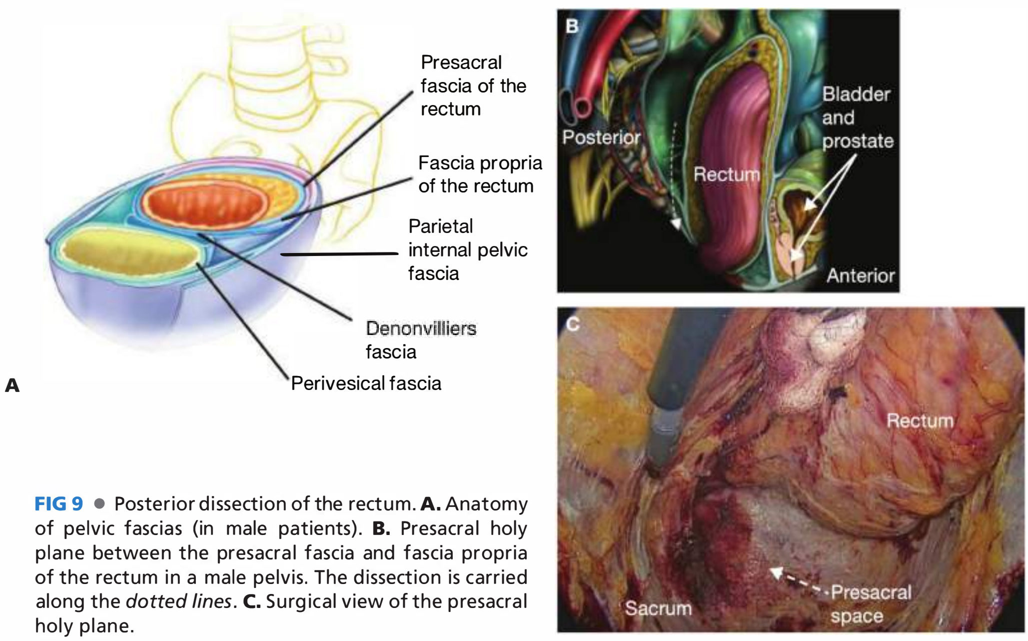

FIG 9 ● Posterior dissection of the rectum. **A.** Anatomy of pelvic fascias (in male patients). **B.** Presacral holy plane between the presacral fascia and fascia propria of the rectum in a male pelvis. The dissection is carried along the *dotted lines*. **C.** Surgical view of the presacral holy plane.

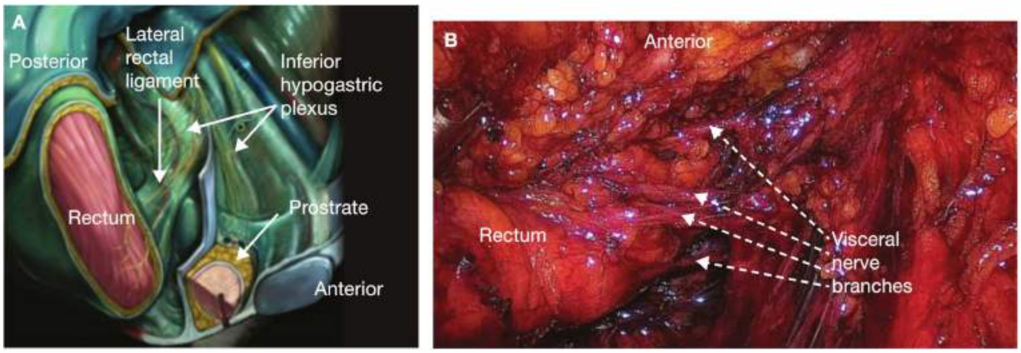

FIG 10 ● Lateral dissection of the rectum. **A.** The rectal branches of the inferior hypogastric plexus traverse along the so-called lateral rectal ligament. **B.** The lateral rectal ligament on the right side of the distal rectum has been skeletonized. The rectal branches of the lateral inferior hypogastric plexus can be seen and will be selectively transected *(dotted lines)* with the LigaSure™ device.

- The peritoneum is incised until seminal vesicles are reached. Under the effect of pneumoperitoneum pressure and of medial retraction, the rectal branches of the inferior hypogastric plexus traverse along the so-called lateral rectal ligament (**FIG 10A**).
- Parietalization of the inferior hypogastric plexus and especially of the sacral branches (3rd and 5th sacral nerves, parasympathetic nerves responsible for male erections) is carried on. Care is taken to avoid violating the parietal endopelvic fascia.
- Between three and five nerve branches can be observed crossing the space between the fascia and the rectum (**FIG 10B**). These branches are divided after skeletonization.
- The least traumatic dissection seems to be the one performed by means of the LigaSure Advance™ device with a 2-mm monopolar electrode, an energy level of 15 Watts being considered sufficient.
- The prostatic branches and the plexus trunk are preserved in order to avoid urinary and ejaculatory autonomic dysfunction.

Anterior Dissection of the Rectum

- In order to open and dissect the space between the anterior aspect of the rectum and Denonvilliers' aponeurosis, minimal cranial and posterior traction should be maintained on the rectum; Denonvilliers' aponeurosis should be retracted anteriorly.
- Retraction is usually easy to perform in female patients. In male patients, especially obese ones, this step is more difficult. We recommend the use of specific retractors developed by KARL STORZ (Endo-Retractors™) (**FIG 11A,B**) in order to reproduce the technique used in open surgery with St. Mark's retractor. It is the use of the three-directional retraction described by Heald's

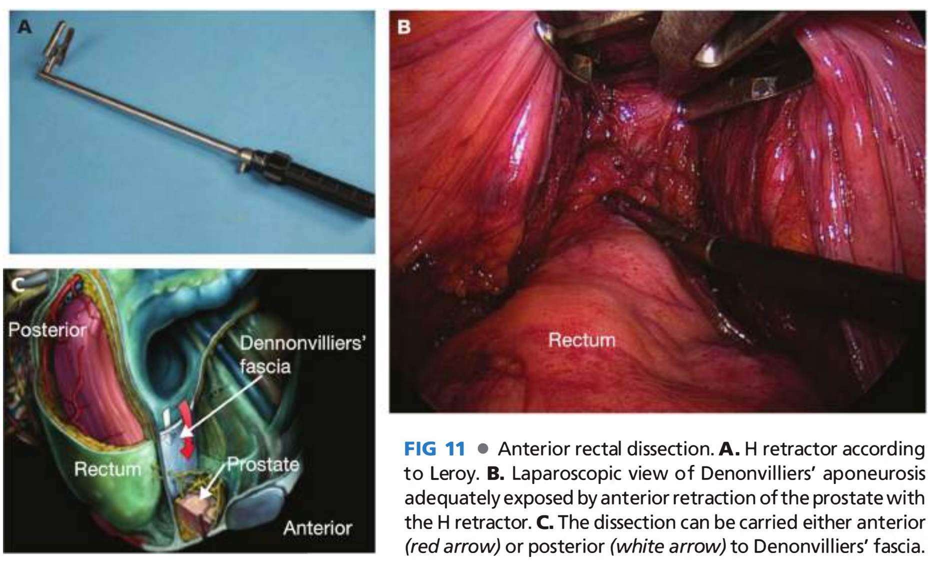

FIG 11 ● Anterior rectal dissection. **A.** H retractor according to Leroy. **B.** Laparoscopic view of Denonvilliers' aponeurosis adequately exposed by anterior retraction of the prostate with the H retractor. **C.** The dissection can be carried either anterior *(red arrow)* or posterior *(white arrow)* to Denonvilliers' fascia.

(3-D retraction), which ensures a safe dissection of the anterior aspect of the rectum.

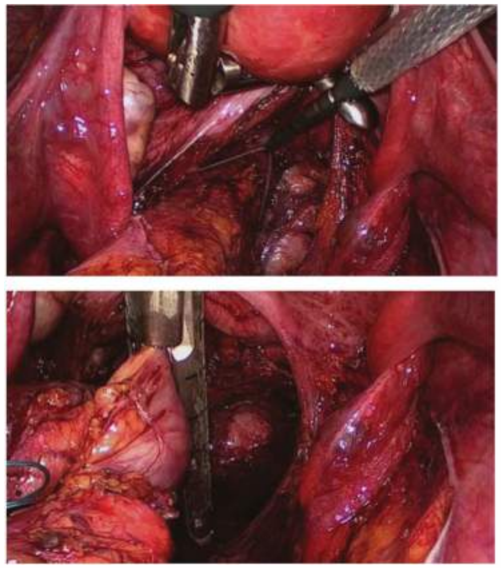
- The plane of anterior dissection can be carried either anterior or posterior to Denonvilliers' aponeurosis (FIG 11C). In advanced rectal cancer, it may be necessary to stay anterior to Denonvilliers' aponeurosis; in this case, the risk of genital nerve injury (impotence) is much higher.
- The dissection is then continued toward the pelvic floor.
- Posteriorly, it is recommended to free the last attachments of the lower rectum by dividing the sacrorectal ligament.
- Once the perirectal spaces have been dissected toward the pelvic floor, the rectum is free, surrounded by its meso, and the meso is entrapped within its fascia.
- This dissection technique is the recommended standard technique for oncologic surgery for cancer of the middle and lower rectum and is also becoming increasingly popular for the upper rectum.

Lower Rectum Division

- Division of the lower rectum must be performed at least 2 cm away from the inferior border of the tumor. For lesions of the middle third and of the upper rectum, respecting this distance is not difficult. For the upper rectum, TME resection is becoming increasingly more favorable, although theoretically, a partial resection of the mesorectum should be sufficient—in that case, a cylindrical division as opposed to a conical division of the meso and of the rectum must be located at least 5 cm away from the tumor.
- The distal end of the rectum is always excluded. To do so, a ligature is performed under the freed mesorectum by means of an extracorporeal ligature (FIG 12A). The rectal stump is then cleansed by means of a Betadine solution according to Balli's technique.
- Division of the rectum is performed, distal to the ligature, with a linear stapler (FIG 12B; Endo GIA™ with Tri-Staple™ technology [Covidien], purple cartridge, 30- or 45-mm long; more rarely, 60-mm long) introduced through the right lower quadrant port. The ligature prevents the spread of the rectal stump and allows applying upward traction on the rectum for a better positioning of the stapler.
- Once the division has been performed, an intact suture line should be visualized, and a patency test may also be performed by injection of a colored solution (Betadine) into the rectal stump.

Mobilization of the Left Colon and Division of the Sigmoid Colon

- The proximal division is performed either intracorporeally or extracorporeally.
- Extracorporeal division is performed after an atraumatic exteriorization of the rectum through a sufficiently large incision protected by a plastic sheath in order to prevent any risk of contamination to the abdominal wall.
- We prefer an intracorporeal transection, which allows reducing the size of the suprapubic abdominal incision.



A

B

FIG 12 ● Distal rectal transection. **A.** Ligation of the distal rectum prior to division. **B.** Division of the rectum with a linear Endo GIA™ stapler introduced through the right lower quadrant port site.

- Division of the sigmoid mesocolon is performed at this moment of the intervention as this will allow appreciating the vascularization of the proximal colonic segment later on after the left colon has been mobilized. The division with the LigaSure™ vessel-sealing device, removing the vascular pedicle and lymph nodes en bloc.
- The mesocolon is divided until contact is made with the proximal colonic segment chosen for the anastomosis.
- Mobilization of the left colon is continued toward the splenic flexure. It is important to have a good knowledge of the different mobilization techniques by means of lateral and posterior division of the splenic flexure attachments.
- In case of limited mobilization of the splenic flexure, we prefer to use a lateral approach by dividing the parietocolic gutter from caudad to cephalad, and then the phrenicocolic ligament and the colo-omental ligament (FIG 13A), thereby opening the lesser sac. Should it be necessary, the transverse mesocolon can be freed from the anterior aspect of the pancreas from lateral to medial.
- If an extensive mobilization of the splenic flexure is required, we prefer using a medial posterior transverse mesocolic approach. We open the transmesocolic axis of the IMV of the lesser sac. Once the lesser sac has been opened, the root of the transverse mesocolon should be divided anteriorly to the pancreas until the tail is reached. Lateral attachments will be freed as described in the previous paragraph (FIG 13B).
- Once the left colon has been mobilized, the sigmoid colon can be divided at the level previously chosen during the dissection of the mesocolon. If the proximal

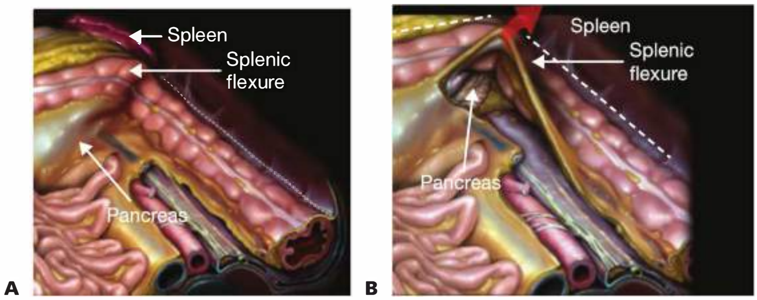


FIG 13 ● Splenic flexure mobilization. **A.** Limited mobilization: a lateral approach, by dividing the parietocolic gutter from caudad to cephalad and then the phrenicocolic ligament and the colo-omental ligament *(dotted lines)*, is used. **B.** Extensive mobilization: We prefer using a medial posterior transverse mesocolic approach, lifting the mesocolon of the tail of the pancreas from medial to lateral *(red arrow)*. The lateral colonic attachments and the phrenocolic and gastrocolic ligaments are then divided *(dotted lines)*.

colon appears to be well-vascularized, division is possible; otherwise, a more proximal division could be necessary. The division is performed intracorporeally with an endoscopic linear stapler (Endo GIA™, Covidien) (**FIG 14**).

Specimen Extraction and Anastomosis

- Specimen extraction is performed after the introduction of a large plastic bag (EndoCatch™ II, Covidien) through a Pfannenstiel's transverse suprapubic incision protected by a plastic sheath (Alexis® wound retractor, Vi-Drape® or SurgiSleeve™ wound protector) (**FIG 15**).
- The proximal colonic segment is then exteriorized through the suprapubic incision to evaluate its vascularization prior to the introduction of the anvil of a conventional circular stapler (DST PC EEA™), 28 mm in diameter. The colon is then reintroduced into the abdominal cavity with the anvil in place.
- Proper contact between the anvil and the rectal stump without tension should be feasible. An intracorporeal end-to-end colorectal mechanical circular anastomosis is then performed (**FIG 16A,B**).
- If the colonic segment does not reach the rectal stump without tension, it may be necessary to complete the colon's mobilization more proximally.

FIG 14 ● Intracorporeal proximal transection. The descending colon is transected with endoscopic linear stapler.

FIG 15 ● Double parietal protection for specimen extraction using a large EndoCatch™ II, introduced through a suprapubic incision protected by a plastic sleeve wound protector.

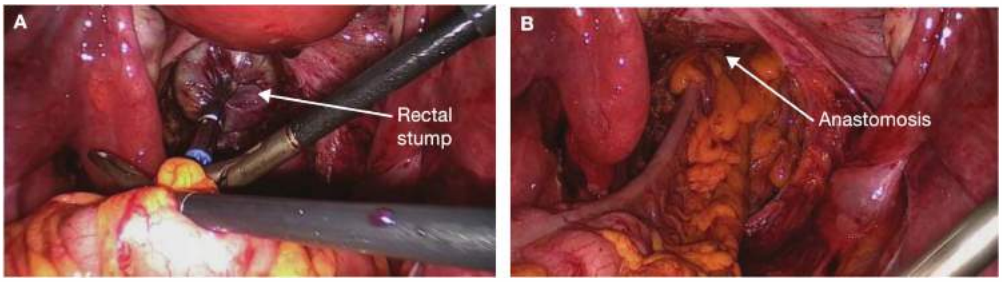

FIG 16 ● End-to-end distal colorectal anastomosis. **A.** Laparoscopic view of the connection between the anvil (placed in the colonic segment) and the shaft of the circular mechanical stapler (placed through the rectal stump). **B.** Pelvic view of a tension-free, end-to-end colorectal anastomosis.

FIG 17 ● Endoscopic inspection of an intact colorectal anastomosis.

- Two intact full-thickness doughnuts should also be obtained. The integrity of the anastomosis will be evaluated by means of an air test if the anastomosis is sufficiently cranial or by means of an endoscopic examination (FIG 17).
- A protective diverting loop ileostomy is recommended for very caudal anastomoses, especially after irradiation and in cases where risk factors such as morbid obesity, smoking, arteriosclerosis, undernourishment, and old age are present. This ileostomy will be reversed after 2 months.
- The intervention is completed with a final control of the abdominal cavity.
- A 14-Fr Blake drain is inserted into the pelvis through the port D's orifice.

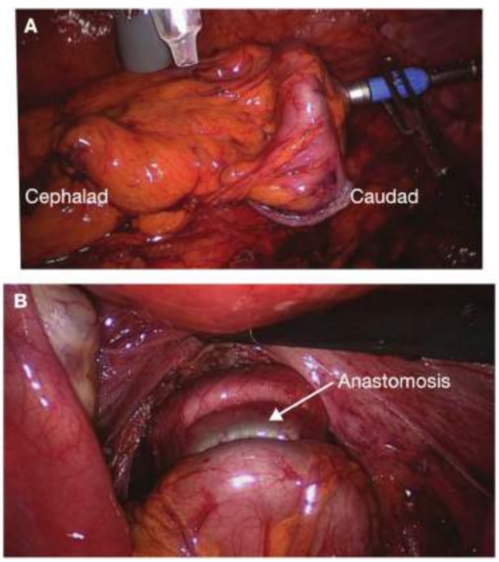

FIG 18 ● Side-to-end colorectal anastomosis. **A.** The anvil (exiting through the antimesenteric border of the colonic segment) has been mated with the end-to-end anastomosis (EEA) stapler shaft (placed through the rectal stump). **B.** Intracorporeal side-to-end anastomosis seen while firing the EEA stapler.

Alternative Anastomotic Techniques

- Side-to-end colorectal anastomosis (FIG 18A,B): It is a first-choice option for very distal anastomoses. It is simpler than J-pouch reservoir anastomoses and provides similar functional results.
- J-pouch colonic reservoir anastomosis (FIG 19A): potentially used in very distal anastomoses (<4 cm from the anal margin). The 5-cm tall reservoir is fashioned using the distal colon retracted upon itself and anastomosed via the antimesenteric border to the rectal stump/anus. The distal anastomosis may be performed by means of a circular stapler or hand sewn using a transanal route.
- The hand-sewn anastomosis is used for very distal tumors and may avoid the need for an abdominoperineal resection (APR) as long as it is possible to obtain a negative distal and radial margin of resection.
- The hand-sewn coloanal anastomosis is performed with interrupted 3-0 full-thickness, reabsorbable sutures placed through the colonic segment and through the internal anal sphincter with the assistance of a Lone Star retractor for exposure (FIG 19B).

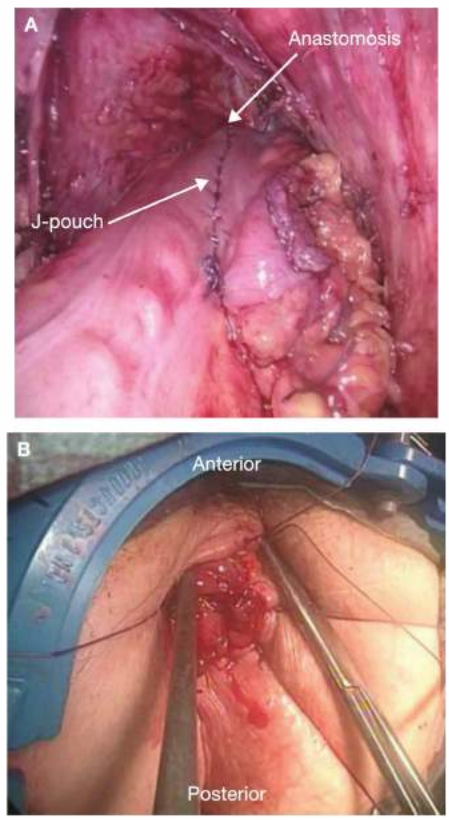

FIG 19 ● J-shaped colonic reservoir anastomosis. **A.** Stapled anastomosis. **B.** Hand-sewn coloanal anastomosis with a Lone Star retractor place to aid with the exposure.

PEARLS AND PITFALLS

Anatomy and embryology	■ Detailed knowledge of the pelvic fascial structures and tissue planes is essential.
Preoperative	■ Adequate staging with colonoscopy and appropriate imaging is important in determining the feasibility of an LAR.
Setup	■ Precise operating room (OR), patient, and team setup is critical to success.

Technique	■ Medial to lateral dissection of the mesocolon
	■ High IMA transection
	■ Pelvic dissection:
	  ■ Posterior first (along the presacral "holy plane")
	  ■ Lateral dissection/transection of the lateral rectal ligaments: Avoid injury to autonomic trunks and genital nerve branches that would lead to autonomic dysfunction postoperatively.
	■ Perform a circumferential dissection. Avoid "conization" of the specimen.
	■ The specimen should have an intact mesorectum.
	■ Anastomosis: Critical that they have excellent blood supply and that they are tension-free.
	■ There is no need to routinely perform J-pouch anastomosis.
	■ For very distal tumors, a hand-sewn coloanal anastomosis may avoid an APR as long as negative distal and radial margins can be obtained.

Postoperative care	■ Driven by a clinical pathway

POSTOPERATIVE CARE

- Postoperative care is driven by clinical pathways that include the following:
  - Pain control: Intravenous acetaminophen for 24 hours (start in the OR) followed by intravenous ketorolac for 72 hours (if creatinine is normal). The transversus abdominis plane (TAP) nerve block greatly reduces the need for narcotics.
  - Deep vein thrombosis (DVT) prophylaxis with enoxiheparin, starting within 24 hours of surgery
  - No additional antibiotics, judicious use of intravenous fluids
  - No nasogastric tube. Remove Foley catheter on postoperative day 1. Remove pelvic drains on postoperative day 2 or 3.
  - Early ambulation, diet ad lib, aggressive pulmonary toilet
  - Targeted discharge: postoperative day 3 or 4

OUTCOMES

- Laparoscopic LAR leads to improvements in short-term outcomes, including less pain, faster recovery, shorter hospital stay, and lower incidence of cardiac/pulmonary complications when compared to open surgery.
- For cancer resection, laparoscopic LAR oncologic outcomes are at least comparable to those of open surgery. TME with an intact mesorectum is critical to minimize locoregional treatment failures in distal rectal cancer.

COMPLICATIONS

- Wound infections and hernias
- Anastomotic leak: It is imperative that the anastomosis is tension-free and has excellent blood supply to prevent this complication.
- Urinary/sexual dysfunction: It is important to preserve autonomic nerves intact.
- Ureteral injury: critical to identify the left ureter prior to IMA transection
- DVT: lower risk with use of DVT prophylaxis

Chapter **29**

Low Anterior Resection: Hand-Assisted Laparoscopic Surgery Technique

Matthew G. Mutch

DEFINITION

- The hand-assisted laparoscopic surgery (HALS) technique uses a hand-assist device that allows the surgeon to insert his or her hand into the peritoneal cavity while maintaining pneumoperitoneum. The location of the hand port is variable and is placed at the expected site of specimen extraction.
- HALS maintains all the short-term advantages of conventional surgery over open surgery.
- By reintroducing tactile feedback into the field, HALS results in higher usage rates, lower conversion rates, and shorter operative times, when compared to conventional laparoscopic surgery.

DIFFERENTIAL DIAGNOSIS

- The main indication for a HALS low anterior resection is rectal cancer. Patients with diverticulitis with inflammation extending into the mesorectum may also require a low anterior resection.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history and physical examination are necessary prior to initiation of therapy for patients with rectal cancer.
- It is important to identify the distance of the tumor from the anal verge. Digital rectal exam and rigid proctoscopy are used for this purpose and to determine whether the tumor is mobile, tethered, fixed, or involving the sphincter complex.
- Prior abdominal surgery is not a contraindication to HALS approach. If the patient has had prior surgery, an incision can be made at the site of the hand port and if there are no or minimal adhesion, the hand port can be inserted. If the adhesions are prohibitive of the laparoscopic approach, the hand port incision can be extended into a full laparotomy incision.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- All patients with rectal cancer should have a complete colonoscopy prior to surgery. If the patient has an endoscopically obstructing lesion, a computed tomography (CT) colonography and contrast enema study are acceptable alternatives.
- Preoperative staging of the tumor is paramount so the appropriate use of neoadjuvant therapy can be prescribed. This can be accomplished with either transrectal ultrasound (TRUS) or a rectal protocol magnetic resonance imaging (MRI). Both studies have equivalent accuracy for determining the T and N stages, which are 80% and 60%, respectively. The TRUS is operator dependent and is limited to examining only those nodes adjacent to the tumor. MRI has the advantage of assessing the tumor encroachment of the mesorectal fascia.
- Based on the preoperative T and N staging, the need for neoadjuvant radiation or chemoradiation therapy is determined. Typically, T3, T4, or N+ tumors receive neoadjuvant chemoradiation therapy. Surgical resection then occurs 8 weeks after completion of neoadjuvant therapy.

SURGICAL MANAGEMENT

Preoperative Planning

- Prior to taking the patient to the operating room, they should be marked for a possible diverting ileostomy. The patient needs to be assessed in the supine, sitting, and standing positions. The stoma should rest on the apex of skin fold and adequate distance from bony prominences, skin creases, and the waistline of their pants. The stoma should be brought through the rectus muscle to minimize the risk of developing a parastomal hernia.
- The use of ureteral stents is left to the discretion of the surgeon.

Positioning

- The use of a mechanical bed that is able to place the patient in the extremes of position is necessary.
- There are many methods by which a patient can be secured to the bed. A beanbag, a nonslip pad, shoulder braces, or foam pads can be used for this purpose.
- The patient should be placed in a modified lithotomy position with Allen or Yellofin stirrups (**FIG 1**). This allows access between the legs to assist with mobilization of the left colon and to the perineum for the anastomosis. The thighs

FIG 1 ● Patient positioning. The patient is placed on a lithotomy position with the hips slightly flexed and the legs in Yellofin stirrups. The thighs are placed parallel to the ground to avoid interference with the surgeon's arms and instruments. The patient is secured to the table with tape applied over a towel across the chest. The arms are tucked to the sides. All pressure points are padded to avoid neurovascular injuries.

are placed parallel to the ground to avoid conflict with the surgeon's elbows.

- Both arms are tucked to the patient's side with the thumbs facing up. This allows the surgeon, assistant, and camera driver plenty of room to maneuver during the case.
- A monitor should be placed off the patient's left shoulder during the mobilization of the left colon and splenic flexure. During the pelvic dissection, a monitor should be placed off the patient's left foot for the surgeon and another should be placed off the patient's right foot for the assistant.

PORT PLACEMENT AND OPERATIVE TEAM SETUP

- There are several options for the position of the hand port:
    - The hand port can be placed through either a Pfannenstiel or a midline incision. The suprapubic position allows for direct visualization into the pelvis. The hand port can then be used to facilitate the rectal dissection, for division of the distal rectum, for the performance of the anastomosis, and to address any pelvic complications such as bleeding or anastomotic failure.
    - The periumbilical position allows the surgeon to put his or her nondominant hand through the hand port.
    - A left lower quadrant (LLQ) position uses a muscle-splitting incision and allows for the right hand to be placed into the abdomen to facilitate the lateral and splenic flexure mobilizations of the left colon.
- For the purposes of this chapter, the suprapubic hand port position is discussed (**FIG 2**).
- The 5-mm or 12-mm camera port is placed in the supraumbilical position. The camera needs to be above the umbilicus, as the wound protector portion of the hand port extends several centimeters beyond the edges of the incision.
- The primary laparoscopic working port (12-mm port) is placed in the right lower quadrant (RLQ), at an equal distance between the hand port and the camera port and lateral to the rectus muscle.
- A 5-mm working port for the first assistant is placed in the LLQ. This will allow the assistant to help with the lateral and splenic flexure mobilization and the pelvic dissection. The lower the port is placed, the less time the assistant works in a reverse motion to the camera during the lateral and splenic flexure mobilization.
- The surgeon stands by the patient's right side with his or her right hand placed in the hand port. The camera operator stands to the left side of the surgeon. The assistant stands by the patient's left side (**FIG 3**).

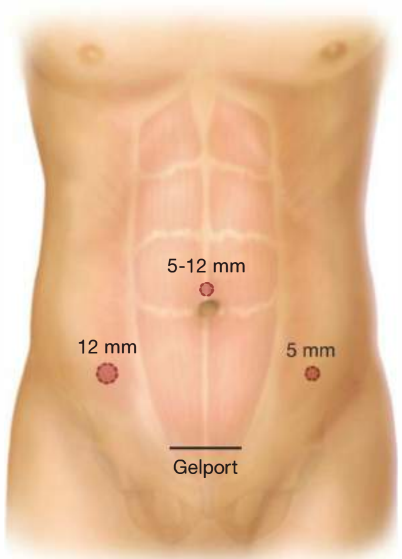

FIG 2 ● Port placement. The GelPort is placed through a 5- to 6-cm Pfannenstiel incision. A 5- or 12-mm supraumbilical port is used for the camera. Two working ports, a 12-mm RLQ and a 5-mm LLQ ports, are inserted.

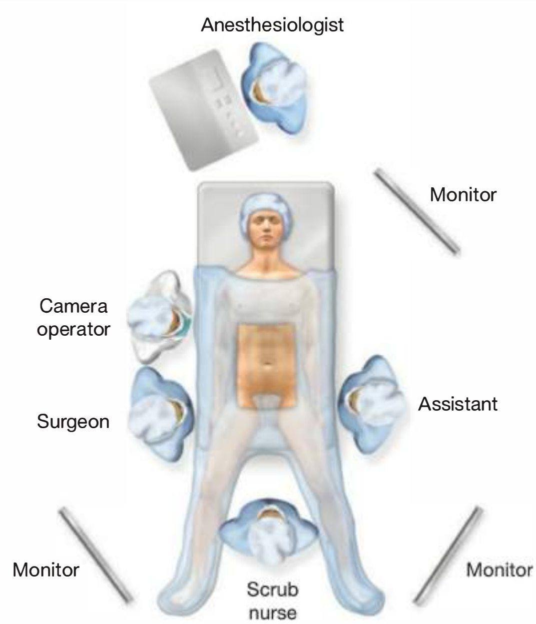

FIG 3 ● Operating team setup. The surgeon stands by the patient's right side with his or her right hand placed in the hand port. The camera operator stands to the left side of the surgeon. The assistant stands by the patient's left side. The scrub nurse stands between the patient's legs. A monitor should be placed off the patient's left shoulder during the mobilization of the left colon and splenic flexure. During the pelvic dissection, a monitor should be placed off the patient's left foot for the surgeon and another should be placed off the patient's right foot for the assistant.

TRANSECTION OF THE INFERIOR MESENTERIC ARTERY

- The patient is placed in a steep Trendelenburg position and in airplane position with the left side up to use gravity to place the small bowel in the right upper quadrant (RUQ) and the omentum in the upper abdomen to expose the transverse colon and splenic flexure. This helps to expose the inferior mesenteric artery (IMA) at its origin off the aorta and the inferior mesenteric vein (IMV) at the level of the ligament of Treitz.
- The surgeon's right hand is placed through the hand port and an energy source is placed through the RLQ working port.
- The retroperitoneum is accessed at the level of the sacral promontory. The superior rectal artery is grasped and elevated (**FIG 4**). A wide incision is made in the peritoneum dorsal to this artery; the wider the incision, the more the artery can be more elevated to obtain better exposure. Because of the curve of the pelvis at this point, the sigmoid mesentery curves up and away from the visual field. Therefore, the retroperitoneal plane is higher than expected, so the more mobile the arterial pedicle is, the easier it is to visualize the correct plane.

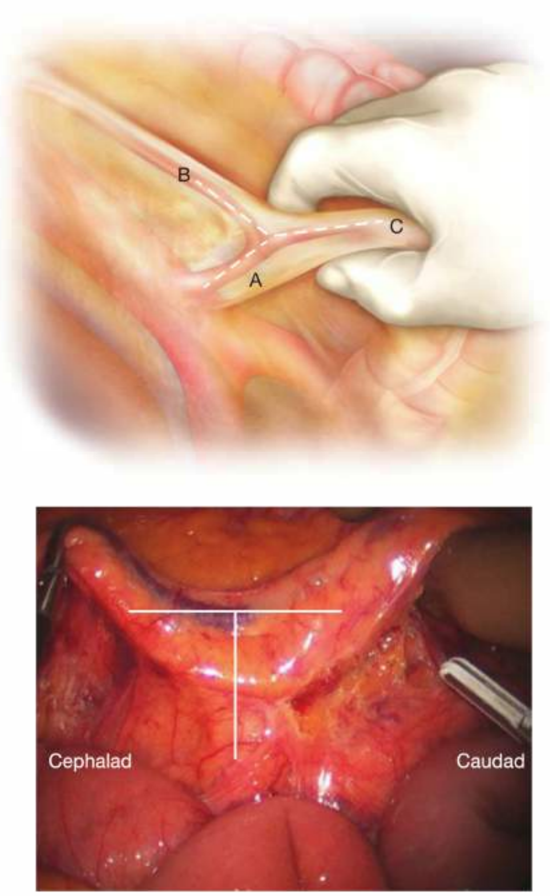

FIG 4 ● Identification of IMA and its branches. Identify the "letter T" formed between the IMA *(A)* and its left colic artery *(B)* and superior hemorrhoidal artery (SHA) *(C)* terminal branches. The IMA takeoff is just cephalad from the aortic bifurcation. The thumb and index finger are lifting the SHA off the groove located anterior to the right common iliac artery.

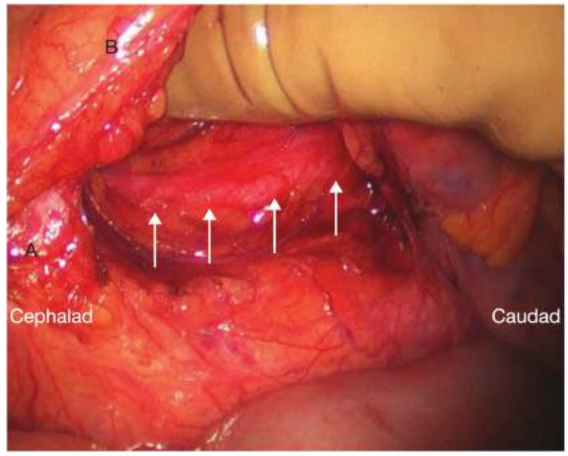

FIG 5 ● Identification of the left ureter. After the IMA *(A)* and superior hemorrhoidal artery (SHA) *(B)* have been lifted off the retroperitoneum, the left ureter *(arrows)* can be identified and preserved intact. Identification of the left ureter at this stage is critical in order to avoid injuring the ureter during the IMA transection.

- Identification of the left ureter is necessary before the IMA can be ligated (**FIG 5**). The following text is a four-step algorithm to identify the left ureter.
  - Mobilization of the superior rectal artery is as described earlier and the ureter is identified.
  - At the level of the IMV: The IMV is grasped and elevated. The peritoneum is incised dorsal to the IMV and the retroperitoneum is accessed. The retroperitoneum is flat in this area and is often more easily accessed. Once in the correct plane, the dissection is carried in a caudad fashion to meet up with the initial plane under the superior rectal artery.
  - If the ureter is still not identified, the sigmoid and left colon is mobilized in a lateral to medial fashion.
  - Finally, the top of the hand port can be removed and the left ureter can be located via an open fashion.
- After the left ureter is identified and swept into the retroperitoneum, the IMA can be isolated at its origin (**FIG 6**). The index finger elevates the superior rectal artery and the middle finger is used to sweep down the retroperitoneum along the course of the IMA. This motion continues until the bare area is exposed cephalad to the IMA and medial to the IMV.
- It is important to sweep down the retroperitoneal tissue in this area to help preserve the sympathetic plexus around the IMA. Once the IMA is safely isolated and the left ureter is clearly out of harm's way, the vascular pedicle can be ligated at its origin from the aorta with the surgeon's energy source of choice or with a linear stapler with a vascular cartridge (**FIG 7**).

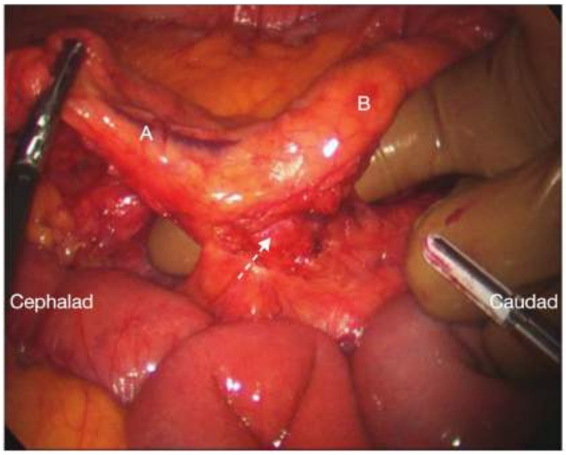

FIG 6 ● Circumferential dissection of the IMA. After the left ureter has been identified, the IMA *(arrow)* is circumferentially dissected at its origin of the aorta. Again, the "letter T" formed between the IMA and its terminal branches, the left colic artery *(A)* and the superior hemorrhoidal artery (SHA) *(B)* can be clearly identified.

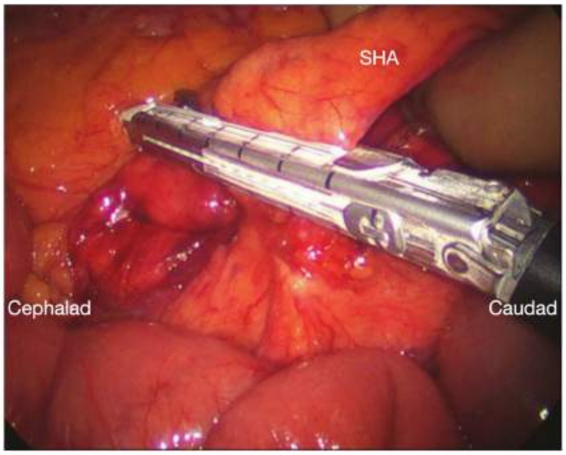

FIG 7 ● Transection of the IMA. With the left ureter safely dissected away into the retroperitoneum, the IMA is transected with a linear vascular stapler at its origin of the aorta. The surgeon's hand is holding the superior hemorrhoidal artery (SHA) anteriorly.

TRANSECTION OF THE INFERIOR MESENTERIC VEIN

- The IMV courses parallel to the left colic artery. The previous IMA dissection plane is carried cephalad with Endo Shears and 5-mm energy device (sweeping the retroperitoneal tissues dorsally) until the left colic artery separates from the IMV as it courses toward the splenic flexure at the level of the ligament of Treitz.
- Now that the IMV is elevated off the retroperitoneum, it is isolated at the inferior border of the pancreas and near the ligament of Treitz (**FIG 8**). It can be isolated with the same technique used for the IMA: The index finger and thumb elevate and create tension on the IMV and the middle finger and/or dissecting instrument sweeps the retroperitoneum dorsally along the course of the vein (**FIG 9**).
- A bare area is then created near the inferior border of the pancreas that allows the IMV to be safely isolated.
- Once isolated, the IMV can be safely transected with an energy device (**FIG 10**). The IMV should be transected cephalad to the left colic artery in order to preserve the marginal artery blood supply to the descending colon intact.

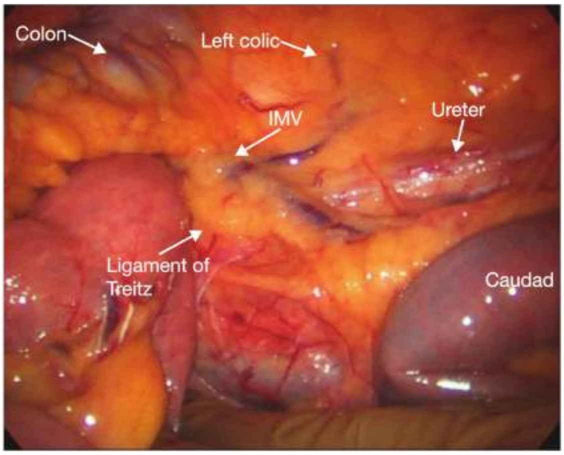

FIG 8 ● Identification of the IMV. The IMV can be identified at the root of the mesotransverse colon at the level of the ligament of Treitz. At this level, the IMV has separated from the left colic artery (which courses away from the IMV and toward the splenic flexure of the colon) and from the left ureter.

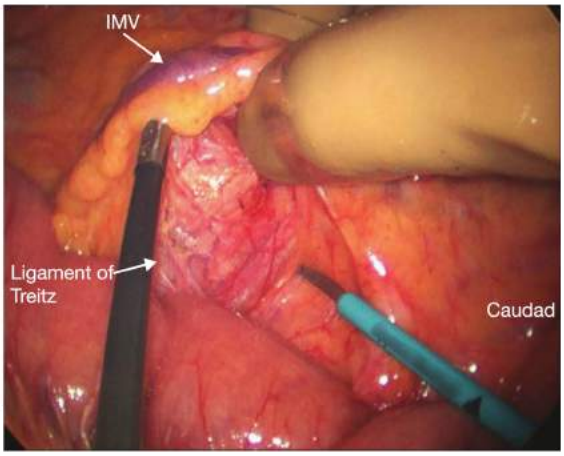

FIG 9 ● Dissection of the IMV. With the surgeon holding the IMV anteriorly, the retroperitoneal tissues are swept down (dorsally).

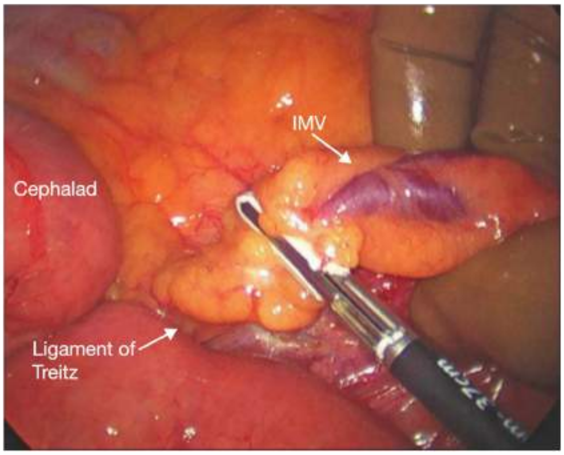

FIG 10 ● IMV transection. The IMV is transected with an energy device at the level of the IMV, cephalad of the left colic artery. This preserves intact the marginal artery of Drummond and ensures excellent blood supply to the descending colon segment for the anastomosis.

MOBILIZATION OF THE LEFT COLON

- The left colon mesentery is now dissected off the retroperitoneum using a medial to lateral dissection approach (**FIG 11**) all the way out to the lateral abdominal wall.
- The hand is placed palm down under the mesentery to elevate it as a fan-type retractor. The plane is dissected bluntly with an energy device from the sigmoid colon up to the splenic flexure. The further laterally and superiorly the dissection is carried, the easier the lateral dissection and splenic flexure mobilization will be later during the case. Care must be taken during mobilization near the inferior border of the pancreas, as it is very easy to carry the dissection deep to the pancreas.
- All that remains at this point are the lateral attachments. The hand is used to depress the sigmoid colon and lateral peritoneum is incised (**FIG 12A**). It is not uncommon for the hand to get in that way at this point, so it may be necessary to pass the energy source through the surgeon's fingers or the hand may be taken out and an instrument can be passed through the hand port to begin the dissection.
- Once the medial plane of dissection is accessed, the hand can be passed in the opening and the lateral attachments are elevated and exposed (**FIG 12B**). At this point, the surgeon uses a grasper for exposure and the first assistant uses the energy source through the LLQ port.

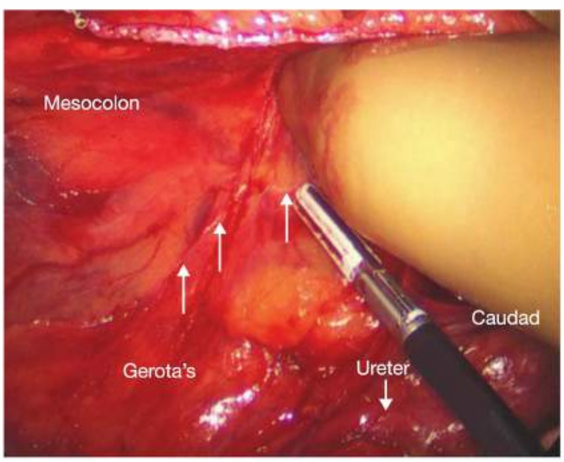

FIG 11 ● Medial to lateral dissection. With the surgeon holding the mesocolon anteriorly (notice the stapled transected IMA stump in between the surgeon's fingers), the retroperitoneal tissues are swept downward (dorsally) with an energy device. The dissection progresses along the transition of the two fat planes: mesocolon and Gerota's *(arrows)*.

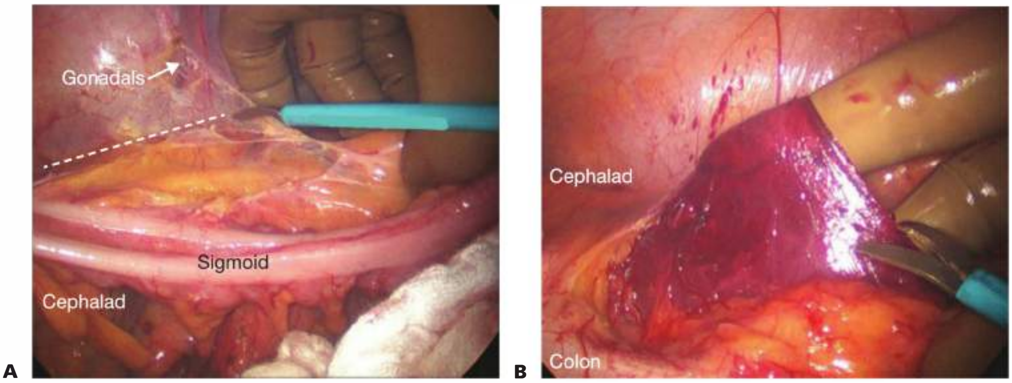

FIG 12 ● Lateral mobilization of the sigmoid and descending colon. **A.** The white line of Toldt *(dotted line)* is transected with an energy device. **B.** The medial to lateral dissection plane is readily entered, greatly facilitating the lateral mobilization of the descending colon.

MOBILIZATION OF THE SPLENIC FLEXURE

- As the splenic flexure is reached, a transition to separate the omentum from the transverse colon must be made. The surgeon's hand reflects the colon downward and the grasper elevates the omentum in a vertical fashion. Only the peritoneum is divided moving along the transverse colon. Eventually, the lesser sac is entered.
- Once the peritoneum attaching the omentum to the transverse colon has been divided to the extent of the dissection, the next layer of attachments of the omentum and the transverse colon mesentery can be divided. The gastrocolic ligament is transected in this way medial to lateral until the splenic flexure is reached (**FIG 13**).
- Returning to the splenic flexure, the colon is grasped laterally with the hand and medially with a grasper. The colon is put on stretch and pulled down and medial to identify the next level of attachment between the splenic flexure of the colon and the diaphragm and spleen. The splenodiaphragmatic and splenocolic ligaments are then transected with an energy device (**FIG 14**).
- All that remains are the posterior attachments to the inferior border of the pancreas. Division of these attachments to the midline allows for a full mobilization of the splenic flexure. This ensures adequate reach of the proximal colon for a tension-free anastomosis.

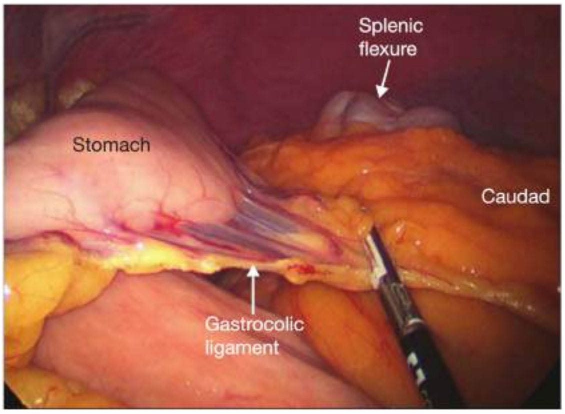

FIG 13 ● Transection of the gastrocolic ligament. After entering the lesser sac (between the stomach and the transverse colon), the gastrocolic ligament is transected from medial to lateral (toward the splenic flexure of the colon) with an energy device.

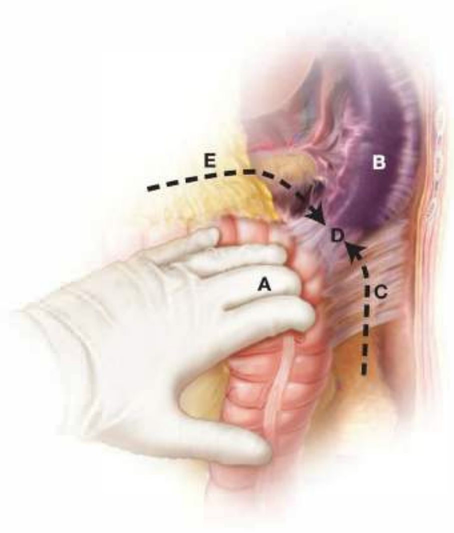

FIG 14 ● Mobilization of the splenic flexure. The surgeon retracts the splenic flexure of the colon *(A)* downward and medially, exposing the attachments of the splenic flexure to the spleen *(B)*. The phrenocolic *(C)* and splenocolic *(D)* ligaments are transected in an inferior to superior and lateral to medial direction, meeting the previously transected gastrocolic ligament dissection plane around the splenic flexure.

THE PELVIC DISSECTION AND DISTAL RECTAL TRANSECTION

- The pelvic dissection can be performed with either the hand used as a retractor, straight laparoscopically, or open through the suprapubic hand port.
- Conceptually, the rectum and mesorectum form a cylinder within the cylinder of the pelvis. This means the lines of dissection are circular and the ability to provide 360-degree exposure is necessary.
- The directions of retraction are anterior, posterior, medial, and lateral, with the goal being to make the plane of dissection perpendicular to the energy source. Avoid pulling the rectum and mesorectum out of the pelvis, as this does not optimize the exposure and space within the pelvis.
- The posterior dissection is performed first. The surgeon stands on the patient's right side with his or her right hand placed in the abdomen. With the thumb rotated medially and the palm up, the mesorectum is elevated and the presacral plane is entered (**FIG 15A**). Care is taken to identify and preserve the right and left hypogastric nerves intact.
- As the hand moves deeper into the pelvis, the fingertips are able to determine and expose the proper line of dissection. The mesorectum should be retracted anteriorly and not pulled out of the pelvis. The goal is to make the plane of dissection perpendicular to the energy source that is dividing the tissue.
- As the dissection proceeds on the right, posterior, and left, the hand subtly rotates the mesorectum to keep the plane of dissection perpendicular.
- Early on in the dissection, it is important to incise the peritoneum lateral to the rectum and mesorectum (Douglas pouch). The division should be carried all the way down to the peritoneal reflection. This helps to facilitate the lateral dissection and avoid carrying the lateral dissection too wide, minimizing the risk of injury to the parasympathetic nerves.
- The lateral dissection follows, with transection of the lateral rectal ligaments (**FIG 15B**).
- The posterior and lateral dissections are carried out down to the pelvic floor. All fat needs to be cleared off the levator muscles at the pelvic floor.
- The anterior peritoneal reflection is incised, with the hand retracting the uterus and cervix or prostate anteriorly. For the anterior dissection, the first assistant retracts the rectum posteriorly and rotates the direction of retraction as the dissection proceeds along Denonvilliers' fascia and behind the prostate/seminal vesicles in men (**FIG 15**) or the vagina in females. Once again, the

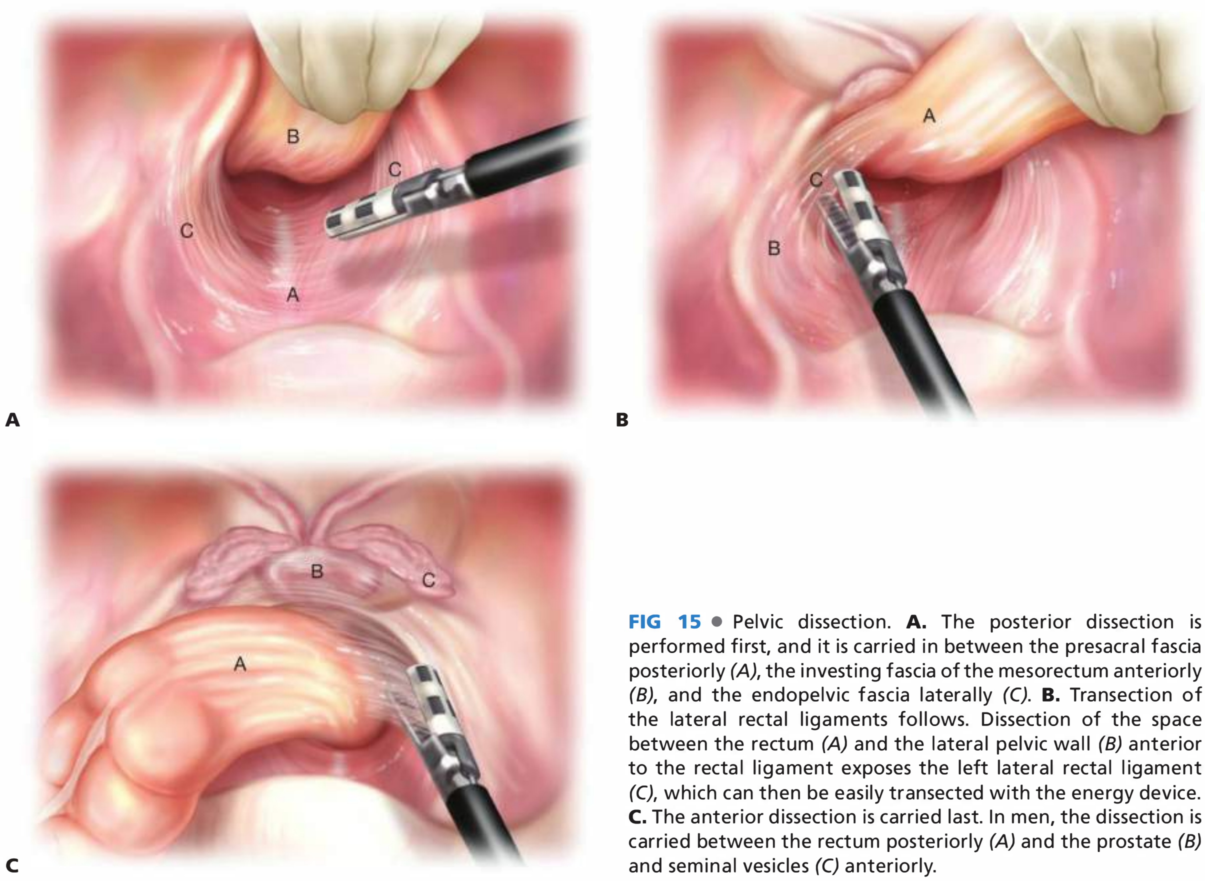

FIG 15 ● Pelvic dissection. **A.** The posterior dissection is performed first, and it is carried in between the presacral fascia posteriorly *(A)*, the investing fascia of the mesorectum anteriorly *(B)*, and the endopelvic fascia laterally *(C)*. **B.** Transection of the lateral rectal ligaments follows. Dissection of the space between the rectum *(A)* and the lateral pelvic wall *(B)* anterior to the rectal ligament exposes the left lateral rectal ligament *(C)*, which can then be easily transected with the energy device. **C.** The anterior dissection is carried last. In men, the dissection is carried between the rectum posteriorly *(A)* and the prostate *(B)* and seminal vesicles *(C)* anteriorly.

assistant should avoid pulling the rectum out of the pelvis, as this does not optimize exposure and space within the narrow confines of the pelvis.

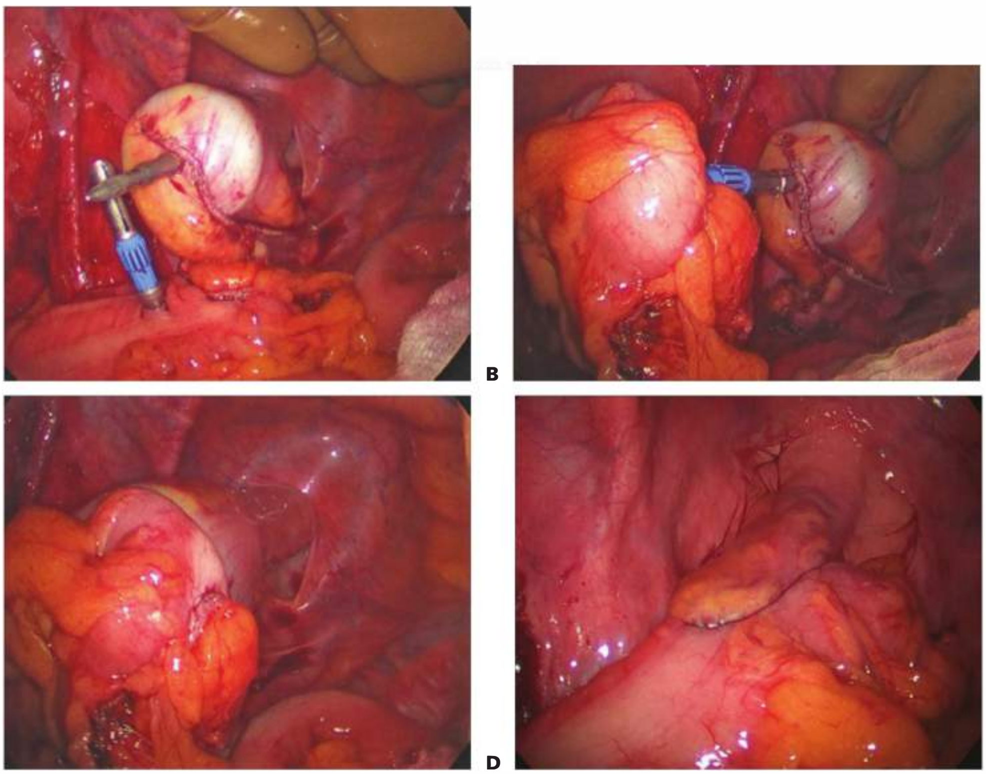
- For a tumor of the upper rectum, a tumor-specific mesorectal excision can be performed with a 5-cm distal margin. For a tumor of the mid to lower rectum, a total mesorectal excision should be performed.
- The rectum can then be stapled and divided with a linear stapler through the open hand port. This allows the rectum to be divided with a single firing of the stapler.

EXTRACORPOREAL PROXIMAL TRANSECTION

- The rectum and colon can then be extracted through the hand port and the proximal site of division of the colon can be selected. For rectal cancer, the ligated IMA pedicle should be resected with the specimen to ensure an adequate lymph node harvest.
- The colon is divided proximally at the desired level between clamps. The specimen is now completely disconnected.
- Once the specimen is removed, it should be inspected and the quality of the mesorectal excision (complete, near complete, incomplete) should be noted and documented.

ANASTOMOSIS

- If an end-to-end anastomosis (EEA) will be constructed, a purse string is then created, and the EEA stapling anvil is placed in the open proximal colotomy. If a side-to-end anastomosis will be constructed, the EEA anvil is introduced through the open end of the descending colon and is exteriorized with the spear through an antimesenteric location in the descending colon approximately 5 cm proximal to the open end of the colon. The open end of the colon is then closed with a linear stapler.
- The type of reconstruction of the neorectum is left up to the discretion of the surgery. Options include a colonic J-pouch, coloplasty, Baker-type anastomosis, and straight colorectal/coloanal anastomosis.
- Once the stapling cartridge is passed transanally to the top of the rectal stump, the spike is deployed and the anvil is reassembled. This can be performed either laparoscopically (FIG 16A–D) or open through the



A B C D

FIG 16 ● An intracorporeal side-to-end colorectal anastomosis. **A.** The anvil of the EEA stapler is in antimesenteric location in the distal descending colon. The spear of the EEA stapler can be seen protruding through the rectal stump. **B.** The anvil and the spear of the EEA stapler have been mated. **C.** While the EEA stapler is fired, care is taken to avoid getting the bladder (or vagina) trapped in the stapler. **D.** The completed side-to-end colorectal anastomosis is tension-free and has excellent blood supply.

hand port. As the anvil is cinched down, ensure that the posterior wall of the vagina or anterior tissue in a male is free from the stapler.

- The anastomosis should be assessed by inspecting the anastomotic doughnuts and by performing an air leak test (FIG 17) or endoscopic visualization of the anastomosis.
- A drain may be placed to drain whatever blood or fluid accumulates in the pelvis to minimize fibrosis of the neorectum.

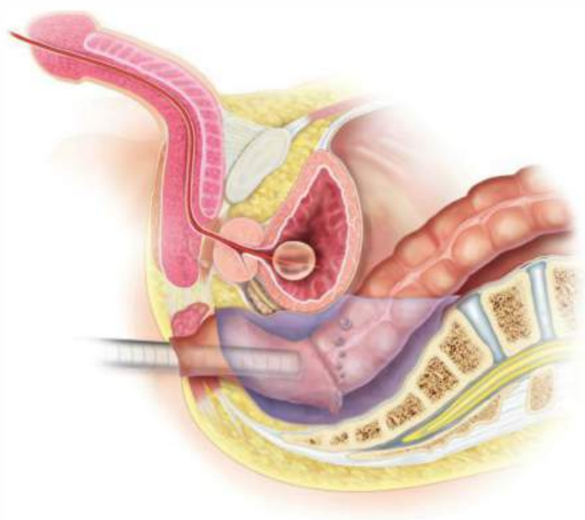


FIG 17 ● Air leak test. The anastomosis is tested under water. The presence of air bubbles would indicate an anastomotic disruption and should trigger a revision of the anastomosis.

CLOSURE OF THE ABDOMEN

- All 12-mm port fascial sites should be closed. The 5-mm port fascial sites do not need to be closed. Skin incisions are closed with subcuticular closure.
- The hand port can be closed with either interrupted or running stitch of no. 1 polydioxanone (PDS) suture.
- The indication for a diverting stoma is left at the discretion of the surgeon.

PEARLS AND PITFALLS

Indications	■ A complete history and review of preoperative staging is necessary to determine the need for neoadjuvant therapy. ■ The distance of the tumor to the anorectal ring needs to be clearly determined and documented. ■ T4 tumors, or those where there is concern for involvement of the circumferential margin, should not be approached laparoscopically.
Placement of the hand port	■ The suprapubic positions offers many advantages such as access to the pelvis to help with the dissection, division of the rectum, performance of the anastomosis, or management of bleeding or anastomotic complications.
Accessing the retroperitoneum	■ Different options include a medial approach, either at the level of the sacral promontory or at the IMV (by the ligament of Treitz), or alternatively, a lateral approach can be used.
Identification of the left ureter	■ A four-step technique was described above. Do not spend a lot of time with one approach if you are having difficulty, as the other steps described are anyway necessary to complete the case. Therefore, alternating your approach to identifying the ureter also helps complete other steps of the procedure.
Mobilization of the splenic flexure	■ The more extensive the medial to lateral dissection of the mesocolon is, the easier it is to mobilize the splenic flexure. ■ Be patient when entering the lesser sac. ■ Incise the peritoneum fusing the omentum to the transverse colon and dissect the omentum off the backside of the mesentery one layer at a time. ■ It is useful to alternate dissection between the lateral and medial aspects of the splenic flexure during this step.
Pelvic dissection	■ Creating space in the pelvis can be challenging. As a result, it is a natural reaction to pull the hand out of the pelvis. The exact opposite is necessary. The hand needs to be deeper in the pelvis; exposure is created by flexing the fingers and leaving the palm in place. ■ Small changes in the direction of tension are vital for increasing exposure and efficiency of the dissection.

POSTOPERATIVE CARE

- The patient can begin a liquid diet on the day of surgery. The diet can be advanced as tolerated. Solid food can be safely provided before the resumption of bowel function.
- A urinary catheter should remain in place for 3 to 4 days postoperatively to minimize the risk of urinary retention.
- Patients can begin ambulation as early as the day of surgery and by postoperative day 1; they are to be encouraged to spend more time out of bed than in bed.
- Venous thromboembolism (VTE) prophylaxis is important because most patients have rectal cancer and underwent a pelvic dissection. Low-molecular-weight heparin (LMWH), subcutaneous heparin, or pneumatic compression boots are all acceptable methods. There is data supporting the use of LMWH for 21 days postoperatively to decrease the risk of VTE.
- The drain can be removed on postoperative day 4 regardless of the volume of the output, unless it is draining urine, stool, or pus.

OUTCOMES

- There are currently three published trials of laparoscopic versus open resection of rectal cancer. The Conventional versus Laparoscopic-Assisted Surgery in Colorectal Cancer (CLASICC), COlorectal cancer Laparoscopic or Open Resection (COLOR II), and Comparison of Open versus laparoscopic surgery for mid or low REctal cancer After Neoadjuvant chemoradiotherapy (COREAN) trials have demonstrated equivalent outcomes for two approaches with regard to margins, lymph node harvest, recurrence, and survival.
- When HALS is compared to conventional laparoscopic-assisted colectomy, multiple prospective randomized trials have demonstrated no difference in short-term outcomes including length of stay, return of bowel function, or pain scores. Furthermore, HALS has been shown to decrease the operative time for a left colectomy by 33 minutes and a total abdominal colectomy by 57 minutes and the risk of conversion over straight laparoscopy as well as to significantly decrease conversion rates.
- Oncologically, recent studies have demonstrated comparable short-term outcomes, lymph node harvest, and margin status when HALS is compared to straight laparoscopic proctectomy.

COMPLICATIONS

- Bleeding
- Anastomotic leak
- Wound infection
- Pelvic abscess
- Ureteral injury
- Urinary and/or sexual dysfunction
- Incomplete mesorectal dissection
- VTE
- Incisional hernia

Chapter 30

Low Anterior Rectal Resection: Robotic-Assisted Laparoscopic Technique

Mehraneh D. Jafari   Alessio Pigazzi

DEFINITION

- Low anterior resection (LAR) is most commonly performed for patients with mid to low non–sphincter-invading rectal adenocarcinoma. A simple surgical definition of LAR is full mobilization and division of the rectum at the level of the levators, leaving behind only a short or no rectal stump.
- LAR for rectal cancer requires a total mesorectal excision (TME) to ensure a radical resection with adequate radial margins.[1] The goal is to achieve an en bloc resection of the cancer with complete dissection of the pararectal lymph nodes contained within the mesorectum.
- Robotic-assisted laparoscopic LAR is a novel surgical technique that allows for a minimally invasive approach to TME. Robotic LAR can be performed via totally robotic or laparoscopic/robotic hybrid techniques. Our preferred method is a hybrid approach involving a laparoscopic medial to lateral mobilization of the colon and of the splenic flexure followed by a robotic TME.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A full history and physical examination will allow the surgeon to determine if a sphincter-sparing operation is possible, whether a temporary ileostomy is likely, and will also aid in discussions regarding postoperative functional status.
- History elements elicited should include baseline functional status, bowel incontinence, sexual dysfunction, urinary dysfunction as well as pain with defecation or tenesmus. Previous history of pelvic radiation and pelvic surgery should also be noted.
  - History of incontinence should prompt discussions regarding postoperative quality of life with a low anastomosis.
  - History of pain or tenesmus suggests involvement of the anal sphincter or a larger tumor. This will alter the course of treatment, and a sphincter-sparing operation may not be possible in this subgroup of patients.
- Physical examination should include a digital rectal examination (DRE), vaginal examination, anoscopy, and a thorough abdominal examination.
  - DRE should assess tumor size, degree of fixation to rectal and pelvic wall, mobility, location (anterior/posterior/lateral), distance from the anorectal ring, and anterior extension into vagina/prostate. Anal sphincter involvement can also be determined by DRE in the majority of patients.
  - Anterior rectal tumors in female patients require a vaginal examination to rule out extension into the vagina.
  - Anoscopy for low rectal tumors may allow for better visualization of the tumor during the physical examination.
  - The abdominal examination should evaluate for liver metastasis. A bilateral groin examination should be performed to evaluate for potential inguinal lymphadenopathy.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- The physical examination in conjunction with endoscopy and imaging modalities will aid in the preoperative surgical evaluation and staging. This preoperative workup will dictate the best surgical approach, the need for temporary diversion, and the need for neoadjuvant therapy.
- Colonoscopy must be performed in all patients with rectal cancer.
  - This will allow for assessment of tumor location and pathology.
  - It will also serve to rule out and possibly remove any synchronous colonic lesions. Malignant synchronous lesions have been reported in 2% to 8% of cases and benign synchronous polyps in 13% to 62% of cases.[2–4]
  - If a colonoscopy has already been done by another provider, it is our preference to perform a flexible sigmoidoscopy in all patients for documentation of the size, location, and distance of the tumor from the anal sphincter complex.
- The use of preoperative tattoos in rectal cancer patients undergoing anterior resection is unnecessary and unreliable to determine distal margins. The best assessment of the margin is obtained via frequent and thorough digital examinations, intraoperative flexible endoscopy, and adherence to the best TME surgery criteria.
- Accurate staging of rectal cancer should be able to determine depth of invasion, presence of lymph node metastases, and resectability of locally advanced tumors.
  - Endorectal ultrasound has an overall 80% to 95% staging accuracy.[5]
    - The ability to visualize the layers of the bowel wall allows for accurate T staging (**FIG 1**).
      - T1 stage is associated with 88% sensitivity and 98% specificity.
      - T2 stage is associated with 81% sensitivity and 96% specificity.
      - T3 stage is associated with 96% sensitivity and 91% specificity.
      - T4 stage is associated with 95% sensitivity and 98% specificity.[5]
    - Detection of lymph node metastasis is associated with 73% sensitivity and 76% specificity.[6]
  - High-resolution pelvic magnetic resonance imaging (MRI) delineates the layers of the bowel wall in T2 weighted images. It is associated with 93% to 97% sensitivity for T staging and 77% sensitivity for lymph node metastasis.[7,8]
  - Computed tomography (CT) scan of chest, abdomen, and pelvis should be obtained for preoperative evaluation metastases as per National Comprehensive Cancer Network (NCCN) guidelines.[9] It is associated with 40% to 86% accuracy in staging rectal cancers.[8,10,11]

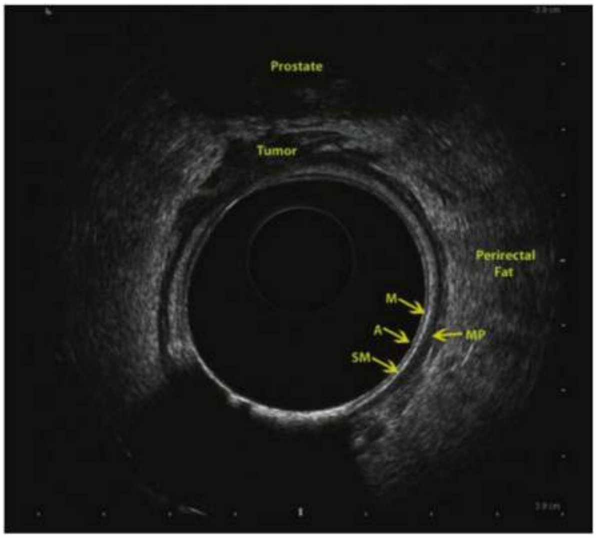

FIG 1 ● Endoscopic ultrasound (EUS) depicts the bowel wall layers: *A* indicates balloon interface, *M* indicates mucosa/muscularis mucosa, *SM* indicates submucosa, and *MP* indicates muscularis propria. This patient has an anteriorly located tumor with invasion of the perirectal fat but no direct extension into the prostate (EUS T3).

SURGICAL MANAGEMENT

Preoperative Planning

- Surgical decision is based on rectal cancer staging. As per NCCN guidelines, neoadjuvant chemotherapy and radiation therapy (CRT) should be considered for all N+ positive tumors based on preoperative imaging. The use of neoadjuvant CRT in T3N0 tumors is somewhat controversial. Proximal T3 tumors with no involvement of the circumferential resection margin (i.e., posterior lesions surrounded by abundant mesorectum) can selectively undergo radical resection without CRT.[9]
- Neoadjuvant CRT has been shown to reduce the local recurrence rate and increase the chances of sphincter-sparing surgery.[9]
- The decision for neoadjuvant chemotherapy should stem from a multidisciplinary discussion amongst the surgeon, oncologist, radiation oncologist, and patient.
- An enterostomal therapist should be involved for counseling and for potential stomal marking prior to operation.
- Despite the debate regarding bowel preparation, we routinely use mechanical bowel preparation at our institution for easier manipulation of the bowel during surgery. Our institution's standard bowel preparation is 510 mg of MiraLAX® in 128 oz of Gatorade®.
- Rectal irrigation via saline solution is performed in all patients.
- A Foley catheter is placed in all patients after induction for bladder decompression.
- Prophylactic ertapenem (Invanz®) antibiotic is administered prior to induction of anesthesia.
- Sequential compression devices are placed in all patients. However, the use of pharmacologic deep vein thrombosis (DVT) prophylaxis is not routinely used. The benefit of chemical prophylaxis remains controversial.[12,13]

Positioning

- The patient is placed in a modified lithotomy position with attention placed to correct technique to minimize injury:
  - The patient is ideally placed on a large high-density viscoelastic foam mat to prevent sliding.
  - The patient is brought to the edge of the table and the legs are placed into Yellofin® or Allen® stirrups with the hips slightly flexed and abducted, the feet flat within the stirrups, and pressure avoided along the lateral aspects of the legs. The ankle, knee, and contralateral shoulder should be aligned.
  - A Velcro belt is strapped over the chest to prevent side-to-side sliding.
- The perineum is prepped if a transanal extraction and or hand-sewn anastomosis is anticipated.

LAPAROSCOPIC MEDIAL TO LATERAL DISSECTION OF COLON

Port Placement

- Pneumoperitoneum is established via a Veress needle at Palmer's point (1 to 2 cm below the left costal border in the midclavicular line [MCL]).
- The ports are triangulated and placed at a minimum of one handbreadth apart (FIG 2).
- The camera (C) port is placed halfway between the xiphoid process and symphysis pubis.
- Three robotic (R) ports will be placed as follows (FIG 2):
  - R1 is a 12-mm trocar inserted in the MCL halfway in between C and the right anterior superior iliac spine (ASIS). This port can be used for ileostomy placement at the end of the surgery.
  - R2 is an 8-mm trocar inserted as a mirror image of R1.
  - R3 is an 8-mm trocar inserted 8 to 10 cm lateral to R2, usually directly above the left ASIS.
- Laparoscopic-assisted (L) ports (FIG 2):
  - L1 is a 5-mm trocar inserted in the MCL about 12 cm superior to R1.
  - L2 is a 5-mm port inserted halfway between MCL and midline about 12 cm superior to L1.
- Both surgeon and assistant stand on the right side of patient (FIG 3).
- R1, L1, L2, and C ports are used during the laparoscopic section.

Laparoscopic Transection of the Inferior Mesenteric Vein

- The peritoneal cavity is explored for evidence of metastatic disease.
- The patient is placed in a Trendelenburg position with the left side elevated.
- The small bowel is swept out of the pelvis. Nontraumatic bowel graspers are used to avoid injury.
- The dissection is begun at the inferior mesenteric vein (IMV), lateral to the ligament of Treitz (FIG 4).

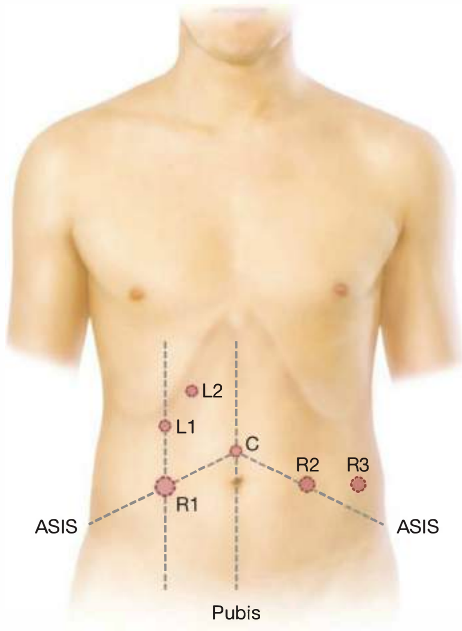

FIG 2 ● Placement of the laparoscopic ports. The ports are triangulated and placed at a minimum of one handbreadth apart. *C* denotes camera port; *L1* and *L2* denote the laparoscopic ports; and *R1*, *R2*, and *R3* denote the three robotic ports.

- The IMV is identified and dissected from its attachments to the left mesocolon.
- The peritoneum is scored with monopolar electrocautery.
- Blunt dissection is used to skeletonize the vessel. Once this is achieved, the vessel is clipped and divided via vessel sealer device just below the pancreas. This can also be accomplished with an Endo GIA vascular stapler.
- Transection of the IMV will serve as a lengthening maneuver, which in turn will decrease tension on the anastomosis.

FIG 3 ● Room setup with the robot docked from the left hip and surgeon and assistant surgeon on the right side of the patient.

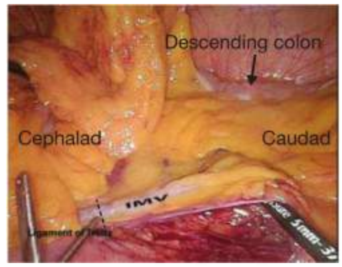

FIG 4 ● The IMV is visualized lateral to the ligament of Treitz and is skeletonized. The IMV will then be transected just below the pancreas *(dotted line)*.

Laparoscopic Transection of the Inferior Mesenteric Artery

- The sigmoid mesocolon is retracted toward the anterior abdominal wall, and the parietal peritoneum medial to the right common iliac artery at the sacral promontory is incised.
- Upward traction is maintained by the assistant and blunt dissection is used to enter the avascular retroperitoneal plane. This plane is developed under the superior hemorrhoidal artery (**FIG 5**).
- The left ureter and the hypogastric nerve are identified and swept posteriorly (**FIG 5**).
- This dissection is continued to the origin of the inferior mesenteric artery (IMA) at the aorta.
- The IMA is skeletonized using monopolar cautery. The junction of left colic artery and superior hemorrhoidal at the IMA can be visualized in a letter "T" configuration (**FIG 6A**).
- The IMA is clipped and divided at its origin from the aorta with a vessel sealer device (**FIG 6B**). This can also be accomplished via Endo GIA vascular stapler.
- The left colic artery is divided at its origin from the IMA (**FIG 6B**).
- Care is taken to avoid damage to the small nerve fibers of the preaortic sympathetic/superior hypogastric plexus.

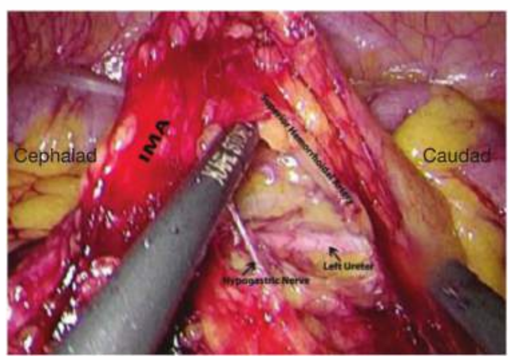

FIG 5 ● The retroperitoneal plane dorsal to the superior hemorrhoidal artery is dissected. The IMA is identified and left ureter and hypogastric nerve are swept posteriorly.

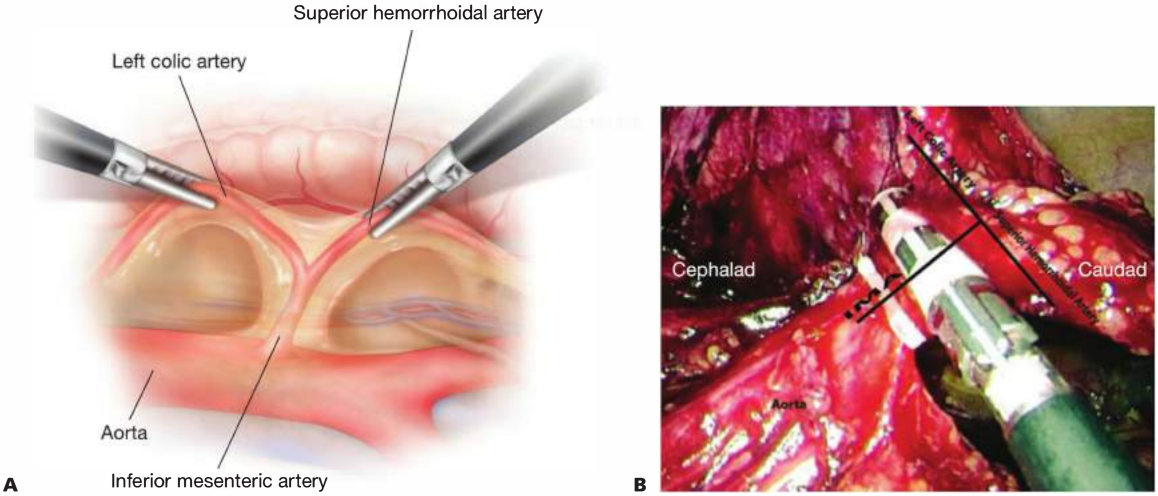

FIG 6 ● **A.** The T configuration formed between the IMA *(A)* and its terminal branches, the left colic *(B)*, and the superior hemorrhoidal artery *(C)* is visualized. Notice the left ureter *(D)* dissected posteriorly in the retroperitoneum. **B.** The IMA is clipped and divided at its origin from the aorta with a vessel sealer device. The left colic artery will be transected at its origin from the IMA also with a vessel sealer device.

Laparoscopic Mobilization of the Left Colon and Splenic Flexure

- The assistant surgeon retracts the colon medially, and with a combination of cautery and blunt dissection, the lateral peritoneal reflections are dissected.

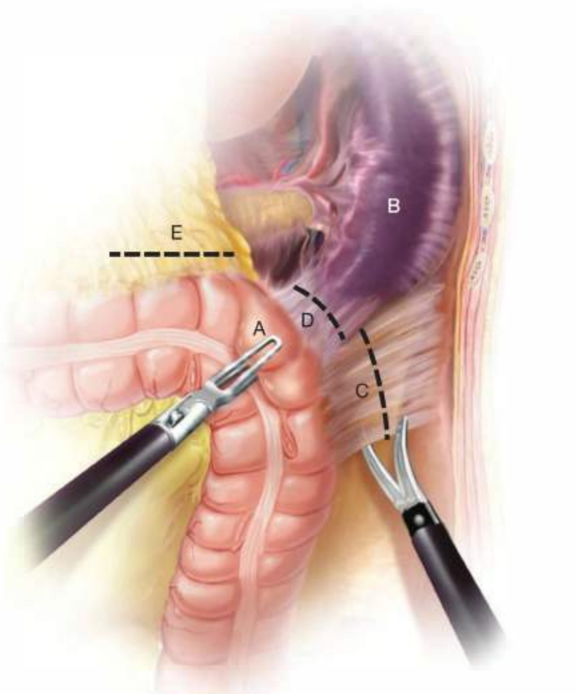

FIG 7 ● Mobilization of the splenic flexure. The phrenocolic *(C)*, splenocolic *(D)*, and gastrocolic *(E)* ligaments are transected. *A*, splenic flexure of the colon; *B*, spleen.

- The embryologic tissue plane between the descending colon mesentery and the retroperitoneum is entered. This bloodless areolar tissue plane is dissected toward the splenic flexure.
- The lateral dissection is continued cephalad by division of phrenocolic and splenocolic ligaments (**FIG 7**).
- The lesser sac is entered and the dissection is carried to the base of the mesentery (**FIG 8**).
- Care is taken to avoid injury to the tail of the pancreas in this location.
- The left and proximal transverse colon are now dissected free of their attachments.

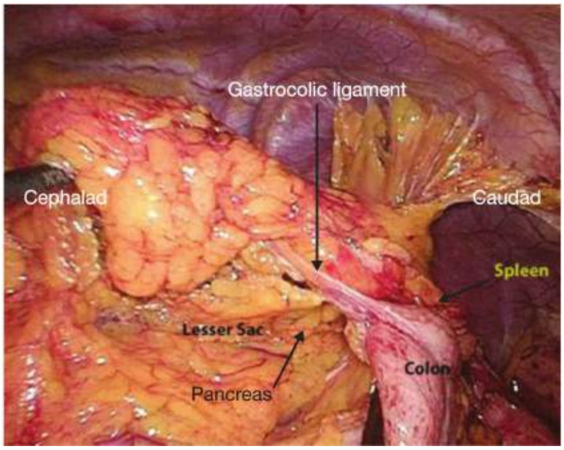

FIG 8 ● Transection of the gastrocolic ligament allows for entry into the lesser sac during the splenic flexure mobilization. The dissection is carried to the base of the mesentery.

ROBOTIC TOTAL MESORECTAL EXCISION

Robot Setup and Docking

- The patient is kept in a Trendelenburg position. A four-arm da Vinci robot is docked from a left hip approach (FIGS 3 and 9). This will allow for easy access to the anus during the case.
- A 0-degree scope is inserted in port C.
- Robotic arms are docked as follows (FIG 10):
  - Arm 1 is docked in R1. A hook cautery or monopolar scissors will be inserted in R1.
  - Arm 2 is docked in R2. A bipolar grasper will be placed in R2.
  - Arm 3 is docked in R3. A "prograsper" will be placed in R3.
- The assistant surgeon will stay on the right side of the patient and will use L1 and L2 to assist in retraction and suction/irrigation.

FIG 10 ● Configuration of robotic arms after docking.

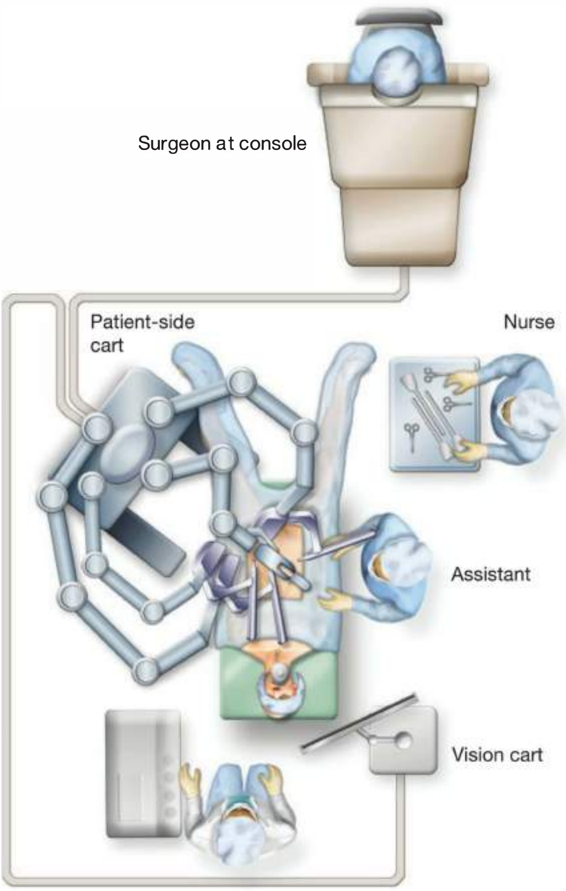

FIG 9 ● The robot is docked from a left hip approach. **A.** Illustration. **B.** Photograph.

Robotic Total Mesorectal Excision

- The following principles should be adhered to during a robotic TME:
  - Minimal manipulation of the rectum
  - Identification of embryologic tissue planes
  - Oncologic resection with negative radial and distant margins without violation of the mesorectal envelope
- The surgeon at the robot's console will start dissection at the sacral promontory dorsal to the superior hemorrhoidal artery, following this plane distally over the promontory and into the presacral space.
- Arm 3 is used for retraction, whereas arms 1 and 2 develop a plane of dissection within the avascular presacral space between the presacral fascia, posteriorly, and the mesorectal fascia, anteriorly.
- Arm 2 of the robot (left hand of the surgeon) should avoid grasping the mesorectum for the strong robotic arm may tear the mesorectum, which would cause bleeding.
- Monopolar scissors are preferred for rapid development of the plane of dissection with minimal use of electrocautery.
- The pelvic dissection proceeds posteriorly first, then laterally, and then anteriorly.
  - Posterior exposure is achieved with the assistant retracting the sigmoid colon cephalad and anteriorly (FIG 11). Waldeyer's fascia (rectosacral fascia) is entered distally at approximately the level of S3. This dissection is carried caudally to the level of levator muscles (FIG 12).
  - Laterally, the hypogastric nerves are identified and preserved. The lateral dissection plane is carried anterior and medial to these nerves (FIG 13A). The nerve fibers are carefully dissected toward the pelvic sidewall (FIG 13B).

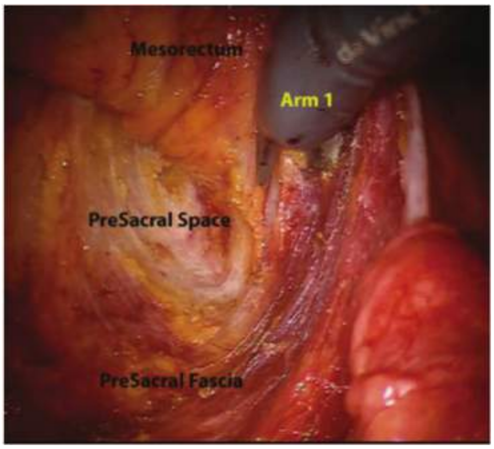

FIG 11 ● The posterior pelvic dissection is carried out within the presacral space, staying between the presacral fascia, posteriorly, and the mesorectal fascia, anteriorly.

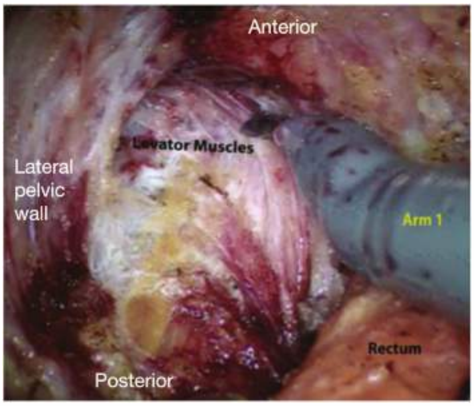

FIG 12 ● The posterior pelvic dissection is carried caudally to the level of the levator muscles.

- For the anterior pelvic dissection, exposure is achieved by the assistant retracting the rectum posteriorly and in a cephalad direction, as arm 3 anteriorly retracts the vagina (in females) or the prostate/seminal vesicles (in males). The Denonvilliers' fascia/pouch of Douglas (rectovesical/rectovaginal pouch) is entered by incising the peritoneal reflection between the anterior wall of the rectum and the posterior wall of vagina or the prostate/seminal vesicles (**FIG 14**). In case of large anterior tumors, Denonvilliers' fascia is resected en bloc with the rectum.

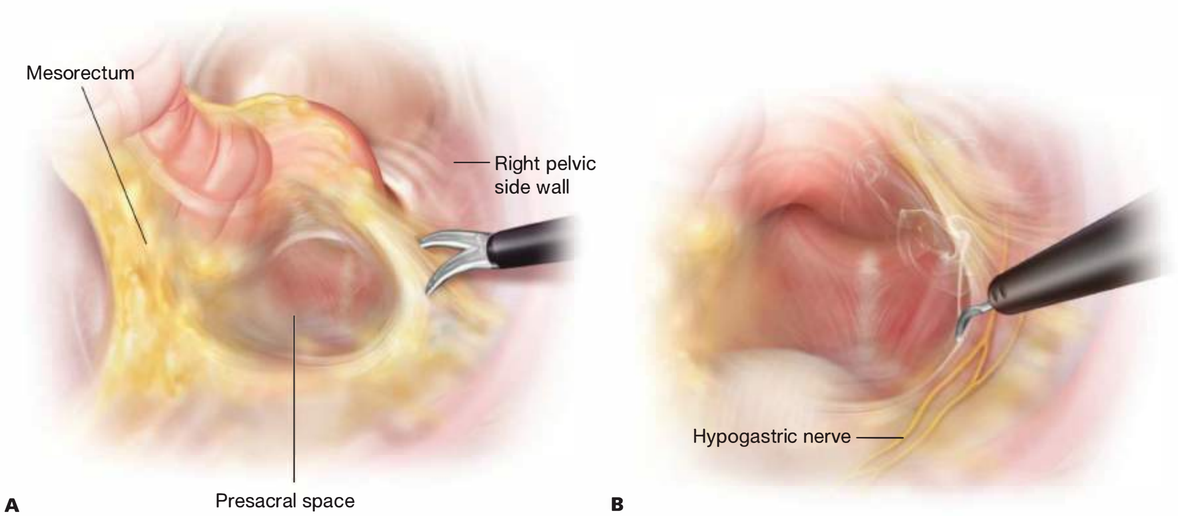

FIG 13 ● Lateral dissection of the mesorectum off the right pelvic sidewall: transection of the right lateral rectal ligament **(A)**. **B.** The hypogastric nerve can be seen posterolateral to the plane of the dissection.

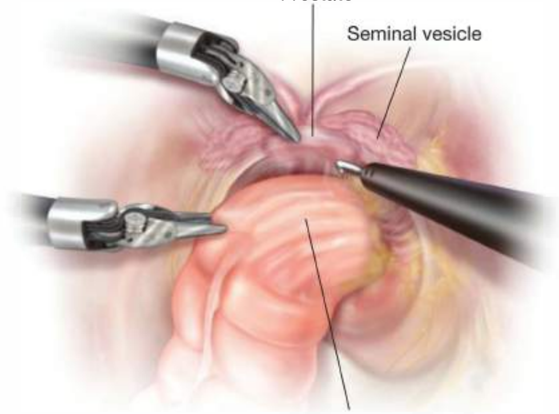

FIG 14 ● Anterior pelvic dissection. Exposure is achieved by the assistant retracting the rectum **(A)** posteriorly and in a cephalad direction, as arm 3 anteriorly retracts the prostate/seminal vesicles **(B,C)**, respectively. The anterior plane of dissection is carried along Denonvilliers' fascia, between the rectum posteriorly **(A)** and the prostate **(B)** and seminal vesicles **(C)** anteriorly.

DIVISION OF RECTUM AND CREATION OF ANASTOMOSIS

Division of Rectum

- DRE or flexible sigmoidoscopy under robotic vision is performed to establish the proper level of rectal division.
- In cases when the tumor is at least 2 to 3 cm from the anorectal ring, the distal rectum is transected with an articulating linear stapler.
  - An Endo GIA stapler is placed through the R1 port or in the lower assistant port (converted to a 12-mm port to accommodate the stapler).
  - The stapler is fired sequentially. Care is taken to avoid crossing staple lines during the sequential firing of stapler cartridges (**FIG 15**).
- For tumors that are less than 2 to 3 cm from the anorectal ring, an intersphincteric resection with hand-sewn coloanal anastomosis can be used (described in Part 4, Chapters 27 and 31).

Specimen Extraction

- Once the specimen is divided, the robot is undocked.
- The transected rectum and the contiguous sigmoid and descending colon are extracted through a 4- to 5-cm Pfannenstiel incision with a wound protector in place to protect the wound from potential oncologic contamination and soilage. The proximal transection is then performed with a linear stapler between the sigmoid and the descending colon. The specimen, including the rectum and sigmoid colon, is now completely disconnected and is sent to the pathologist for evaluation. The specimen should include the IMA pedicle and an intact mesorectum without any distal tapering (**FIG 16**).

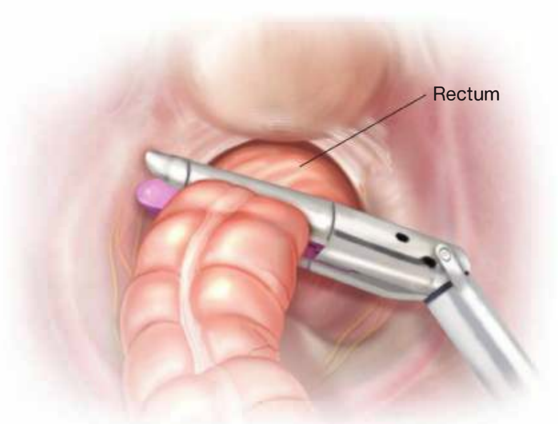

FIG 15 ● The distal rectum is transected with an Endo GIA. The stapler is fired sequentially. Care is taken to avoid crossing staple lines during the sequential firing of stapler cartridges.

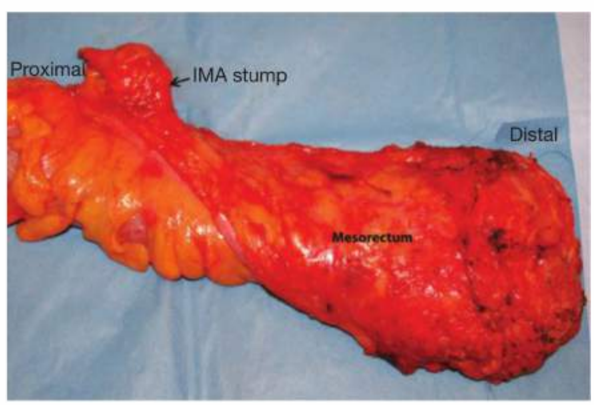

FIG 16 ● The extracted specimen demonstrates the IMA pedicle and an intact mesorectal envelope without any distal tapering.

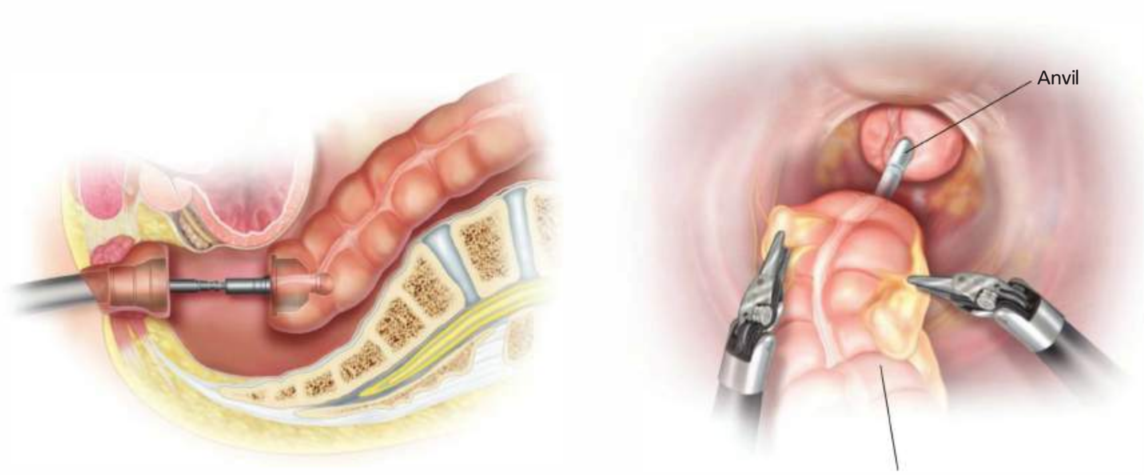

FIG 17 ● **A,B.** Intracorporeal laparoscopic anastomosis. The descending colon is anastomosed to the rectal stump with a 29F EEA circular stapler.

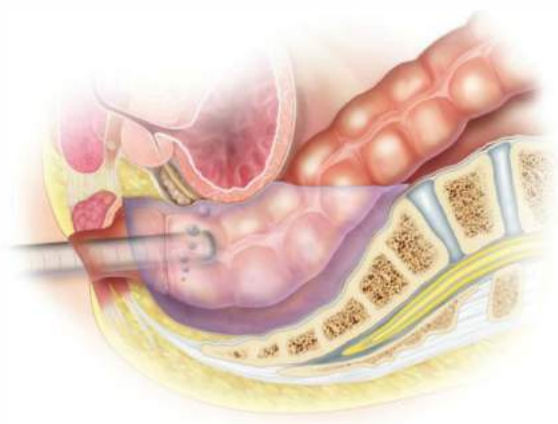

FIG 18 ● Assessment of anastomotic integrity by sigmoidoscopy. The completed colorectal anastomosis is tested underwater. Air bubbles identified during insufflation of the anastomosis indicate an anastomotic leak.

- The anvil of a 29F end-to-end anastomosis (EEA) stapler is secured with a purse-string suture in the descending colon and the colon is returned into the abdomen. A colonic J pouch can be created at this point if preferred.

Creation of Anastomosis

- Once the colon is returned into the abdomen, an end-to-end stapled anastomosis with a circular 29F EEA stapler is created laparoscopically (FIG 17A,B).
- A flexible sigmoidoscopy is then performed to assess the anastomosis integrity and to test for an air leak. If there is an air leak, this indicated the presence of an anastomotic leak (FIG 18). In this situation, and at the discretion of the surgeon, the decision is made to either redo the anastomosis or reinforce it with sutures.
- A round Blake drain is routinely placed within the pelvis near the anastomosis.

Creation of Ileostomy

- A temporary diverting loop ileostomy is created based on surgeon preference and patient factors. However, it is generally recommended for low anastomoses.

PEARLS AND PITFALLS

Preoperative workup	■ Obtain a complete and thorough history of urinary and bowel incontinence and sexual dysfunction. ■ Perform own endoscopy and verify the location of tumor.
Port placement	■ Maintain triangulation. ■ For narrower pelvic inlet, consider more medial robotic ports.
Division of IMA	■ Visualize the T configuration to assure high ligation.

Robotic TME	■ Avoid using arm 2 (surgeon's left hand) to grasp mesorectum. ■ Dissection should be within the avascular plane of the presacral space. ■ Avoid injury to hypogastric nerves laterally. ■ Identify bilateral ureters prior to proceeding.
Division of rectum	■ During repeated stapler firings, do *not* cross over previous transection points.
Anastomosis	■ Visualize anastomosis via endoscope to assure good blood supply and integrity.

POSTOPERATIVE CARE

- The Foley catheter should be continued for 48 to 72 hours given the high likelihood of postoperative urinary retention after low pelvic surgery.
- The pelvic drain is discontinued prior to discharge.
- Stoma teaching is performed by the enterostomal nurse prior to discharge.

OUTCOMES

- Given improved surgical technique and adjuvant therapy, overall survival rates of rectal cancer have improvement over the recent decades.[14,15]
  - Overall 5-year survival for patients undergoing curative resection is 80% with 10% local recurrence rates.[16]
- Robotic TME is comparable to laparoscopic TME in retrospective reviews of this technique. However, studies report lower conversion rates to open surgery compared to conventional laparoscopy.[17–21]

COMPLICATIONS

- Symptomatic anastomotic leaks after LAR have been reported to occur in 12% to 18% of patients with an associated risk of mortality of 15%.[16,22–26]
- Patients may complain of anorectal, sexual, and urinary dysfunction postoperatively. This may be due to dissection during surgery and/or secondary to pelvic radiation.
- LAR syndrome may occur and refers to a combination of symptoms including increased bowel frequency, fecal incontinence, and urgency.

Chapter 31

Total Mesorectal Excision with Coloanal Anastomosis: Laparoscopic Technique

John H Marks Elsa B. Valsdottir

DEFINITION

- Total mesorectal excision with coloanal anastomosis via a transanal abdominal transanal proctosigmoidectomy (TATA) is defined as the complete removal of the embryologic tissue block of the rectum, leaving the sphincter muscles intact and thus avoiding a permanent stoma. Neoadjuvant chemoradiotherapy is an essential component to successful sphincter preservation. The abdominal part of the procedure can be performed with laparoscopic technique.

DIFFERENTIAL DIAGNOSIS

- Several conditions, both benign and malignant, can have similar presentation to rectal cancer. These include adenomatous polyps, solitary rectal ulcer, radiation injury, carcinoid tumor, and squamous cell carcinoma. Hence, a tissue biopsy confirming the diagnosis of rectal cancer is imperative.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Careful patient selection is crucial for successful sphincter preservation in rectal cancer. A detailed history and physical examination are mandatory. Contraindications include inability to receive neoadjuvant chemoradiation therapy for distal rectal cancers, either because of comorbidities or previous radiation to the pelvis, previous radical surgery on rectum, distance of tumor from the dentate line, invasion of tumor into the sphincter muscles after completion of neoadjuvant chemoradiation therapy, and fecal incontinence on presentation.
- Detailed past medical history is obtained, emphasizing fecal continence, bowel habits, personal and family history of cancers and current medications and allergies, previous radiation to the pelvis, and previous abdominal surgeries.
- Prior radiation therapy for other cancers in the pelvis, such as cervical or prostate, is usually a contraindication. It is, however, helpful to review the previous records with regard to the dose and field treated and make decisions on individual basis.
- A detailed family history of cancers can help identify increased risk for other types of cancer as well as identify family members who are at an increased colon cancer risk. Recommendations should be given to first-degree relatives with regard to screening.
- Patient age, nodal status, or tumor size are not contraindications for sphincter preservation as long as the patient is a reasonable surgical candidate and negative margins (distally and circumferentially) can be obtained.
- Physical examination must include a thorough abdominal exam, including palpation of inguinal lymph nodes bilaterally. Most importantly, a careful digital rectal exam and a rectoscopy or flexible sigmoidoscopy are performed.
- The location of the tumor (anterior, posterior, or lateral), distance from the anorectal ring, size, fixity, circumference, configuration, and ulceration of the tumor need to be documented. This is imperative in preoperative planning as well as allowing for assessment of response to neoadjuvant treatment later (**FIG 1**).

IMAGING AND OTHER DIAGNOSTIC STUDIES

- All patients require preoperative staging of the disease with regard to the tumor, lymph node status, and distant spread, both clinically and radiographically.
- The most accurate way to determine size, length, and depth of the tumor invasion as well as any enlarged lymph nodes is with magnetic resonance imaging (MRI) or endoscopic rectal ultrasound (ERUS) (**FIG 2**).
- A computed tomography (CT) of the abdomen and chest should be obtained to evaluate for distant spread of the disease to the liver or lungs.
- Preoperative blood work should include a hemogram, blood chemistries, and a carcinoembryonic antigen (CEA) level.
- Full colonoscopy is needed to evaluate the entire colon for other pathology and synchronous malignant lesions or polyps.
- Histologic assessment with biopsy of the primary tumor is necessary and usually obtained at the time of colonoscopy.

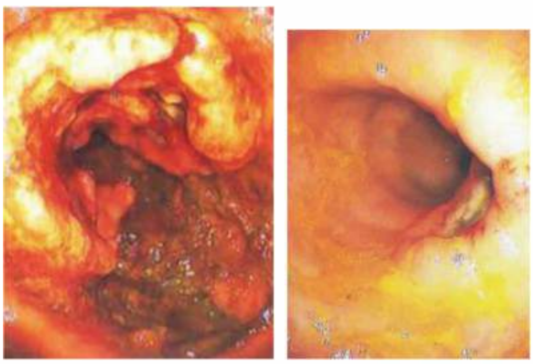

FIG 1 ● Rectal cancer before **(left)** and after **(right)** neoadjuvant chemoradiation. This patient had a good response to treatment.

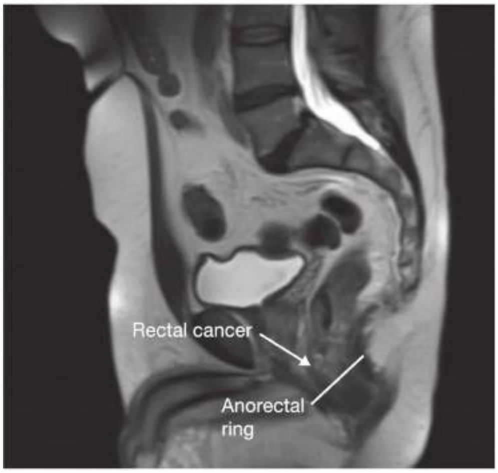

FIG 2 ● Pre–neoadjuvant treatment MRI of a rectal cancer suitable for TATA.

SURGICAL MANAGEMENT

Preoperative Planning

- Neoadjuvant chemoradiotherapy is the key to successful sphincter preservation. The radiation therapy is a high-dose, long-term treatment to maximize tumor downstaging. Preferred radiation dose is 5,580 cGy, with 4,500 cGy to the entire pelvis with a boost to the presacral area and tumor location, delivered over the course of 5 weeks. Concurrent chemotherapy based on 5-fluorouracil (5-FU) either orally or intravenously increases the sensitivity of the tissues to radiation, enhancing efficacy (**FIG 3**).
- Neoadjuvant chemoradiation apoptotic effect occurs only at cell division. Maximum cytotoxic effect is 8 to 12 weeks after completion of treatment. Extending the interval between completion of radiation therapy and surgery up to 8 to 12 weeks therefore gives the patient the fullest benefit of the treatment, maximizing downstaging and extending the options for sphincter preservation.
- Decision regarding sphincter preservation should be based on the status of the cancer *after* completion of chemoradiotherapy. All patients, except those whose cancers remain fixed at or below the 3-cm level are offered sphincter preservation.
- Accepting a distal margin of resection from the cancer as small as 5 mm is necessary for very low tumors. This does not adversely affect outcome. Dissection is started transanally to assure a known distal margin. This is particularly helpful in the postirradiated rectal cancer where there is often only a small scar left, making decisions as to where a stapler would be placed from above difficult.
- The patient should receive a bowel preparation the day before surgery.
- Perioperative antibiotics and deep vein thrombosis prophylaxis should be given.

Positioning

- The operation has both an abdominal part and perineal part. The surgeon and first assistant stand between the legs during the perineal part. For the abdominal part, which is performed laparoscopically, they stand at the patient's right side. It is important that the surgical team is free to move around the patient. The laparoscopic equipment and energy sources are positioned to patient's left (**FIG 4**).
- The patient is placed in the lithotomy position with the buttocks extending 2 cm over the padded table edge. Both arms are padded and tucked. The chest is taped to the table to further prevent slipping of the patient as the table is maneuvered. The Foley catheter is taped over the right thigh. The abdomen is prepped with Betadine and the perineum with povidone-iodine. In women, the vagina is prepped with povidone-iodine.

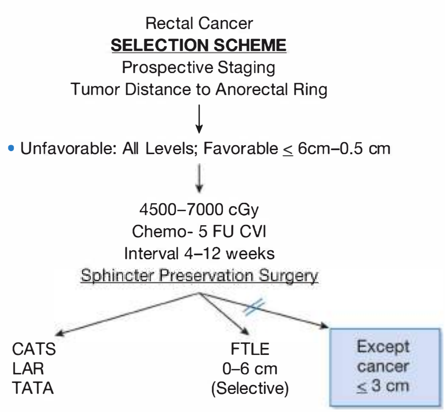

FIG 3 ● Author's treatment algorithm for low rectal cancers (distal 3 cm of the true rectum). cGy, centiGray; 5-FU, 5-fluorouracil; CVI, continuous venous infusion; CATS, combined abdominal trans-sacral rectal resection; LAR, low anterior resection; TATA, transanal transabdominal rectal resection; FTLE, full-thickness local excision.

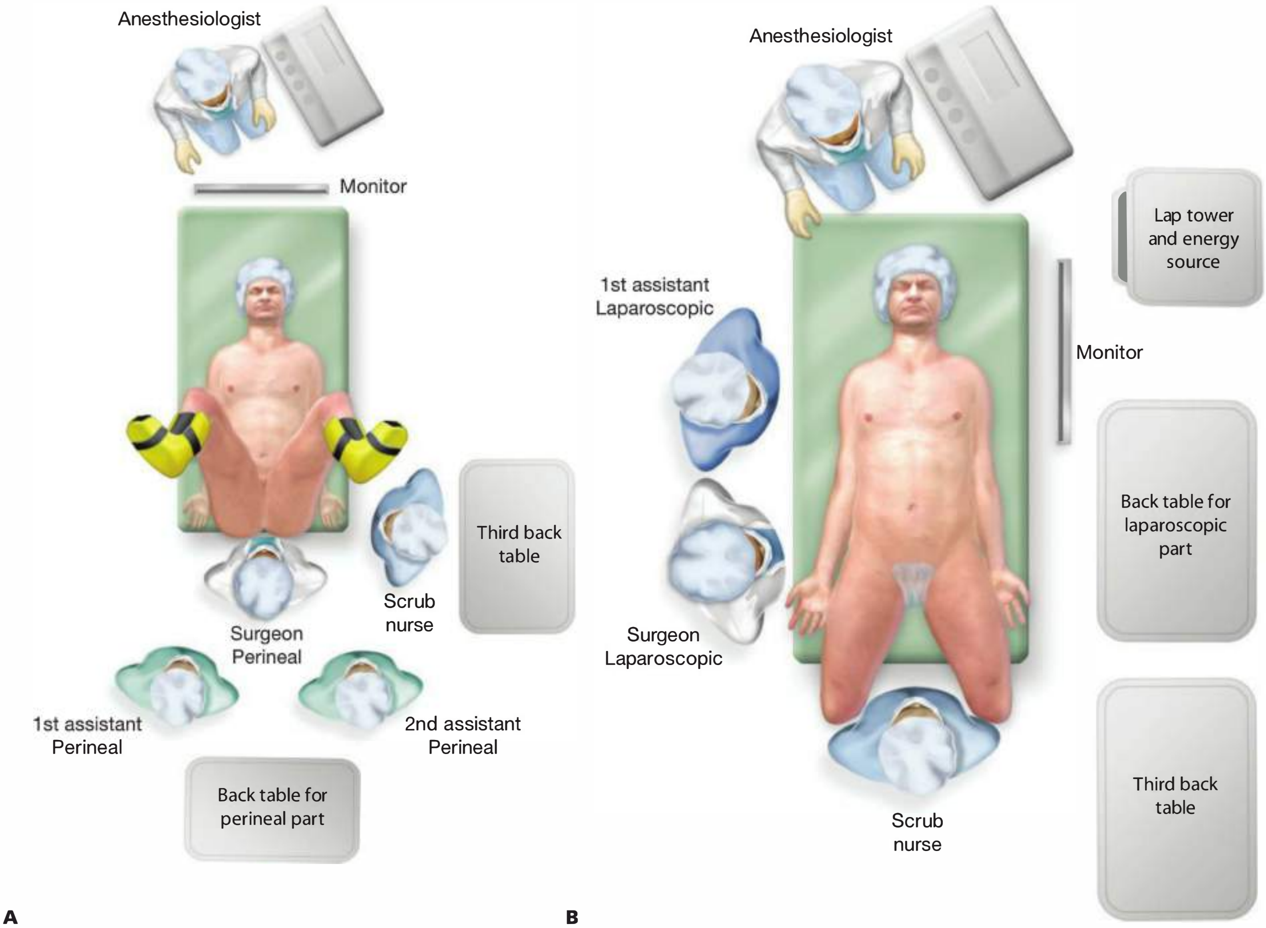

FIG 4 ● **A,B.** Operating room setup.

TRANSANAL, INTERSPHINCTERIC RESECTION OF RECTUM

- Place a sponge soaked in povidone-iodine in the anal canal or irrigate it with povidone-iodine. In order to minimize the possibility of dislodging tumor cells, avoid digitalizing the canal after this.
- To allow visualization of the dentate line, Alice-Adair clamps are placed circumferentially around the anal canal to evert the anal tissue (**FIG 5**).
- The dentate line is incised circumferentially with electrocautery through the mucosa, thus defining the distal resection margin. This is a critical step to avoid radial tearing later in the dissection (**FIG 6**).
- The Metzenbaum scissors are spread posterolaterally and slightly off the midline, perpendicular to the axis of the anus, to enter into the plane between the transected upper half of the internal sphincter and the underlying puborectalis. This plane is developed circumferentially (**FIG 7**).
- Alice-Adair clamps are applied to the transected distal portion of the rectum to facilitate retraction. One never applies more than four clamps at a time, as this is usually too bulky. The shiny, glistening white aspect of the puborectalis is identified using the scissors. Visualization of this white tissue is the key to ensuring that the dissection is carried out in the proper plane (**FIG 8**). Placing a small Deaver retractor allows development of the plane between the rectum and the levator ani complex. Once the proper plane is entered, the dissection is essentially bloodless.
- The sharp dissection is brought around anteriorly (**FIG 9**). In women, a finger in the vagina allows palpation of the vaginal wall, and it is generally not a problem to avoid this structure. In men, one has to be careful when proceeding anteriorly to avoid taking the dissection anterior to the prostate. The length of dissection cephalad is up to the seminal vesicles in men and to the cervix in women. This dissection is carried circumferentially until the rectum is fully mobilized (**FIG 10**).
- The rectum is oversewn in a watertight fashion with a 0-Vicryl stitch, turning the edges inward to avoid potential spilling of feces or tumor cells during the abdominal part of the procedure. The pelvis is irrigated from below with saline; a sponge is placed through the anus with an occlusive dressing in the perineum.

FIG 5 ● To allow visualization of the dentate line, Alice-Adair clamps are placed circumferentially around the anal canal to evert the anal tissue.

FIG 6 ● Line of incision of the mucosa at the dentate line.

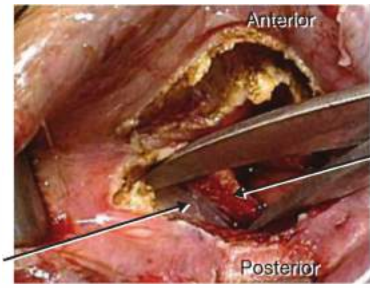

FIG 7 ● The Metzenbaum scissors are spread slightly off the midline, perpendicular to the axis of the anus, to enter into the plane between the transected upper half of the internal sphincter and the underlying puborectalis. This defines the circumferential resection margin.

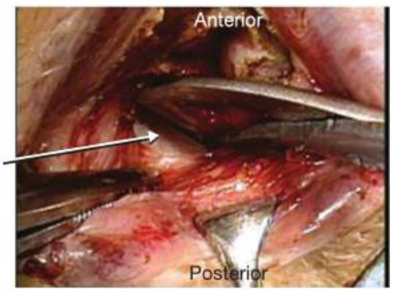

FIG 8 ● The shiny, glistening white aspect of the puborectalis is identified using the scissors. Visualization of this white tissue is the key to ensuring that the dissection is carried out in the proper plane.

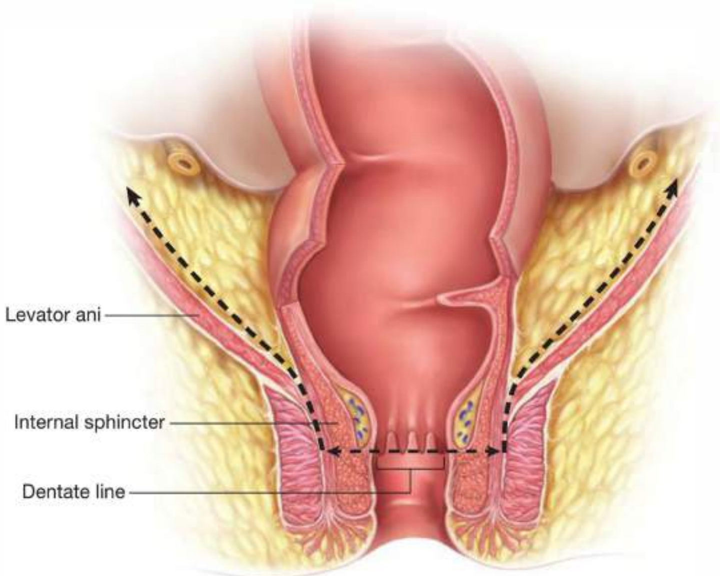

FIG 9 ● The drawing shows the lines of pelvic dissection.

FIG 10 ● The distal rectum is fully mobilized.

ABDOMINAL LAPAROSCOPIC PROCTOSIGMOIDECTOMY

- The patient's knees are lowered from full lithotomy so that they are flat to the abdomen to allow laparoscopic access to the abdomen and particularly the splenic flexure. The surgical team changes gowns and gloves. Five ports are placed as follows: (1) 5-mm port 20 cm above the pubic symphysis; (2) 12-mm port at the height of the umbilicus lateral to the rectus sheath; (3) 12-mm port in the right fossa, a hands width above the pubic tubercle; (4) 5-mm port suprapubically; and (5) 5-mm port in the left fossa (FIG 11).
- A careful exploration is carried out to rule out metastatic disease.
- The patient is placed in reverse Trendelenburg position of 15 degrees with the right side down 10 degrees. The monitor is placed at the left shoulder and the surgeon and assistant stand at the patient's right side (FIG 4).
- The first operative step is releasing the splenic flexure. The surgeon works with a bowel grasper in the left hand in port 2 and a LigaSure in the right hand in port 3. The 5-mm camera is in port 1. The gastrocolic ligament is identified and opened at the level of the middle epiploic perforating artery to enter the lesser sac. The gastrocolic ligament is divided laterally toward the lower pole of the spleen (FIG 12). Next, the lateral attachments of the flexure are taken down, using the epiploic to retract the colon medially. The splenocolic ligament is divided

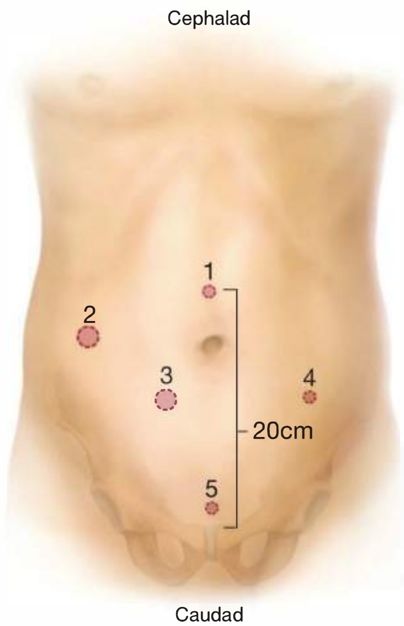

FIG 11 ● Port placement for the abdominal (laparoscopic) phase of the operation. Five ports are placed as follows: *(1)* 5-mm port 20 cm above the pubic symphysis; *(2)* 12-mm port at the height of the umbilicus lateral to the rectus sheath; *(3)* 12-mm port in the right fossa, a hands width above the pubic tubercle; *(4)* 5-mm port suprapubically; and *(5)* 5-mm port in the left fossa.

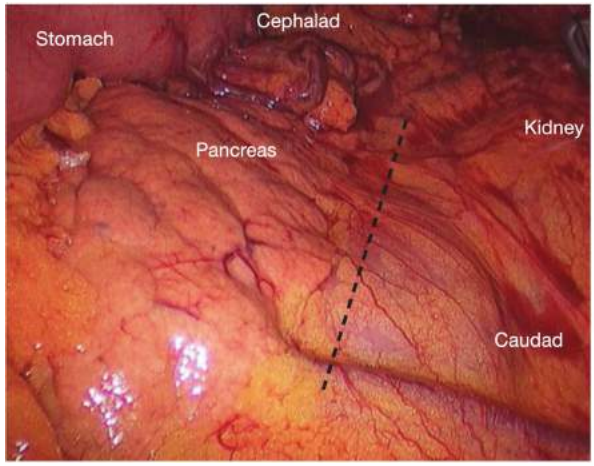

FIG 13 ● An incision is made in the peritoneal sheath of the mesentery of the transverse colon 1 cm below the inferior border of the pancreas.

and the tail of pancreas identified. Finally, an incision is made in the peritoneal sheath of the mesentery of the transverse colon 1 cm below the inferior border of the pancreas (**FIG 13**). The avascular space between the fascia of Toldt and Gerota's fascia is entered and the colonic mesentery is peeled off the Gerota's fascia. The splenic flexure is now fully mobilized and the retroperitoneal structures are visualized (**FIG 14**).

- The second step is repositioning the small bowel to gain access to the pelvis and vasculature. The patient is placed in steep Trendelenburg position (20 degrees); the right side remains down. The camera is changed to a 10-mm, 30-degree scope and moved to port number 2 and the surgeon's right hand to port number 1. The omentum is placed over the transverse colon; the small bowel is swept out of the pelvis and is placed in the right upper quadrant to expose the ligament of Treitz and the inferior mesenteric artery (IMA). The junction of the descending and sigmoid colon is marked with a suture to determine the level of transection to be performed later.

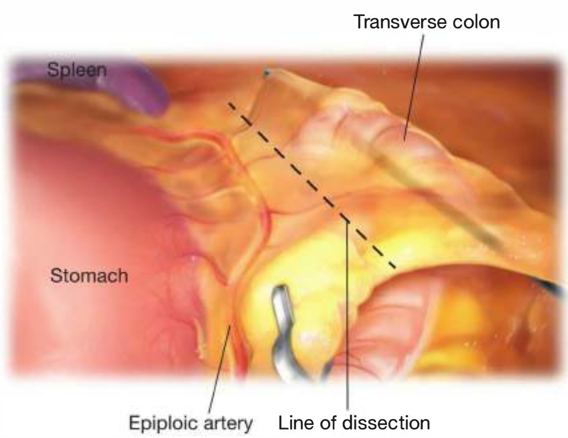

FIG 12 ● The gastrocolic ligament is identified and opened at the level of the middle epiploic artery to enter the lesser sac. The gastrocolic ligament is divided laterally toward the lower pole of the spleen.

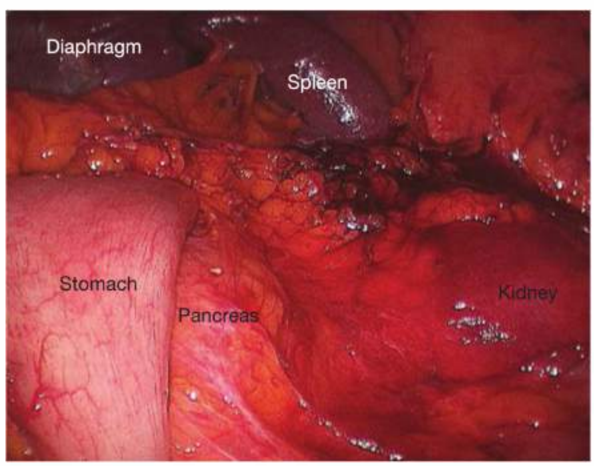

FIG 14 ● Once the splenic flexure is fully mobilized and the colonic mesentery is peeled off Gerota's fascia, the structures of the retroperitoneum can be visualized.

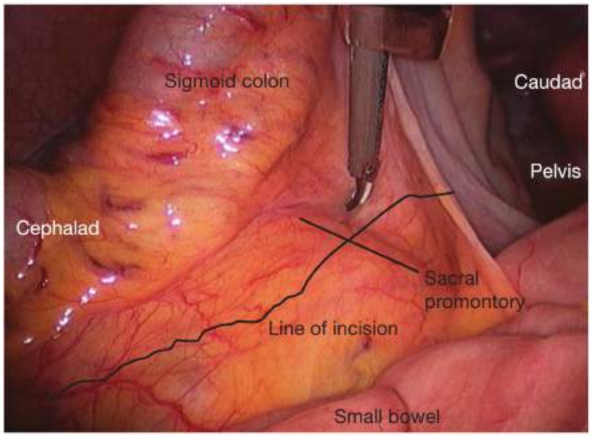

FIG 15 ● Point of incision at the sacral promontory. The peritoneum is incised at the level of the promontorium of the sacrum and opened down to the right pararectal sulcus and cephalad along the aorta toward the ligament of Treitz.

- The third step is a high ligation of the IMA. The right iliac artery and the left ureter are recognized. The peritoneum is incised at the level of the promontorium of the sacrum and opened to the right pararectal sulcus distally and then cephalad along the aorta toward the ligament of Treitz (**FIG 15**). Blunt dissection is used to lift the mesentery of the proximal rectum off the retroperitoneum, revealing the left ureter (**FIG 16**). The nerves of the hypogastric plexus are the key to the dissection. They are identified and preserved intact under the IMA and gently pushed down toward the aorta. The base of the IMA is skeletonized circumferentially and the artery is divided with an energy device, clips, or endovascular stapler (**FIG 17**).

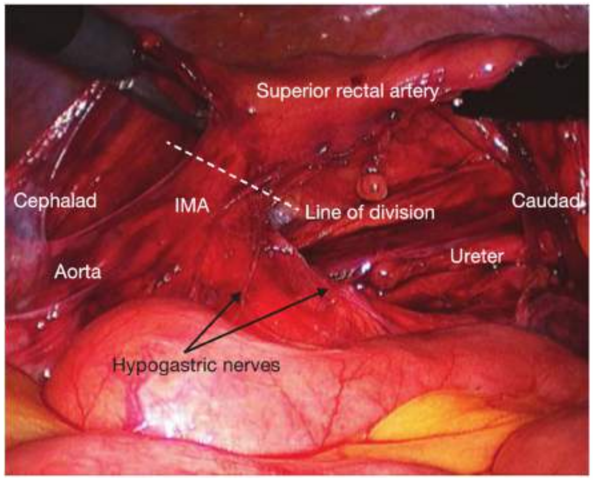

FIG 17 ● The nerves of the hypogastric plexus are the key to the dissection. They are identified under the IMA and gently pushed down toward the aorta and preserved. The base of the IMA is skeletonized circumferentially and the artery is divided along the *dotted line*.

- The fourth step is the high ligation of the inferior mesenteric vein (IMV) (**FIG 18**). The IMV is dissected and divided at the level of the ligament of Treitz, where it dives under the duodenum to join the splenic vein. The remaining mesentery of the descending and sigmoid colon is then lifted off the Gerota's fascia, completing the medial to lateral mobilization of the colon.
- The fifth step is the mobilization of the lateral attachments of the descending and sigmoid colon. This is relatively easy as the majority of the dissection has already

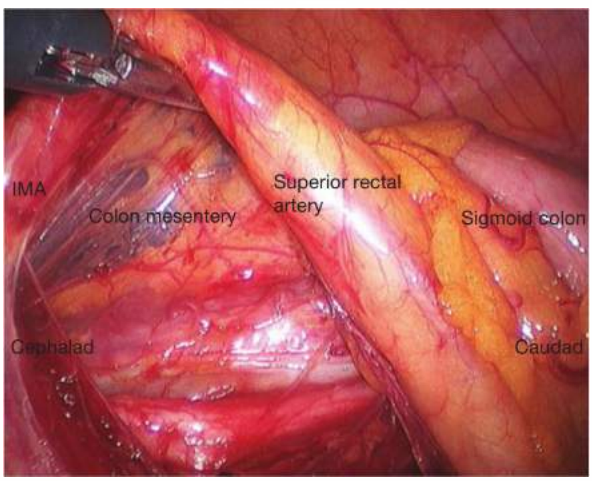

FIG 16 ● Blunt dissection is used to lift the mesentery of the proximal rectum off the retroperitoneum, revealing the left ureter.

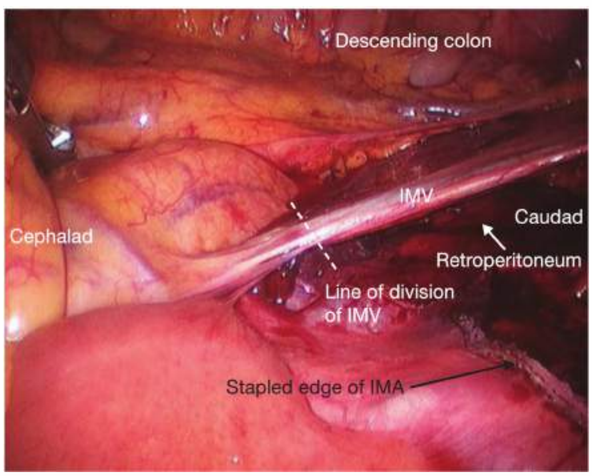

FIG 18 ● High IMV transection. The IMV has been lifted up along with the mesentery of the descending colon and is transected *(dotted lines)* at the level of the ligament of Treitz.

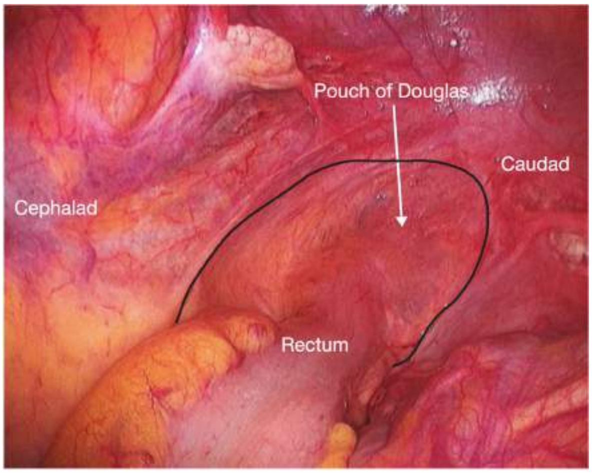

FIG 19 ● The peritoneum of the rectum is incised to open the box circumferentially, going down the left and right pararectal sulcus and anteriorly across the pouch of Douglas.

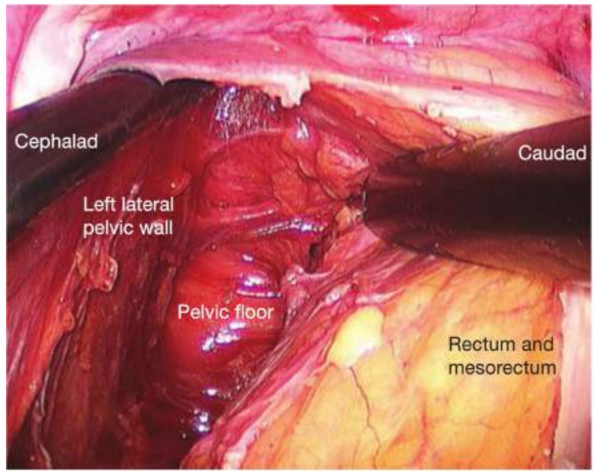

FIG 21 ● The lateral dissection is brought around the left (shown here) and right sides.

been done in a medial to lateral fashion. Starting at the pelvic brim, the peritoneum in incised up to the previous mobilization of the splenic flexure and a connection made with the dissection from the medial side.

- The sixth step is the total mesorectal excision (TME) of the rectum. To accomplish this laparoscopically, a few key points are made. First, the remaining peritoneum of the rectum is incised to "open the box" circumferentially, going down the left and right pararectal sulcus and anteriorly across the pouch of Douglas or the rectovesical fold (**FIG 19**). In anteriorly based lesions, this incision is a centimeter higher. The LigaSure is exchanged for Endo Shears with electrocautery attached to allow for finer dissection. The dissection is carried posteriorly along the mesorectal plane first (**FIG 20**), then brought around the right and the left sides (transection of the lateral rectal ligaments) (**FIG 21**), and is then finished anteriorly (**FIG 22**). This is repeated, alternating sides, as the dissection carries on deeper into the pelvis. To facilitate this, three-dimensional retraction is created by the surgeon retracting the rectum and assistants applying anterior and lateral retraction from the two 5-mm ports (**FIG 23**). The dissection is kept in the plane outside the mesorectal fascia, taking care not to taper the specimen and it is continued until it meets the previous perineal dissection from below. The sponge that was placed previously can be seen (**FIG 24**). The nerves are followed to direct the dissection in the proper plane.
- The rectum is delivered out the pelvis and the completeness of the dissection checked as well as the hemostasis (**FIG 25**).

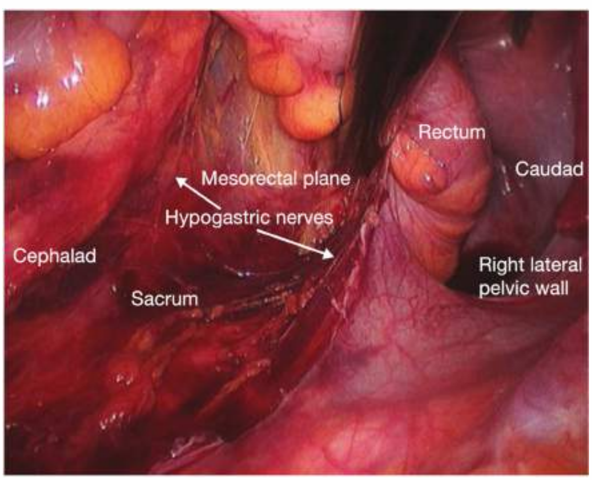

FIG 20 ● The dissection around the rectum is carried posteriorly first.

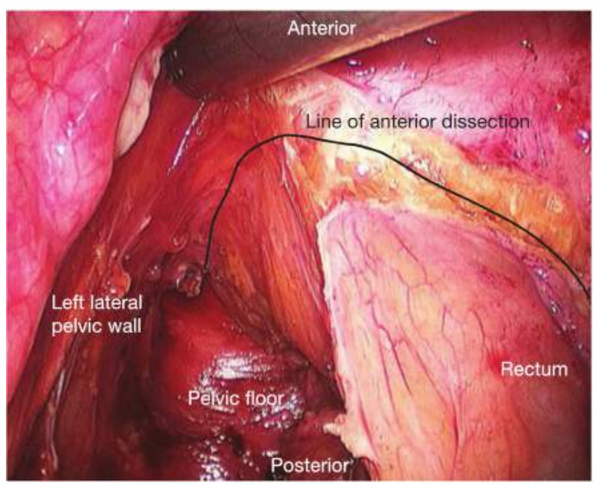

FIG 22 ● The dissection around the rectum is finished anteriorly.

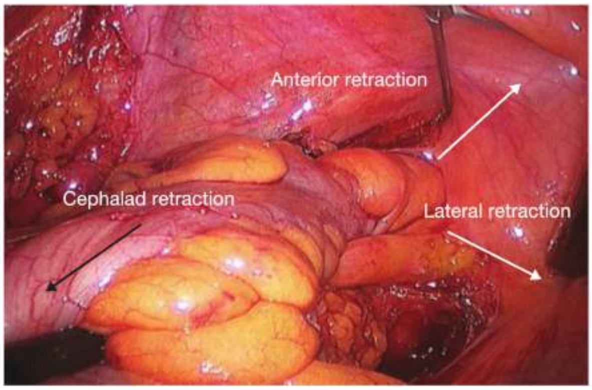

FIG 23 ● To facilitate the dissection around the rectum, three-dimensional retraction is created by the surgeon retracting the rectum with the left hand and assistants applying retraction from the two 5-mm ports toward the sides and anteriorly.

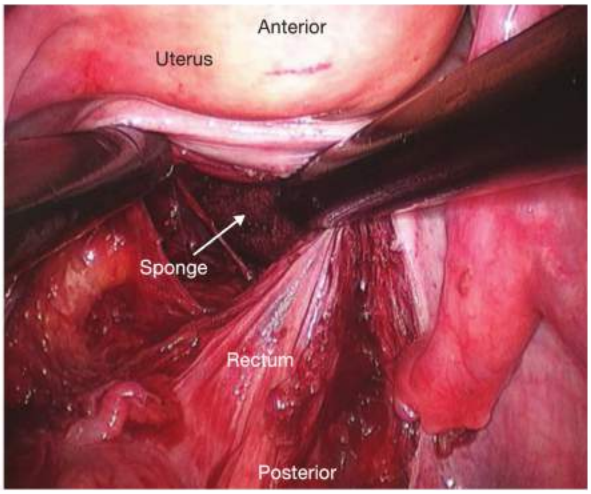

FIG 24 ● The dissection is continued until it meets the previous perineal dissection from below and the sponge that was placed previously can be seen.

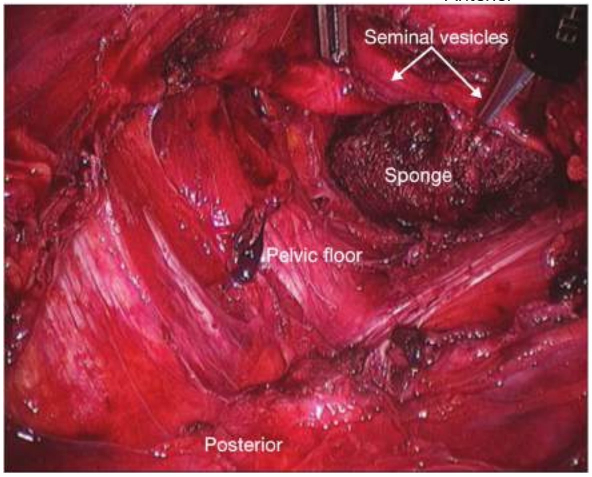

FIG 25 ● The rectum is delivered out through the pelvis and the completeness of the dissection and hemostasis are checked.

COLOANAL ANASTOMOSIS

- The surgeon moves back to the perineum. The patient's knees are raised again. The sponge and the perineal occlusive dressing are removed from the anus.
- The specimen is pulled through the anus carefully under direct laparoscopic visualization to assure orientation and is transected at the marking suture previously placed between the sigmoid and descending colon (**FIG 26**).
- The coloanal anastomosis is hand sewn. This can be direct, or a colonic pouch can be created if there is adequate length. Small Deaver retractors are used for exposure. Full-thickness bites are taken through the descending colon wall and the transected lower border of the internal sphincter, including the overlying anoderm. Four corner sutures are placed at 12, 3, 6, and 9 o'clock positions and left untied until one or two full-thickness bites have been placed between each corner suture (**FIG 27**).
- The anastomosis is either a direct coloanal, side-to-end or a colonic J-pouch, depending on the patient's body habitus and amount of fat (**FIG 28**).
- Digital examination is performed to ensure there are no gaps and the anastomosis is patent.

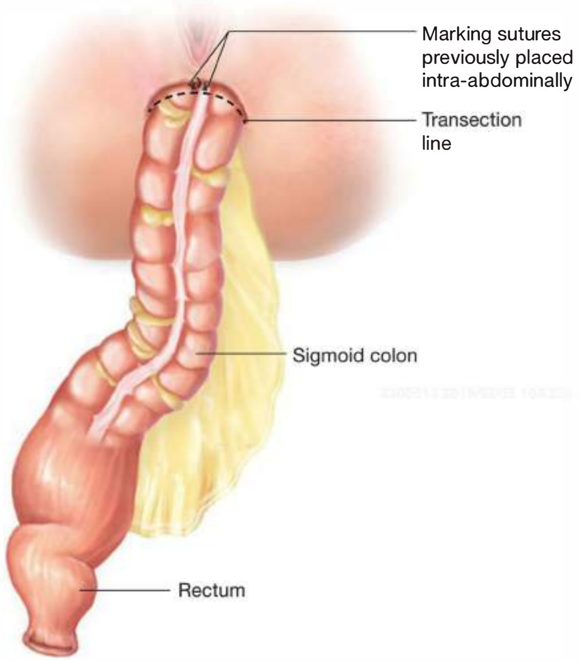

FIG 26 ● The specimen is pulled through the anus carefully under direct laparoscopic visualization to assure orientation and is transected along the *dotted line* at the previously placed marking suture.

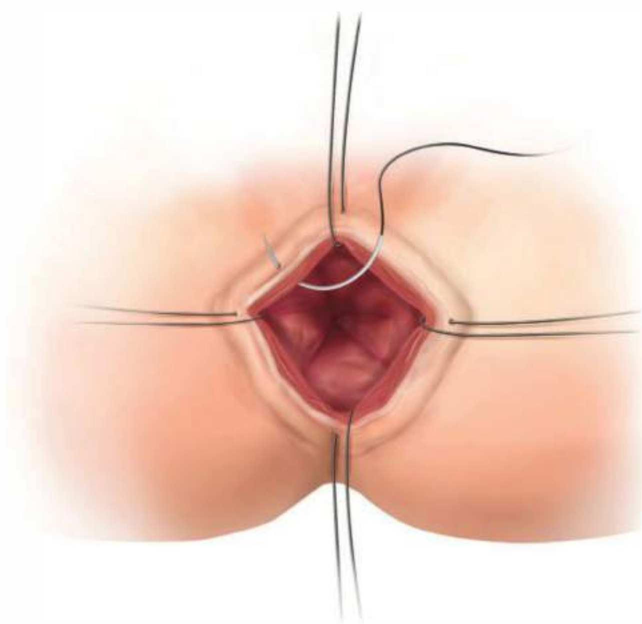

FIG 27 ● The coloanal anastomosis is hand sewn. This can be direct or a colonic pouch can be created if there is adequate length. Small Deaver retractors are used for exposure. Full-thickness bites are taken through the descending colon wall and the transected lower border of the internal sphincter, including the overlying anoderm. Four corner sutures are placed at 12, 3, 6, and 9 o'clock positions and left untied until one or two full-thickness bites have been placed between each corner suture.

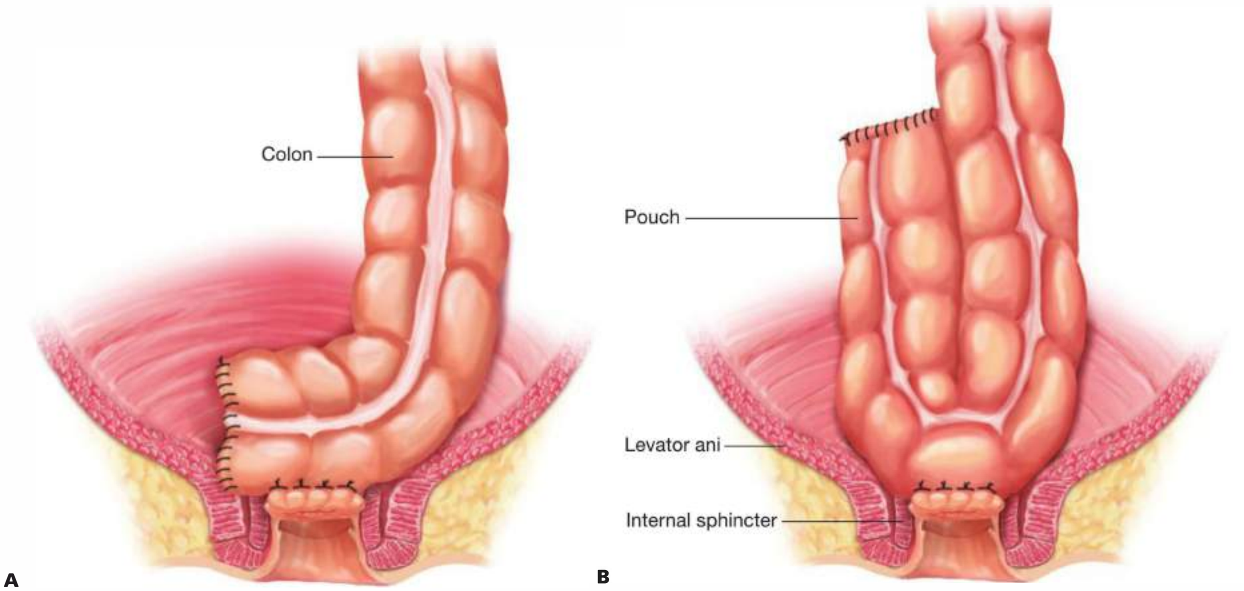

FIG 28 ● The anastomosis is either a direct coloanal (**A**), a side-to-end, or a colonic J-pouch (**B**).

CREATION OF STOMA

- The last step is bringing out a loop of ileum in preparation for a diverting loop ileostomy. A locked bowel grasper is used to grasp the ileum about 20 cm proximal to the terminal ileum. This loop is brought out at the site of port 3 or at the infraumbilical fat fold and a pin placed underneath it.
- The abdominal part of the procedure is then concluded. The insufflation air is evacuated through the trocars. The fascia at the 12-mm port sites is closed with 1-0 Vicryl suture and all skin incision with 4-0 Vicryl. Steri-Strips and dressings are applied. Finally, the diverting loop ileostomy is matured; stoma plate and bag applied (**FIG 29**).

FIG 29 ● The abdomen after all port sites have been closed and the diverting stoma has been matured.

PEARLS AND PITFALLS

Surgical decision making	■ Final decision on sphincter preservation based on *post* chemoradiation cancer characteristics
Patient selection	■ Patients whose cancer is not fixed to the levators in the distal third of the rectum after chemoradiation are offered sphincter preservation ■ Adequate baseline continence ■ Clinical staging and careful documentation of tumor location and size
Preoperative planning	■ Staging with MRI/ERUS, CT, physical exam ■ Full colonoscopy ■ Neoadjuvant chemoradiation therapy
Intersphincteric dissection	■ Incise mucosa at dentate line, marking distal margin ■ Stay in the plane between the internal sphincter and the puborectalis sling—identified by glistening white of the puborectalis ■ Carry the dissection cephalad to the cervix in women and to the seminal vesicles in men
Rectosigmoid resection	■ Wide mobilization of the splenic flexure with freeing of the distal transverse mesocolon from the retroperitoneum ■ Full medial to lateral mobilization of the left colon ■ High transection of the IMA and the IMV ■ TME resection of rectum ■ Avoid urethra or venturing anterior to the prostate in men
Anastomosis	■ Maintain orientation when delivering specimen through the anus ■ Full-thickness bites with interrupted sutures ■ Can be colonic J-pouch, side to end, or direct coloanal

POSTOPERATIVE CARE

- No nasogastric tube is needed. Oral diet is resumed on the first postoperative day. Intravenous pain medications are given for the first 24 hours, transition to oral after that as tolerated. Antibiotics are continued for 10 days postoperatively due to the poor vascularity of the radiated tissue and the ultralow anastomosis.
- The diverting stoma is closed at 3 months postoperatively, after flexible sigmoidoscopy, digital exam, and barium enema show that the anastomosis is intact. If the patient needs adjuvant chemotherapy, stoma closure is usually postponed until after completion of therapy.
- Close follow-up is mandatory for at least 5 years, with physical exam, flexible sigmoidoscopy, CT, and CEA measurements. Physical exam is performed every 3 months for 24 months, then every 4 months for 24 months, and then every 6 months for 12 months. Endoscopic evaluation (flexible sigmoidoscopy) is performed every 6 months for 24 months, then every 12 months for the next 3 years.

OUTCOMES

- Local recurrence is low and equivalent to best results after abdominoperineal resection, or 2.5% (at the author's institute) to 7.0%. The same holds for distant recurrence with metastasis (8% to 10%).
- Five-year survival for all patients undergoing sphincter preservation surgery for rectal cancer at the author's institution is 97%. Others have reported numbers from 71% to 82%.
- Sphincter preservation has been achieved in 90% of patients who have been considered for the procedure.
- Function is adequate in the majority of patients. In a survey among patients at the author's institute, more than half of patients report no or little inconvenience due to incontinence and 80% would not prefer to have kept their stoma.

COMPLICATIONS

- Infections
- Bleeding
- Anastomotic leak
- Ischemic neorectum
- Incontinence
- Rectal prolapse
- Bowel obstruction

Chapter **32**

Abdominoperineal Resection: Open Technique

Curtis J. Wray   Stefanos G. Millas

DEFINITION

- The abdominoperineal resection (APR) refers to the operation for surgical treatment of distal rectal cancer. The APR, as originally described by Ernest Miles, involves the en bloc removal of the distal sigmoid colon, rectum, mesorectum, and anal canal. The operation uses both an abdominal and perineal approach.
- The APR requires a permanent end colostomy.

DIFFERENTIAL DIAGNOSIS

- This operation should be performed for those with a biopsy-proven diagnosis of malignancy (e.g., rectal or anal cancer, anal melanoma).

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients can present with tenesmus, rectal bleeding, rectal pain, and/or obstructive symptoms. Iron deficiency anemia is common at presentation and should always prompt a full colonoscopy in adult patients. Asymptomatic patients are typically diagnosed during screening colonoscopy.
- A thorough history should be obtained to assess the patient's functional status and to ensure sufficient physiologic reserve to undergo a major abdominal operation.
- A detailed family history is necessary to identify risk of an inherited colon and rectal cancer syndrome as well as risk for metachronous colorectal cancer.
- Digital rectal examination and rigid proctosigmoidoscopy can be performed in the ambulatory office and provide an accurate measurement of tumor distance from anorectal ring when compared to a flexible sigmoidoscopy. It also allows for evaluation of potential tumor fixation to the anal sphincter, pelvic side walls, sacrum, and/or urologic/gynecologic organs.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- A complete colonoscopy is obtained to evaluate for potential synchronous lesions that may have to be addressed at the time of surgery.
- A computed tomography (CT) scan of the chest, abdomen, and pelvis with intravenous and oral contrast should be obtained to assess for the presence of metastatic disease and the extent of tumor involvement within the pelvis.
- A magnetic resonance imaging (MRI) of the pelvis with intravenous (IV) contrast, or endorectal ultrasound performed by a qualified endoscopist, should be obtained for local tumor staging that will guide neoadjuvant chemotherapy and radiation as per National Comprehensive Cancer Network guidelines. Endorectal ultrasound has a higher sensitivity and specificity for tumor depth rather than lymph node involvement as compared to MRI. MRI allows for a better assessment of the circumferential margin at the mesorectal envelope.
- Laboratory blood work should include a complete blood count, serum electrolytes, liver function tests, and a carcinoembryonic antigen level as a baseline measurement that will be the reference for future cancer surveillance.

SURGICAL MANAGEMENT

- Although controversial, a margin less than 2 cm between the tumor and the anorectal ring will typically require an APR to ensure adequate tumor clearance and a satisfactory functional outcome.
- The patient may be placed in the lithotomy position and two surgical teams can work simultaneously. Alternatively, one team can perform both portions of the operation sequentially.

Preoperative Planning

- The patient should take a mechanical bowel preparation (GoLYTELY) the day before surgery.
- Recent evidence suggests an oral antibiotic preparation reduces postoperative surgical site infections.
- The colostomy site should be marked preoperatively with the patient in a sitting and supine position to ensure skin folds and crevices do not interfere with the appliance. Ideally, this marking should be performed by a qualified enterostomal therapist (wound, ostomy, and continence nurse [WOCN]).
- The stoma is marked over the (left) rectus abdominus, typically below the level of the umbilicus, though it can be placed above the umbilicus to facilitate a large pannus or high belt line.
- Tumor fixation by rectal exam is unreliable in determining whether or not a low rectal tumor is resectable.
- Tumor fixation within the pelvis does not necessarily imply infiltration of tumor into surrounding structures.
- Inflammatory adhesions within the pelvis does not portend a worse prognosis with respect to local recurrence or overall mortality.
- Ultimate decision on whether to proceed with an APR is made at the time of laparotomy.

Positioning

- The patient is placed in a modified lithotomy position with Allen stirrups.
- The thighs are level with the abdomen as this allows efficient placement of a self-retaining retractor without creating excessive pressure between the retractor and the patient's thighs (**FIG 1**).
- The perineum is positioned flush with the edge of the operating room table.

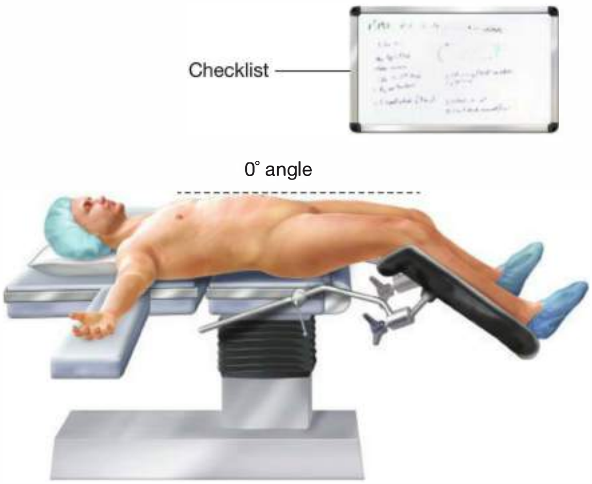

FIG 1 ● Patient positioning on the operating table. Note the horizontal position of the thighs to ensure free movement of surgeon's arms and hands. The perineum is flushed to the end of the table.

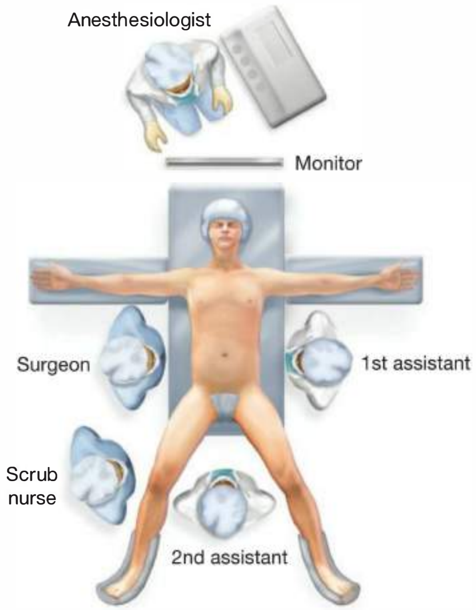

FIG 2 ● Team setup. For the abdominal phase of the operation, the surgeon stands by the patient's right side with his or her assistant standing at the patient's left side. A second assistant, if available, stands in between the patient's legs. The scrub nurse stands by the surgeon's right side.

- The pelvis is supported with a folded sheet to lift the entire perineum and facilitate exposure during the perineal dissection.
- The arms are placed in a neutral position and supported with suitable armrests.
- The anus is closed with a purse-string monofilament suture (0-Prolene with circle taper 1 [CT-1] Ethicon needle, or equivalent).
- For the abdominal phase of the operation, the surgeon stands by the patient's right side, with his or her assistant standing at the patient's left side. A second assistant, if available, stands in between the patient's legs. The scrub nurse stands at the surgeon's right side, by the patient's right leg (**FIG 2**). The surgeon and the first assistant will switch sides as necessary during the pelvic dissection.
- During the perineal phase, the surgeon and the first assistant will be situated in between the patient's legs, with the second assistant by the patient's right or left side.

EXPOSURE

- Exposure of the abdomen is obtained with a lower midline incision from the umbilicus to the pubic symphysis. A wound protector may be inserted to protect the wound from infectious and oncologic soilage (**FIG 3**).
- The abdomen should be fully explored for the presence of gross metastatic disease.
- Care should be taken to evaluate all peritoneal surfaces, the entire gastrointestinal tract, the omentum, and the liver.
- Any concerning lesions away from the primary tumor should be biopsied and evaluated by intraoperative cryosection.
- A self-retaining retractor is positioned to optimize exposure of the pelvis.
  - Two short Richardson attachments are used to retract the abdominal wall laterally, in a perpendicular orientation to the incision to avoid undue traction on the femoral nerves at the pelvic inlet (**FIG 4**).
  - A bladder blade is positioned at the inferior aspect of the incision to retract the bladder and uterus. A 2-0 silk, figure-of-eight suture through the fundus of the uterus can facilitate positioning the uterus behind the bladder blade.

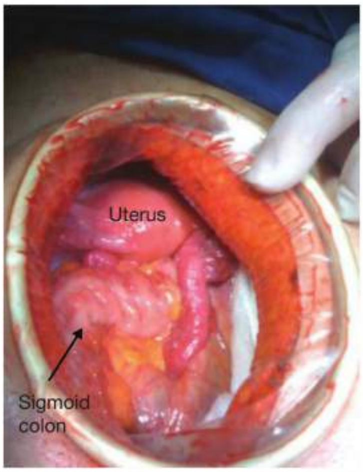

FIG 3 ● Placement of a wound protector protects the wound from infectious and oncologic soilage.

TECHNIQUES

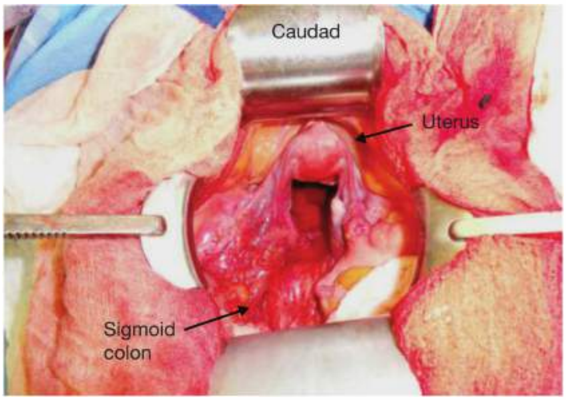

FIG 4 ● Exposure of the lower abdomen using a Bookwalter retractor. Two short Richardson attachments are used to retract the abdominal wall laterally, in a perpendicular orientation to the incision to avoid undue traction on the femoral nerves at the pelvic inlet. A bladder blade is positioned at the inferior aspect of the incision to retract the bladder and uterus. The small bowel is packed into the upper abdomen and held in place with malleable retractor.

- The small bowel is packed into the upper abdomen; this maneuver is facilitated by not extending the incision beyond what is required to access the origin of the inferior mesenteric artery.
- A malleable retractor attachment for the Bookwalter and moistened laparotomy pads aid in keeping the small bowel out of the pelvis.

Mobilization of Sigmoid Colon and Transection of the Inferior Mesenteric Artery

- The lateral peritoneal attachments to the sigmoid colon are divided, exposing the plane between the sigmoid mesocolon and the retroperitoneum (**FIG 5**).
- Mobilization of the sigmoid mesocolon allows for exposure and preservation of the left ureter and gonadal vessels, which should always be identified prior to dividing the inferior mesenteric artery at its origin (**FIG 6**).

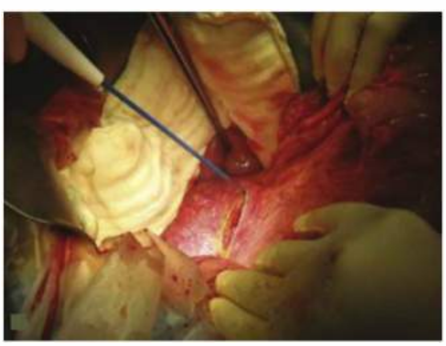

FIG 5 ● Sigmoid colon mobilization. With the descending colon retracted medially, the lateral peritoneal attachments are transected with electrocautery along the left paracolic gutter.

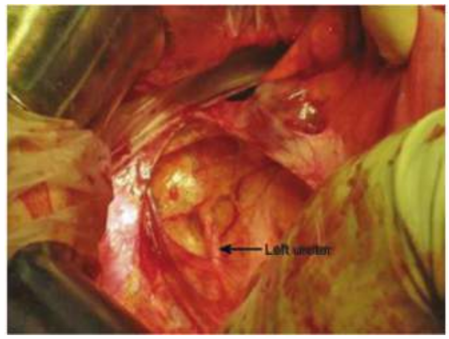

FIG 6 ● Identification of the left ureter. After full mobilization of the descending colon, the left ureter is exposed in the retroperitoneum. The surgeon is retracting the descending colon medially.

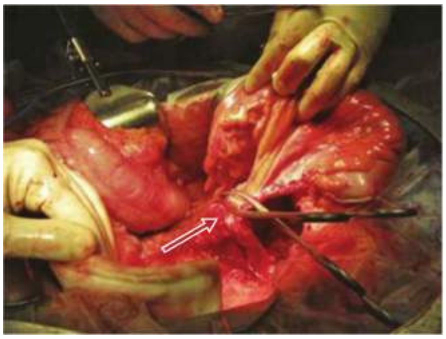
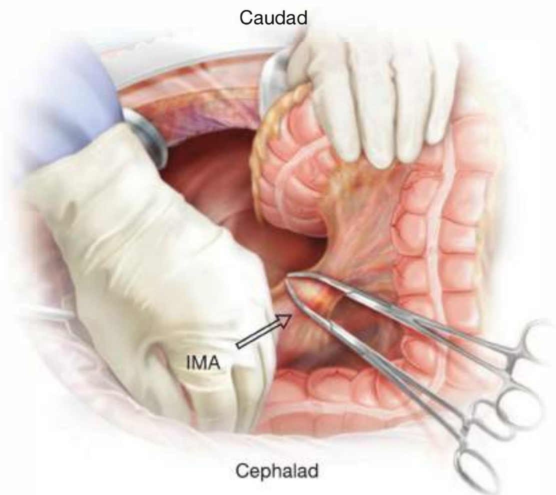
- The left ureter courses over the left psoas and is located medial to the gonadal vessels; it travels over the left iliac artery at its bifurcation at the pelvic inlet.
- Direct exposure of the left psoas often indicates an incorrect dissection plane where the ureter and gonadal vessels are mobilized medially with the sigmoid mesocolon.
- The peritoneal reflection on the right side of the sigmoid mesocolon is incised to complete the dissection of the mesentery away from the retroperitoneum. Again, care must be taken to maintain the ureter in its normal, anatomic position in the retroperitoneum.
- The origin of the inferior mesenteric artery (IMA) is identified at its origin off the aorta. The IMA is then ligated between Sarot clamps, incised, and doubly ligated with braided 2-0 suture (**FIG 7A,B**). High IMA ligation allows for an excellent lymph node harvest.
- The colon is then transected proximally between the sigmoid and descending colon segments with a linear stapler. The intervening mesentery is divided with an energy device.

Mobilization of the Rectum

- Once the sigmoid mesocolon is mobilized, dissection along the same anatomic plane between the mesentery and retroperitoneum is continued toward the pelvic inlet where the total mesorectal excision (TME) is initiated.
- The mesorectum is fully mobilized posteriorly using sharp dissection, typically with electrocautery. Care is taken not to injure the left and right hypogastric nerves posteriorly, as they can be intimately associated with the mesorectum (**FIG 8**).
- Dissection along the presacral plane is facilitated with anterior traction on the mesorectum provided by the St. Mark's retractors (**FIG 9A,B**).
- As the dissection proceeds posteriorly, the curve of the sacrum and coccyx needs to be followed (**FIG 10**), as inadvertent injury to the venous plexus of the sacrum posteriorly and hypogastric veins laterally can result that can be very difficult to control. Division of the rectosacral facia exposes the pelvic floor (levator ani).
- Once the rectum is fully mobilized posteriorly, the lateral mobilization can commence. This phase of the dissection



A



B

FIG 7 ● **A,B.** IMA division. The IMA is transected between clamps and will subsequently be ligated with heavy silk sutures.

is facilitated by the St. Mark's retractors, and the dissection proceeds along the avascular mesorectal plane that was initiated posteriorly. The lateral rectal ligaments are transected with an energy device (**FIG 11**).

- Care must be taken to avoid inadvertent entry into the mesorectum as well as injury to lateral pelvic sidewall structures, including the ureter at the pelvic inlet and branches of the internal iliac vein deeper within the pelvis. The appropriate plane is properly exposed with sufficient traction.

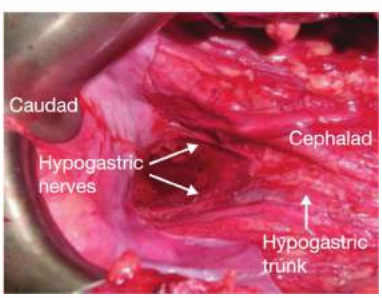


FIG 8 ● View of sympathetic plexus and origin of the left and right hypogastric nerves.

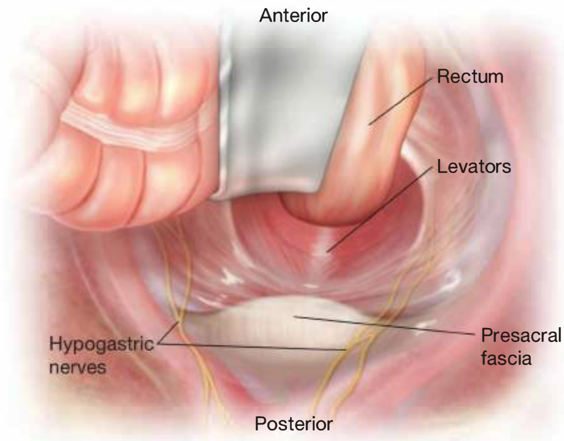
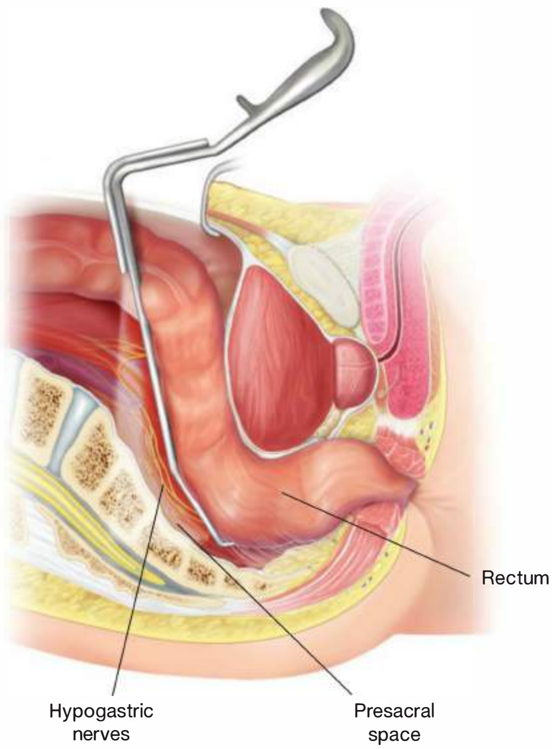


A



B

FIG 9 ● Posterior pelvic exposure with the lighted St. Mark's retractor. **A.** The rectum is retracted anteriorly, exposing the presacral space posteriorly. The hypogastric nerves are exposed and should be swept posteriorly and away from the mesorectum. This begins the superior and posterior portion of the total mesorectal excision. **B.** The presacral plane of dissection should be followed down to the levator muscles and the pelvic floor.

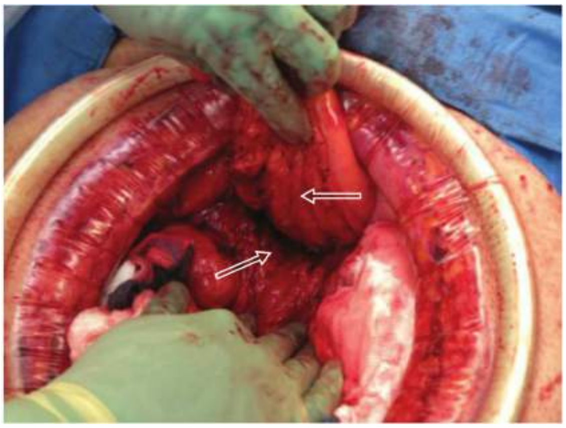


FIG 10 ● The posterior plane of dissection proceeds in a semicircular fashion to release the posterolateral rectal attachments and to allow a better anterior retraction on the rectum. This allows continued exposure of the posterior plane of dissection down to the pelvic floor and prevents vascular and nerve injuries along the lateral pelvic walls. Mesorectum *(top arrow)*; presacral fascia *(bottom arrow)*.

- The anterior dissection is initiated with division of the rectovesical reflection in men and rectovaginal reflection in women. Mobilization is continued anterior to Denonvilliers' fascia, exposing the seminal vesicles in men (**FIG 11**) and the vagina in women.
- For posterior tumors in men, consideration can be given to dissecting posterior to Denonvilliers' fascia as this may lower the risk of injury to the nervi erigentes with concomitant sexual dysfunction.
- For distal tumors overlying the anal canal, creating a "waist" near the tumor when dividing the levators has been associated with inadvertent bowel perforation, circumferential margin involvement, and local recurrence. An extended resection whereby the levators are resected at their origin can improve the aforementioned oncologic parameters.
- The posterior, lateral, and anterior dissections are carried down to the level of the levators circumferentially.

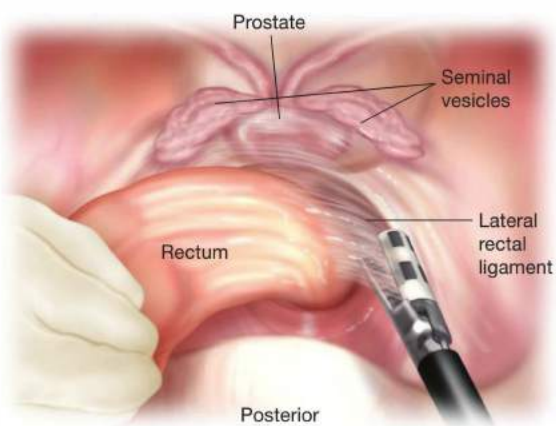

FIG 11 ● Transection of the lateral rectal ligaments and anterior pelvic dissection. Posterolateral retraction of the rectum allows for good exposure of the lateral rectal ligament (the right one is shown here), which can then be transected with cautery or with an energy device. The anterior dissection will then proceed behind Denonvilliers' fascia, in the space between the rectum posteriorly, and the prostate and seminal vesicles anteriorly.

Dissection of the Perineum

- This component of the operation can be performed concurrently with the abdominal dissection of the rectum.
- This technical description is applicable to a patient who has been placed in the lithotomy position and the legs are elevated in Allen stirrups. During the abdominal component of the operation, the Allen stirrups are lowered such that the thighs are level with the torso and abdomen, as this facilitates placement of the self-retaining retractor. For the perineal dissection, the Allen stirrups are elevated to fully expose the perineum. The self-retaining retractor should be repositioned if it places pressure on the thighs as they are elevated into position.
- The surgeon should have a separate electrocautery, with dedicated grounding pad, and a separate suction to allow the two operating teams to work independently. An instrument table should also be assembled for the perineal dissection, and the instruments should also be kept separate from those used in the abdomen and pelvis. The instrument set used is a major abdominal set, with the addition of two Gelpi retractors if they are not included in the set.
- A monofilament suture (0-Prolene) is used to close the anus prior to initiating the dissection; a large needle (CTX) is used to place two half-circle throws 1 cm lateral to the anal verge and the anus is closed by tying the suture (**FIG 12**). This helps prevent infectious and oncologic soilage of the perineal wound. The surgeon can perform this step at the beginning of the operation or when the decision to proceed with an APR is made.
- Two Gelpi retractors are placed in an "X" configuration such that the anus and perianal skin are adequately exposed for the incision and subsequent dissection (**FIG 12**).
- A circular skin incision is placed around the anal verge to include all of the anoderm as well as a margin of perianal

FIG 12 ● Closure of the anus with purse-string suture. This helps prevent infectious and oncologic soilage of the perineal wound.

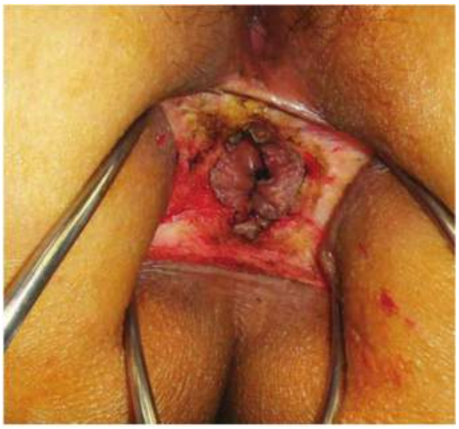

FIG 13 ● Perineal dissection: lateral incision around the anal canal. The incision is carried through the skin and subcutaneous tissues.

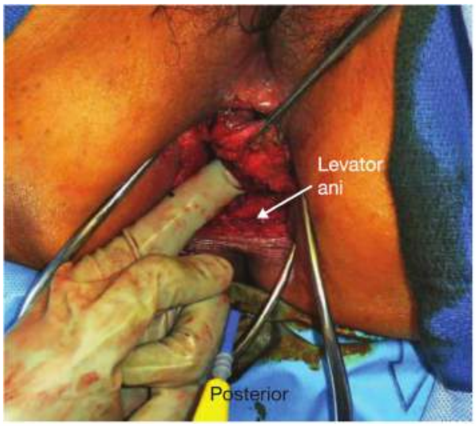

FIG 15 ● Perineal dissection: posterior palpation of coccyx during perineal dissection. The transection of the levators starts posteriorly anterior to the coccyx. The index finger of the surgeon is placed into the pelvis and hooked on to top of the levator muscle, pulling it into the field. This allows for safe transection of the levator muscle with electrocautery.

skin. The Gelpi retractors are repositioned inside of the skin incision to enhance exposure (FIG 13). A 3-cm margin (radius) around the closed anus is sufficient.

- Dissection should include the external sphincter muscle as the surgeon proceeds toward the levator ani (FIG 14). The lymphatic-bearing tissue surrounding the anal canal should be included with the specimen.
- The Gelpi retractors should be repositioned to maintain exposure. Handheld Richardson retractors can also be helpful and are held by the surgeon's assistant.
- As the external sphincter, perianal fat, and lymphatic tissue are mobilized, the coccyx should be palpated to ensure that dissection proceeds anterior to this structure. The surgeon in the abdominal field should place his or her hand posteriorly and serve as a guide for entry into the abdomen (FIG 15). A curved Mayo scissors is used to divide the anococcygeal ligament and levator ani muscle, which ultimately connects the abdominal and perineal dissections.
- The transection of the levators starts posteriorly anterior to the coccyx (FIG 15). The index finger of the surgeon is placed into the pelvis and hooked on to top of the levator muscle, pulling it into the field. This allows for safe transection of the levator muscle with electrocautery. The posterior and lateral component of the levator ani should be divided first, as the anterior dissection can be difficult, especially in anterior tumors.

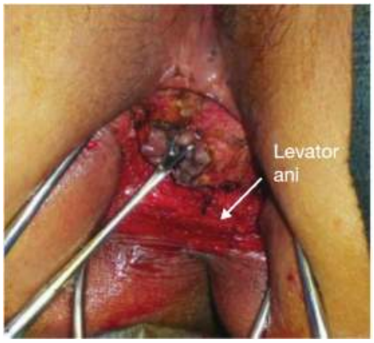

FIG 14 ● Perineal dissection: dissection through levator muscle complex.

- The surgeon's finger should then guide division of the perineal body anteriorly. In women, this component of the dissection is completed along the rectovaginal septum. In men, the surgeon should pay very close attention to the prostate gland anteriorly, as entry into the prostate can produce significant bleeding. Furthermore, if the dissection is too anterior, entry into the membranous urethra can occur. The appropriate plane of dissection is anterior to Denonvilliers' fascia as the abdominal and perineal dissections are connected.
- The specimen, now completely disconnected proximally and distally, is then extracted through the perineal wound. The rectum should exhibit an intact mesorectum with no distal "waisting" (FIG 16) in order to ensure excellent oncologic outcomes.
- Anterior tumors in men can lead to loss of the normal plane between the rectum and prostate or even invasion into the prostate. In this case, removing the prostate en bloc with the rectum may be the best way to achieve a satisfactory oncologic margin.
- Division of the levator ani circumferentially allows removal of the rectum through the perineum.
- The pelvis is irrigated with saline and hemostasis achieved before the perineal wound is closed. Persistent bleeding from the remaining levator ani, the prostate, or vagina may be controlled with well-placed suture ligatures.

Closure of Perineal Wound

- Once hemostasis is achieved, the levator ani are reapproximated with interrupted 0-Vicryl sutures. If the defect is large or insufficient levator ani muscle remains,

FIG 16 ● APR specimen. The rectum should exhibit an intact mesorectum *(A)* with no distal "waisting" *(B)* in order to ensure excellent oncologic outcomes.

consideration should be given to closure with a vertical rectus abdominus myocutaneous (VRAM) flap.

- The more superficial layers are sequentially closed with interrupted 2-0 Vicryl sutures and the skin can be reapproximated with interrupted 4-0 Monocryl sutures.
- A mobilized omental flap can be used to fill the pelvic cavity and help keep the small bowel in the upper abdomen. Closure of the peritoneum at the pelvic inlet can also facilitate keeping the small bowel in the upper abdomen.
- A closed suction drain is placed in the pelvis.

Creation of Descending Colostomy

- The site marked for the colostomy is identified. A Kocher clamp is used to lift the skin at the center of the mark and a circular skin incision is made approximately 2 cm in diameter.
- The subcutaneous fat is divided longitudinally, exposing the anterior rectus sheath, which is divided longitudinally as well. The rectus abdominus is bluntly separated and the posterior rectus sheath is divided longitudinally. Handheld Army-Navy retractors can facilitate exposure. The opening for the colostomy site should snugly accommodate two fingerbreadths.
- The descending colon should be sufficiently mobilized to allow a tension-free anastomosis between the colon and the skin. In patients with a thick layer of abdominal fat, additional length can be obtained by mobilizing the splenic flexure. If excessive tension at the skin persists, maturing the stoma as a loop-end can be the best option.
- Reinforcing the colostomy site with a retrorectus biologic mesh can decrease the incidence of parastomal hernia formation.
- The abdominal facia is closed in a standard manner.
- The staple line on the colon is removed with cautery and the stoma is matured to the dermis with interrupted 3-0 absorbable suture.
- Sterile dressings and a stoma appliance are placed such that the skin surrounding the stoma is completely protected with the wafer of the appliance.

PEARLS AND PITFALLS

Digital rectal exam and rigid proctoscopy	■ Should always be performed at initial consultation as lesion may decrease in size after neoadjuvant chemoradiation
Ureteral stent placement	■ Bulky pelvic tumors present a challenge and ureteral stents may assist in the identification of the ureters.
Pelvic dissection	■ Posterior first (along the presacral plane) ■ Lateral dissection/transection of the lateral rectal ligaments: Avoid injury to autonomic trunks and genital nerve branches that would lead to autonomic dysfunction postoperatively. ■ Anterior dissection: Staying inside of Denonvilliers' fascia reduces the incidence of injury to autonomic nerves to the prostate. Bulky anterior lesions may necessitate dissection anterior to Denonvilliers' fascia.
Perineal phase	■ Perform a circumferential dissection. Avoid "conization" of the specimen. The specimen should have an intact mesorectum without a "waist" effect distally.
Colostomy site	■ A location lateral to the rectus musculature increases the likelihood of peristomal hernia.
Perineal closure	■ Following neoadjuvant chemoradiation, a pedicled flap closure to the perineum warrants consideration in patients at high risk for wound breakdown (i.e., obese, diabetes, history of tobacco use).
Position in stirrups	■ Padded and positioned to avoid peroneal nerve injury
Omental flap	■ Save the omentum, mobilize the omental pedicles, and place omental flap into pelvic defect. This may prevent small bowel from becoming entrapped in the new "potential" space created in the pelvis.

POSTOPERATIVE CARE

- Recent evidence has demonstrated enhanced recovery after surgery pathways to improve a number of important postoperative outcomes following colorectal surgery.

OUTCOMES

- Survival from rectal cancer after multimodality treatment is dependent on disease stage. Overall 5-year survival is approximately 90% for stage I, 74% to 65% for stage II, and 81% to 33% for stage III of disease. Development of distant metastasis occurs in less than 10% in patients with stage I disease but increases up to 28% and 50% in patients with stages II and III rectal cancers, respectively.
- Local pelvic recurrence of rectal cancer is also dependent on tumor and nodal stage. Local recurrence is 5% or less for patients with stage I rectal cancer but increases to 15% for stage II disease and 22% for stage III disease. If a pelvic recurrence can be treated with a margin-negative surgical resection, 5-year survival can approach 40%. Often, this requires a pelvic exenteration, which demands a multispecialty surgical approach.

COMPLICATIONS

- Wound infections
- Incisional hernias
- Urinary/sexual dysfunction: important to preserve hypogastric nerves and parasympathetic ganglia intact
- Ureteral injury: critical to identify the left ureter prior to IMA transection
- Deep vein thrombosis (DVT): lower risk with use of adequate DVT prophylaxis
- Cardiac and pulmonary complications
- Pelvic abscess: reduced incidence with placement of an omental pedicle flap in the pelvis.
- Perineal wound breakdown is a notorious problem, especially in high-risk patients.

Chapter **33**

Abdominoperineal Resection: Laparoscopic Technique

Joël Leroy Didier Mutter Jacques Marescaux

DEFINITION

- An abdominoperineal resection, or APR, involves removal of the anus, the rectum, and part or all of the sigmoid colon along with the associated regional lymph nodes, through incisions made in the abdomen and perineum. The end of the remaining colon is brought out as a colostomy.
- The laparoscopic abdominoperineal amputation of the rectum is a totally laparoscopic intervention, as specimen removal is performed through a perineal excision without compromising the oncologic aspect of the surgical procedure.

INDICATIONS

- Indications for laparoscopic APR:
  - Rectal cancer: when unable to obtain a negative distal margin and/or in patients with poor sphincter function or severe comorbidities
  - Anal cancer: after failure of chemotherapy/radiation therapy or in the palliative setting
  - Inflammatory bowel disease (i.e., Crohn's with severe perianal disease)

PATIENT HISTORY AND PHYSICAL FINDINGS

- Most patients with rectal tumors generally present after an incidental finding during screening colonoscopy or with occult bleeding and anemia.
- A thorough history and physical examination should include the following:
  - Presence of rectal pain and/or tenesmus
  - Presence of obstructive symptoms
  - Description of anorectal function, with any fecal incontinence or leakage documented preoperatively
  - Documentation of urinary and erectile function/dysfunction
  - A detailed personal and family history of colorectal cancer, polyps, and/or other malignancies
- Physical examination should include the following:
  - Routine abdominal examination, noting any previous incisions
  - Digital rectal examination with assessment of sphincter function
  - Bilateral inguinal nodal examination
  - Rigid proctoscopy is arguably the most critical portion of the physical examination and is the key to proper patient selection of patients for an APR.
- Proctoscopy should be standardized and documented at minimum.
  - The distal and proximal extent of the lesion measured from the anal verge
  - Exact position of the lesion and extent of the rectal circumference involved
  - Presence or absence of fixation to perirectal structures

IMAGING AND OTHER DIAGNOSTIC STUDIES

- A colonoscopy with documentation of all polyps should be performed. Suspicious lesions should be tattooed to facilitate localization during surgery.
- Staging with endorectal ultrasound or rectal magnetic resonance imaging (MRI) should be performed to determine the need for neoadjuvant therapy and to plan operative strategy. A computed tomography (CT) of the chest, abdomen, and pelvis evaluates for potential metastases.
- A preoperative carcinoembryonic antigen level should be obtained.

SURGICAL MANAGEMENT

Preoperative Planning

- Informed consent is obtained preoperatively. The patient has been informed of the necessity to perform a definitive colostomy.
- The colostomy site is marked by a skin tattoo the evening before the intervention.
- We follow the Society of American Gastrointestinal and Endoscopic Surgeons' (SAGES) bowel preparation guidelines.
- Appropriate intravenous antibiotics are administered within 1 hour of skin incision.

Equipment and Instrumentation

- 10-mm, 0-degree camera (30-degree camera is optional) with high-resolution monitors
- Laparoscopic endoscopic scissors and a blunt tip, 5-mm energy device (10-mm in obese patients)
- Laparoscopic linear staplers

Positioning and Port Placement

Patient setup

- Patient setup is a major operative step.
- The patient should be adequately secured to the table.
- Adequate padding is essential to prevent nerve and venous compressions.
- The patient is placed in a supine position with a cushion placed underneath the left flank in order to obtain a moderate lateral decubitus, which will retract bowel loops toward the right part of the abdomen.
- A rotation to the right and a caudal head tilt (Trendelenburg position) will help to retract bowel loops by means of gravity.
- The patient's legs will then be spread apart in a semiflexion using adjustable leg supports to allow for a double abdominal and perineal access.
- One should control the perfect positioning of the buttocks at the distal edge of the table to allow for an easy access to the anal and perineal area.

FIG 1 ● Team setup. Surgeon *(1)*. First assistant *(2)*. Second assistant *(3)*. Scrub nurse *(4)*. Anesthesiologist *(5)*.

- The arms are padded and tucked alongside the body.
- An orogastric tube is inserted; it will be removed at the completion of the surgery.
- A Foley catheter is inserted; it will be left in place for 24 hours.

Team positioning

- This procedure is performed with two assistants and a scrub technician.
- A table is prepared for the abdominal part of the intervention.
- A second table is used for the peritoneal part of the operation.
- During the abdominal part of the procedure (**FIG 1**), the surgeon stands on the right flank of the patient, his or her first assistant lateral to the patient's right shoulder, and the second assistant in between the patient's legs. The scrub technician is then located to the right of the surgeon lateral to lower limbs.
- During the perineal part of the procedure, the entire team shifts toward the extremity of the table once the perineum has been exposed.
- The monitors are placed in front of the operating team and at eye level to improve ergonomics.

Port placement

- One 12-mm supraumbilical port (port A) is introduced first using a mini-open technique. It will be used to accommodate the camera (**FIG 2**).
- Two other ports, a 5-mm port in the right flank (port B) and a 12-mm port in the right iliac fossa (port C), are used as operating ports (**FIG 2**).
- The fourth port in the left flank at the level of the umbilicus is inserted through the rectus muscle (port D, 5 mm in diameter), where the colostomy will be performed (**FIG 2**).
- The last port introduced in the suprapubic area (port E, 12-mm in diameter) is used for pelvic retraction and for exposure of the sigmoid colon's root (**FIG 2**).
- Port fixation in the wall should be perfect in order to prevent any risk of parietal injury and to prevent increased operative times due to a loss in abdominal pressure. One should not hesitate to fix ports to the skin.
- Additional ports may be used in case of difficulty in exposure. In this case, a port will be positioned in the right hypochondrium (port F) to retract the ileocecal area. This is particularly useful in obese patients.

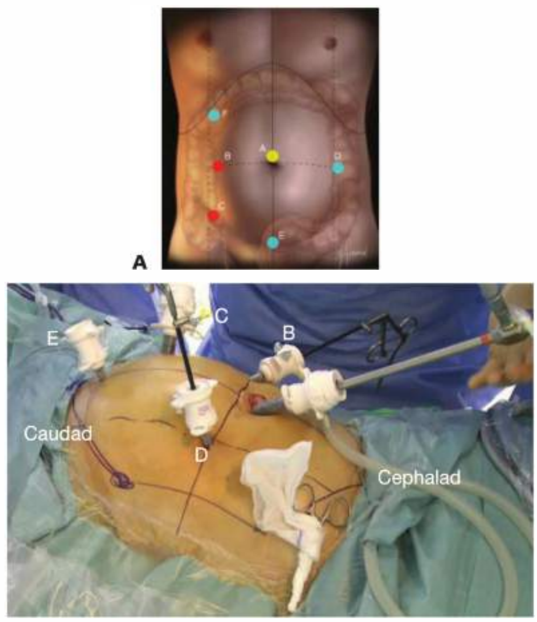

FIG 2 ● Port placement. **A.** Optical port *(A)*. Working ports *(B,C)*. Retracting ports *(D,E)*. Additional retracting port *(F)*. **B.** External view from the left side of the patient.

LAPAROSCOPIC ABDOMINOPERINEAL RESECTION

Exploration and Exposure

- The intervention is begun by an exploration of the abdominal cavity to locate the tumor and evaluate for possible metastases. It also allows to expose the pelvis and to evaluate the length and quality of the sigmoid loop, which will allow determining the type of mobilization of the left colon and of the splenic flexure.
- The tumor's identification may be necessary and especially so for tumors located proximally. Combined endoscopy may be required in cases where an effective preoperative marking could not be performed on the day before the intervention.
- Exposure is improved by placing the patient in a Trendelenburg position with the table tilted to the right.
- In women, exposure of the posterior pelvis and of the rectovaginal (Douglas') pouch can be obtained by direct or indirect suspension of the uterus by means of the T'Lift™ (VECTEC, France) tissue retraction device (**FIG 3A,B**) or suprapubic transparietal sutures (**FIG 4A,B**).
- Visceral obesity (in male patients) is more incapacitating than subcutaneous obesity (in female patients). The use of retractors is very helpful.

Primary Vascular Oncologic Approach to the Sigmoid Colon

- As for any oncologic surgical procedure, a primary vascular approach is the rule.

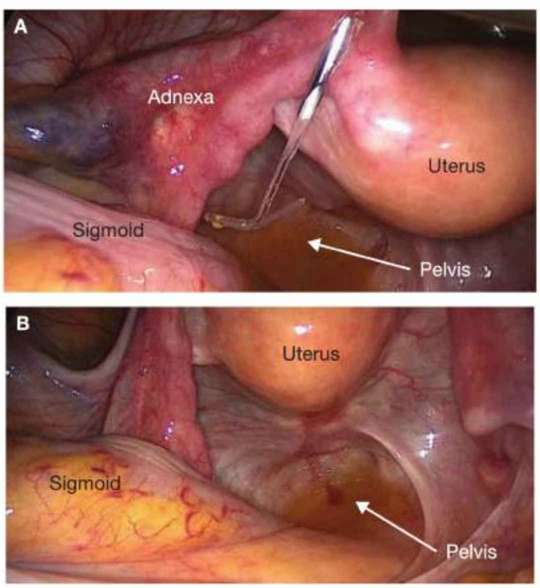

FIG 3 ● T'Lift™ tissue retraction system. **A.** T'Lift™ tissue retraction system passed through the round ligament. **B.** Pelvic exposure in women after bilateral uterine suspension with T'Lift™ tissue retraction system.

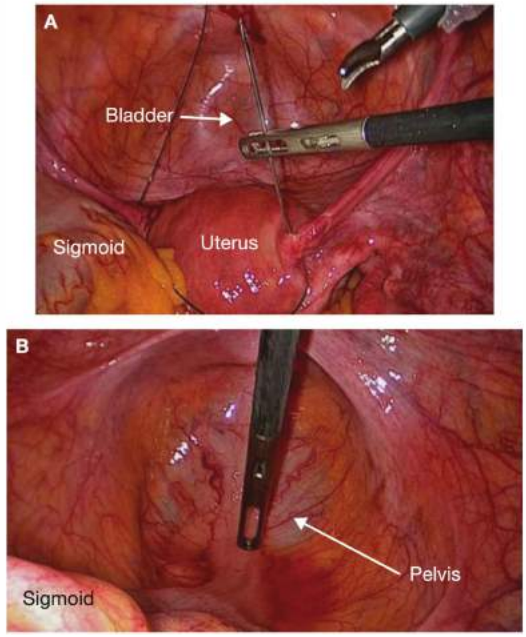

FIG 4 ● **A.** Transparietal suprapubic sutures for uterine suspension. **B.** Exposure of the pelvis in women after transparietal suprapubic suture uterine suspension.

- In rectosigmoid cancer, one should approach the inferior mesenteric vessels at their origin in order to perform an "en bloc" removal of all lymph nodes associated with the rectosigmoid junction (D3 resection). It does not prevent the potential preservation of the proximal inferior mesenteric artery (IMA) and of the left colic artery (LCA).
- We always start with a primary approach to the IMA. The inferior mesenteric vein (IMV) is then approached in order to prevent any venous overload related to the late ligation of the IMA.
- Once the root of the sigmoid mesocolon has been exposed, the left retroperitoneal space is opened by incising the posterior peritoneum from the anterior aspect of the promontory up to the left border of the duodenojejunal junction (ligament of Treitz) (**FIG 5A**).
- Once the retroperitoneum has been opened, dissection is initiated opposite the promontory on the posterior aspect of the inferior mesenteric vascular sheath (i.e., the superior rectal artery at this level). This step is facilitated by the anterior traction on the mesocolon, which induces the pneumodissection of the retrovascular space, thanks to intraabdominal carbon dioxide pressure.
- Dissection is carried on in contact with the vascular sheath cranially until the origin of the IMA on the aorta.
- The dissection is continued from caudad to cephalad in contact with the artery, which is skeletonized over approximately 2 cm in order to achieve ligation and division 1 or 2 cm away from the aorta (**FIG 5B**).

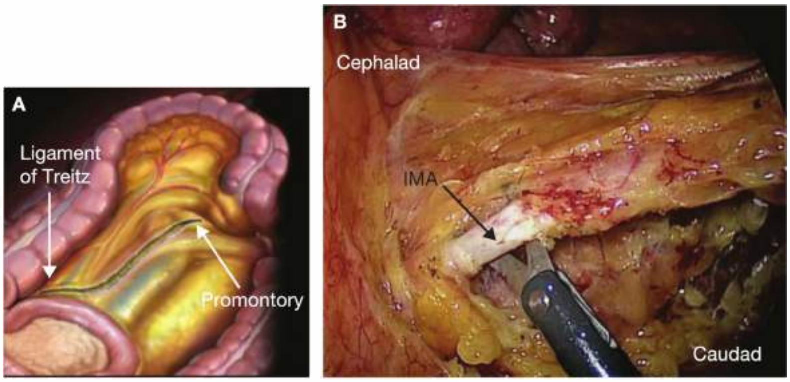

FIG 5 ● Dissection of the IMA. **A.** Opening of the left retroperitoneal space by incising the posterior peritoneum from the anterior aspect of the promontory to the ligament of Treitz. **B.** The IMA has been dissected 1 to 2 cm from the aorta.

- This technique allows preserving sympathetic nerve plexuses, which course along the aorta on its right anterior aspect.
- Division of the IMA is performed with the LigaSure™ vessel-sealing device using a ligation with a loop on the IMA stump.
- Once the IMA has been divided, the assistant standing between the patient's legs will grasp the artery using an atraumatic forceps introduced into the suprapubic port (port D) and apply anterior traction to ideally expose dissection planes in contact with the left posterior and lateral aspects of the artery.
- It helps to preserve the nerve plexus in contact with the artery, and notably the left sympathetic trunk of the neurovegetative system that will be progressively freed and parietalized.
- The next operative step will be to identify the IMV lateral to Treitz's flexure underneath the inferior edge of the pancreas (**FIG 6A**).
- The IMV is then transacted at the level of the ligament of Treitz with the LigaSure™ vessel-sealing device or in between clips.

Mobilization and Division of the Sigmoid Colon

- Our main objective is to perform a medial to lateral mobilization of the mesocolon.
- A medial to lateral mobilization of the sigmoid colon allows for traction on the upper rectum with a perfect exposure of the anterior, posterior, and lateral aspects of the rectum.
- Mobilization of the mesocolon is performed using a medial to lateral approach (**FIG 6A,B**) by opening the plane between Toldt's fascia anteriorly and Gerota's fascia posteriorly.
- The dissection is carried laterally until the posterior aspect of the descending colon is reached laterally.

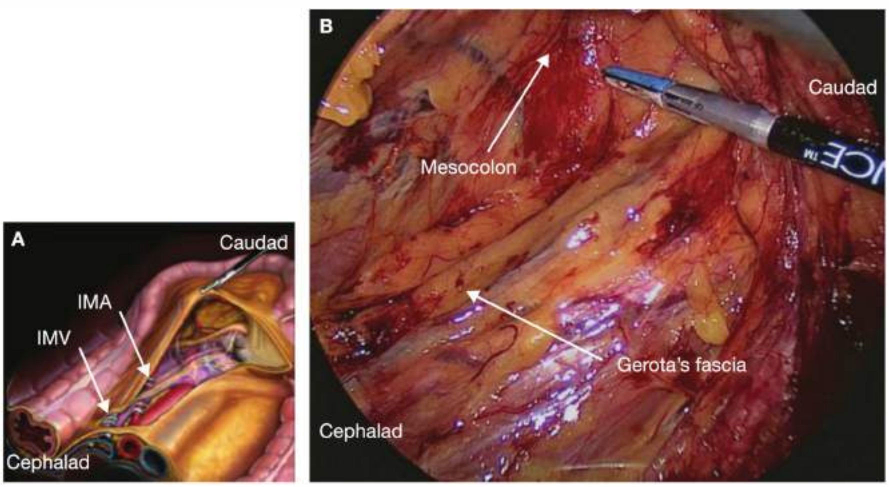

FIG 6 ● Medial to lateral mobilization of the mesocolon and IMV transection. **A.** IMV transection at the level of the ligament of Treitz. The IMA was previously transected off the aorta. The retroperitoneal structures are exposed. **B.** The mesocolon is separated from the retroperitoneum (Gerota's fascia) using a medial to lateral approach.

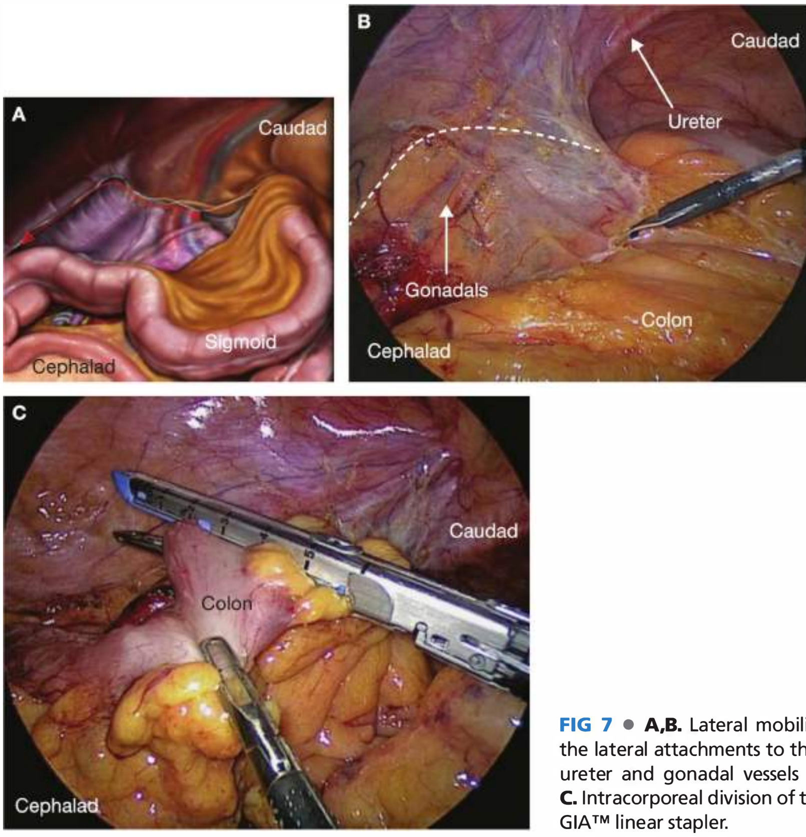

FIG 7 ● **A,B.** Lateral mobilization of the sigmoid loop by dividing the lateral attachments to the abdominal wall *(dotted line).* The left ureter and gonadal vessels are visualized in the retroperitoneum. **C.** Intracorporeal division of the proximal sigmoid colon with an Endo GIA™ linear stapler.

- Caudally, the dissection is carried toward the pelvic inlet. One should be cautious when in contact with the aorta as well as with the left iliac vessels where nerve rami of the superior hypogastric sympathetic plexus courses.
- The left ureter is identified during the dissection. It is located between the aorta and the genital vessels, well protected by Gerota's fascia.
- Mobilization of the sigmoid colon is completed with a division of its lateral attachments to the abdominal wall (**FIG 7A,B**).
- Division of the sigmoid loop is then performed intracorporeally with an Endo GIA™ linear stapler (**FIG 7C**).
- Mobilization of the splenic flexure is not performed routinely in APR cases.

Dissection of the Rectum According to the Total Mesorectal Excision (Heald's) Technique

- The principle of total mesorectal excision (TME) relies on the study of the embryologic development of the pelvis and of organs located within it. A surgical intervention cannot be envisaged without a detailed knowledge of pelvic and fascial anatomy (**FIG 8A**) that is essential to obtaining appropriate surgical specimens.
- Heald's principles rely on the dissection of the space located between the fascia propria of the rectum and the presacral fascia posteriorly, the lateral pelvic fascia laterally, and Denonvilliers' fascia anteriorly.
- In APR, the inferior limit of the dissection will depend on tumor's size and on its distal location.
- It is not recommended to dissect in contact with the tumor in a conical way but rather in a cylindrical manner. That is why distal dissection is performed using a perineal approach as proposed by Miles.

Posterior Dissection of the Rectum

- Once the sigmoid colon has been mobilized, a cranial and anterior traction is exerted on the rectum in order to expose the posterior aspect of the upper rectum.
- The presacral space (**FIG 8B,C**) is opened under the effect of traction and of pneumoperitoneum pressure, along with an atraumatic anterior retraction of the posterior rectal wall—a small swab at the tip of an atraumatic grasper is used. The tracts, which cross the space, are divided by means of a 2-mm electrode located at the tip of a LigaSure Advance™ vessel-sealing device.
- Dissection should be continued toward the pelvic floor. When progressing downward, dissection should continue

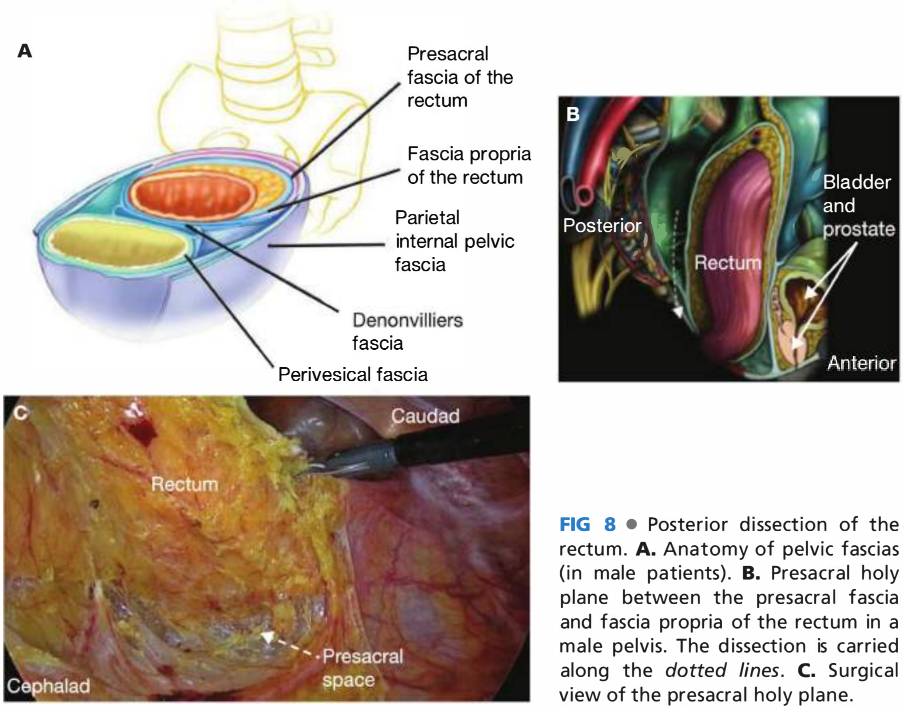

FIG 8 ● Posterior dissection of the rectum. **A.** Anatomy of pelvic fascias (in male patients). **B.** Presacral holy plane between the presacral fascia and fascia propria of the rectum in a male pelvis. The dissection is carried along the *dotted lines*. **C.** Surgical view of the presacral holy plane.

along the presacral fascia until it fuses with the fascia propria (Waldeyer's fascia).

- During this dissection, left and right branches of the inferior hypogastric plexuses can be observed. The lateral pelvic fascia protects them along the pelvic side walls (**FIG 9A**).

Lateral Dissections of the Rectum

- Cranial and medial retraction is maintained on the rectum in order to open the lateral pelvic space. This step is begun on the right side.
- The peritoneum is incised until seminal vesicles are reached. Under the effect of pneumoperitoneum pressure and of medial retraction, parietalization of the inferior hypogastric plexus and especially of the sacral branches (3rd and 5th sacral nerves, parasympathetic nerves responsible for male erections) is carried on (**FIG 9A**). Care is taken to avoid violating the parietal endopelvic fascia.
- Between three and five nerve branches can be observed crossing the space between the fascia and the rectum (**FIG 9B**). These branches will be divided after skeletonization in order to preserve the trunks and prostatic branches as much as possible (**FIG 9C**).
- The least traumatic dissection seems to be the one performed by means of the LigaSure Advance™ device with a 2-mm monopolar electrode, an energy level of 15 Watts being considered sufficient.

Anterior Dissection of the Rectum

- In order to open and dissect the space between the anterior aspect of the rectum and Denonvilliers' aponeurosis, minimal cranial and posterior traction should be maintained on the rectum; Denonvilliers' aponeurosis should be retracted anteriorly.
- Retraction is usually easy to perform in female patients. In male patients, especially obese ones, this step is more difficult. We recommend the use of specific retractors developed by KARL STORZ (Endo-Retractors™) in order to reproduce the technique used in open surgery with St. Mark's retractor. It is the use of the three-directional retraction described by Heald's (3-D retraction), which ensures a safe dissection of the anterior aspect of the rectum.
  - The plane of anterior dissection can be carried either anterior or posterior to Denonvilliers' aponeurosis (**FIG 10A,B**). In advanced rectal cancer, it may be necessary to stay anterior to Denonvilliers' aponeurosis; in this case, the risk of genital nerve injury (impotence) is much higher.
- Dissection is not pursued farther than the inferior pole of the prostate.

Extraperitoneal Colostomy Technique

- Prior to initiating the perineal part of the procedure, the sigmoid colon is divided using the Endo GIA® linear stapler after en bloc division of the mesocolon.

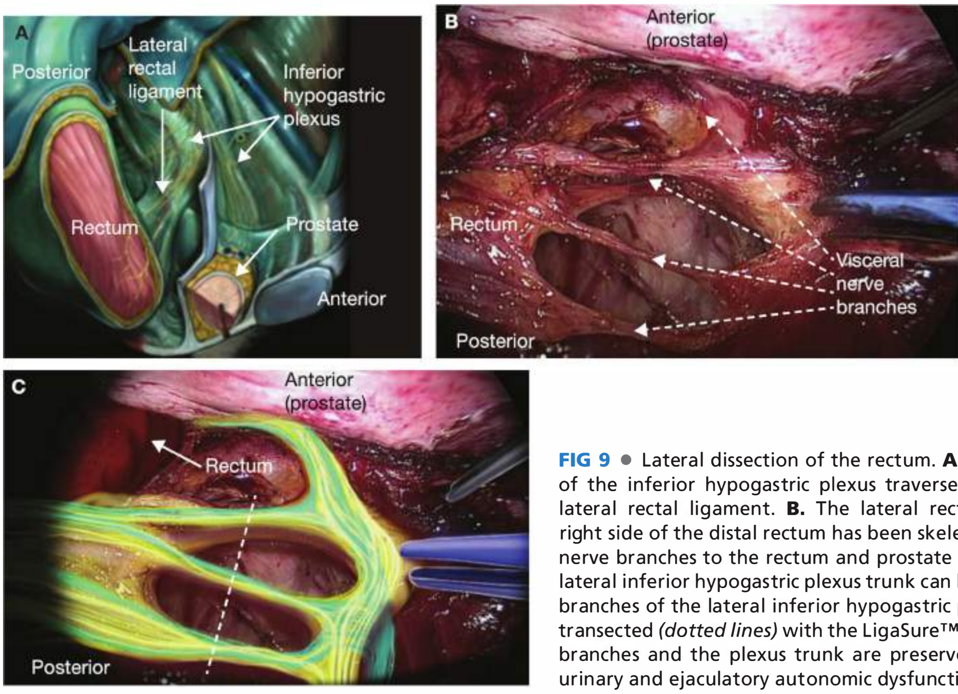

FIG 9 ● Lateral dissection of the rectum. **A.** The rectal branches of the inferior hypogastric plexus traverse along the so-called lateral rectal ligament. **B.** The lateral rectal ligament on the right side of the distal rectum has been skeletonized. The visceral nerve branches to the rectum and prostate originating from the lateral inferior hypogastric plexus trunk can be seen. **C.** The rectal branches of the lateral inferior hypogastric plexus are selectively transected *(dotted lines)* with the LigaSure™ device. The prostatic branches and the plexus trunk are preserved in order to avoid urinary and ejaculatory autonomic dysfunction.

- Patient quality of life will depend on an adequate colostomy technique. We prefer a preperitoneal terminal colostomy technique proposed in open surgery by Goligher.
- The objective is to limit the risk of peristomal eventration and stomal prolapse, which is all the more frequent in laparoscopic surgery as the risk of intraabdominal adhesions is low.
- Once colostomy location has been determined, preferably in the left transrectal space at the level of the umbilicus, the skin is incised over 5 to 6 cm, and the subcutaneous tissue is incised until the aponeurosis of the rectus sheath is reached.
- Muscular fibers are then retracted to expose the posterior leaflet of the aponeurosis that is incised vertically to visualize the peritoneum, which is preserved.
- It is then necessary to detach the peritoneum from the posterior aspect of the rectus sheath aponeurosis, moving toward the left paracolic gutter and staying posteriorly to the aponeurosis of the transverse and oblique abdominis muscles.

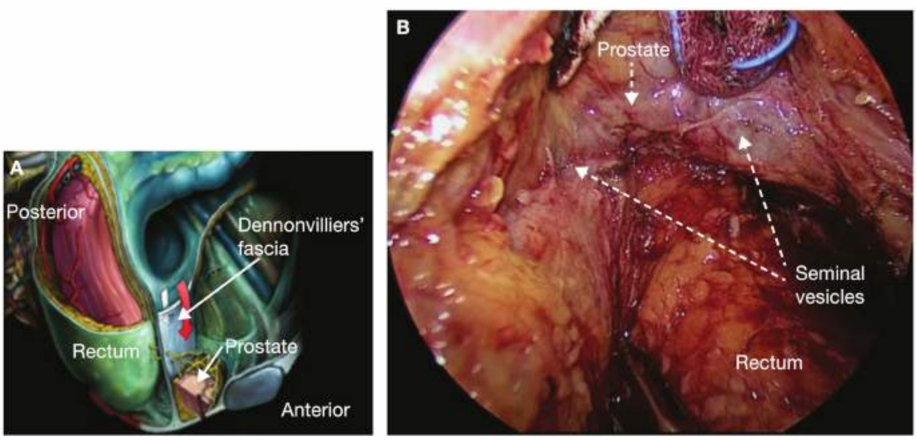

FIG 10 ● Anterior dissection of the rectum. **A.** The dissection can be carried either anterior *(red arrow)* or posterior *(white arrow)* to Denonvilliers' fascia. **B.** Surgical field after anterior dissection.

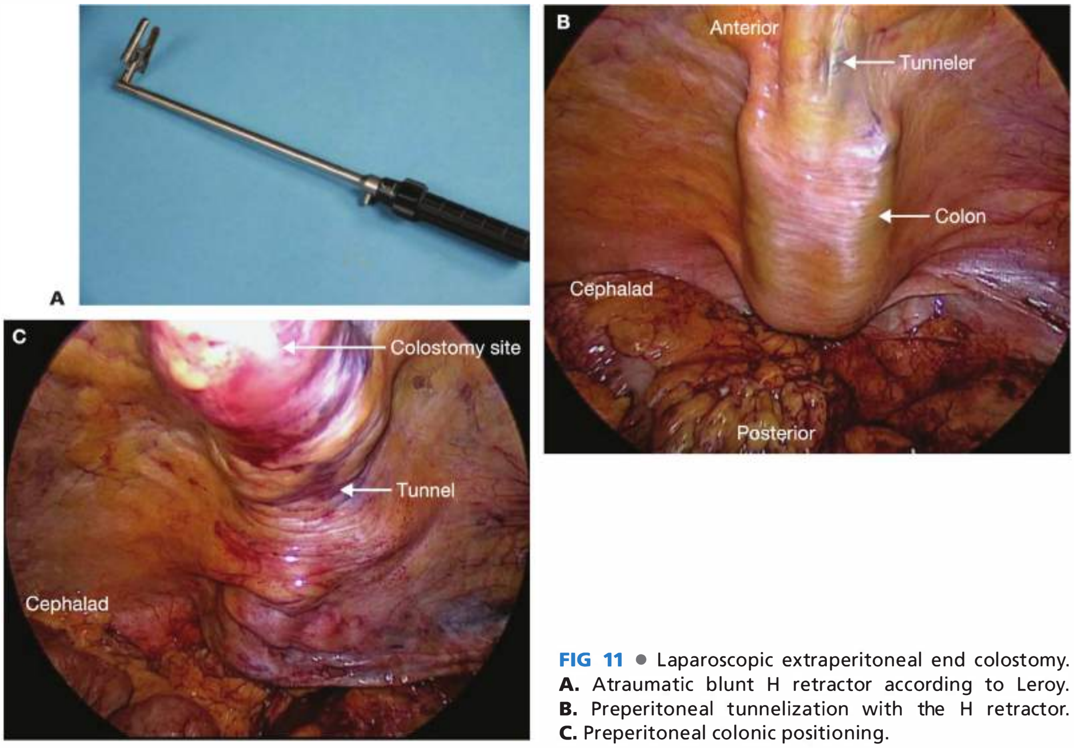

FIG 11 ● Laparoscopic extraperitoneal end colostomy. **A.** Atraumatic blunt H retractor according to Leroy. **B.** Preperitoneal tunnelization with the H retractor. **C.** Preperitoneal colonic positioning.

- A tunnel is then created. It joins the intraabdominal detachment of the left flank peritoneum performed during mobilization of the sigmoid and left colon.
- The tunnel is fashioned with a bougie or, even better currently, using an atraumatic blunt H retractor according to Leroy (KARL STORZ, Tuttlingen, Germany), the extremity of which may be angulated and enlarged to obtain a tunnel more adapted to the size of the colon (**FIG 11A**).
- During dissection, a permanent laparoscopic control helps to check the route and the width of the tunnel (**FIG 11B,C**).
- In order to retrieve the colon, a long laparoscopic forceps is introduced into the tunnel. The extremity of a Vicryl® purse string (Ethicon™) is grasped and taken out through the colostomy skin incision. Control is performed to make sure that the colon is perfectly positioned.
- The colostomy will be matured as usual after closure of all wounds by fixing the colonic serosa to the dermis with either interrupted or running sutures using a rapid resorption suturing material (Monocryl® 3-0, Ethicon™). Stitches transfix the dermal layer and extramucosal layer of the colon.

Perineal Dissection

- Once the perineal region has been perfectly exposed, the entire team is positioned opposite the perineum.
- The anal opening is closed by a purse string (**FIG 12A**). The skin incision is generally vertical and elliptical, away from the tumoral area in case of sphincteric invasion.
- Once a retracting system (either a Gelpi retractor [**FIG 12B**] or the self-retaining Lone Star™ [CooperSurgical Inc] retractor system) has been placed on the incision margins, dissection of deep structures is performed in a circular fashion first using the electrocautery and then using the LigaSure Atlas® vessel-sealing device or ultrasonic scissors.
- It is essential to maintain dissection along a vertical axis in order to prevent any conical route. Therefore, the inferior rectal vessels and the levator ani muscles should be divided as laterally as possible.
- Posteriorly, the dissection is directed toward the coccyx and to the presacral area to find the posterior pelvic plane.
- Anteriorly, the dissection is more subtle. In male patients, it is recommended to stay dorsal to the urethra without injuring or devascularizing it.
- More cranially, the dissection is carried dorsal to the prostate until reaching the anterior pelvic dissection plane.
- In female patients, the dissection is easier and it proceeds dorsal to the vagina.
- Some authors suggest an extension of the lateral dissection, also called "extended APR," "extralevator abdominoperineal excision (ELAPE)," "cylindrical APR," or "Holm cylindrical abdominoperineal excision." This may be unnecessary, especially after radiochemotherapy.

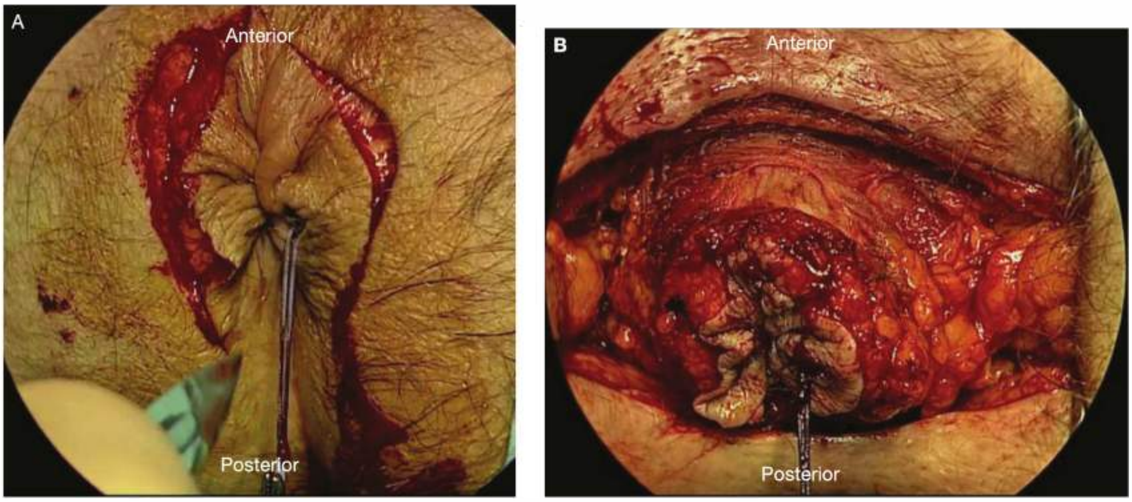

FIG 12 ● Perineal dissection. **A.** Closure of anal canal with a purse-string and elliptical skin incision. **B.** Cylindrical dissection of the distal rectum is facilitated by the use of Gelpi retractors.

Specimen Extraction, Perineal Closure, and Colostomy Completion

- Specimen extraction is performed through the perineal incision.
- In order to obtain a good oncologic outcome, it is necessary to obtain a cylindrical specimen with an intact mesorectum and without a waist effect, removing the specimen along with the levator ani fixed to the anus (**FIG 13**).
- Total hemostasis of the pelvis is then controlled through the perineal incision.
- Once two suction drains have been placed (either 12-Fr Redon drain or 14-Fr Blake drain) in the presacral space, the perineal incision is then closed in layers.
- The deep cellular adipose plane is reapproximated using an absorbable suture.
- An omentoplasty may be used to fill the pelvic space and to limit the risk of perineal hernia and urinary dysfunction due to a posterior falling of the urinary tract (**FIG 14**).
- The extensive cylindrical rectal resection does not allow to reapproximate the muscular plane of the levator ani.
- The skin is closed using interrupted sutures.
- The intervention is always completed with a final laparoscopic examination of the abdominal and pelvic cavity.

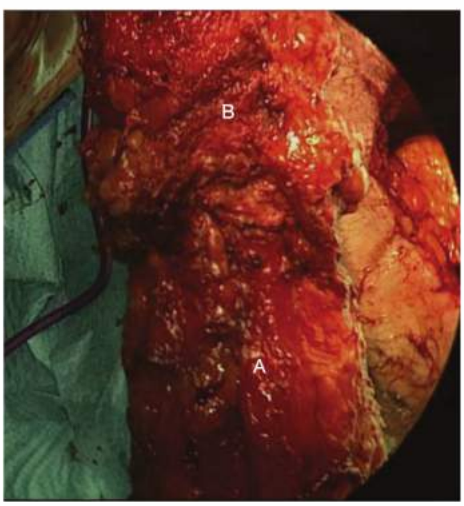

FIG 13 ● Cylindrical specimen with an intact mesorectum (A) without a waist effect (B).

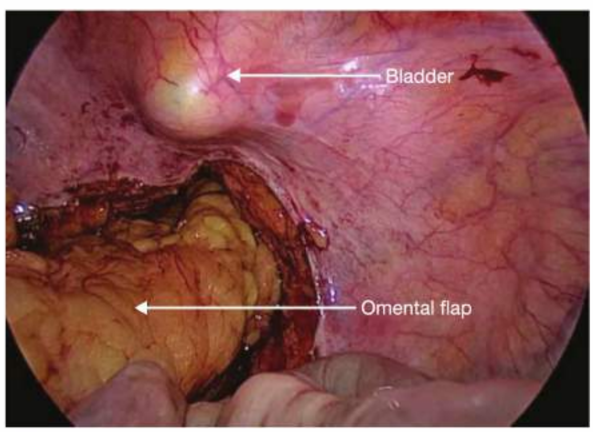

FIG 14 ● An omental pedicle flap is used to obliterate the pelvic space after resection.

PEARLS AND PITFALLS

Anatomy and embryology	▪ Detailed knowledge of the pelvic fascial structures and tissue planes is essential.
Preoperative	▪ Adequate staging with colonoscopy and appropriate imaging is important in determining the need for an APR.
Setup	▪ Precise operating room (OR), patient, and team setup is critical to success.

Technique	▪ Medial to lateral dissection of the mesocolon
	▪ High IMA transection
	▪ Pelvic dissection:
	  ▪ Posterior first (along the presacral "holy plane")
	  ▪ Lateral dissection/transection of the "lateral rectal ligaments": Avoid injury to autonomic trunks and genital nerve branches that would lead to autonomic dysfunction postoperatively.
	▪ Perineal phase: Perform a circumferential dissection.
	▪ Avoid "conization" of the specimen.
	▪ The specimen should have an intact mesorectum without a "waist" effect distally.
	▪ "Tunnelization" of the colostomy in the abdominal wall minimizes parastomal hernias.

Postoperative care	▪ Driven by a clinical pathway

POSTOPERATIVE CARE

- Postoperative care is driven by clinical pathways that include the following:
  - Pain control: Intravenous acetaminophen for 24 hours (start in the OR) followed by intravenous ketorolac for 72 hours (if creatinine is normal). The transversus abdominis plane (TAP) nerve block greatly reduces the need for narcotics.
  - Deep vein thrombosis (DVT) prophylaxis with enoxiheparin, starting within 24 hours of surgery.
  - No additional antibiotics, judicious use of intravenous fluids
  - No nasogastric tube. Remove Foley catheter on postoperative day 1. Remove pelvic drains on postoperative day 2 or 3.
  - Early ambulation, diet ad lib, aggressive pulmonary toilet
  - Use soft pillow/jelly doughnut while seating.
  - Targeted discharge: postoperative day 3 or 4

OUTCOMES

- Laparoscopic APR leads to improvements in short-term outcomes, including less pain, faster recovery, shorter hospital stay, and lower incidence of cardiac/pulmonary complications when compared to open surgery.
- For cancer resection, laparoscopic APR oncologic outcomes are at least comparable to those of open surgery. TME with an intact mesorectum is critical to minimize locoregional treatment failures.

COMPLICATIONS

- Wound infections and hernias
- Perineal wound infection/dehiscence and pelvic abscess incidence are reduced with the use of an omental pedicle flap to fill the pelvis.
- Urinary/sexual dysfunction: It is important to preserve autonomic nerves intact.
- Ureteral injury: critical to identify the left ureter prior to IMA transection
- DVT: lower risk with use of DVT prophylaxis

Chapter 34

Hand-Assisted Laparoscopic Abdominoperineal Resection

Daniel Albo

DEFINITION

- An abdominoperineal resection, or APR, involves removal of the anus, the rectum, and part or all of the sigmoid colon along with the associated regional lymph nodes, through incisions made in the abdomen and perineum. The end of the remaining colon is brought out as a colostomy.
- Hand-assisted laparoscopic surgery (HALS) is a minimally invasive surgical approach that uses conventional laparoscopic-assisted (LA) surgery techniques with the addition of a hand-assist device (placed in the projected specimen extraction site) that allows for the introduction of a hand into the surgical field. HALS in colorectal surgery retains all of the same advantages of conventional LA surgery over open surgery, including less pain, faster recovery, lower incidence of wound complications, and reduction of cardiopulmonary complications, especially in the obese and in the elderly.
- Advantages of HALS over conventional LA colorectal surgery include the following:
  - Reintroduces tactile feedback into the field
  - Shorter learning curves; easier to teach
  - Shorter operative times and lower conversion to open rates
  - Higher usage rates of minimally invasive surgery

DIFFERENTIAL DIAGNOSIS

- Indications for HALS APR
  - Rectal cancer: when unable to obtain a negative distal margin and/or in patients with poor sphincter function or severe comorbidities
  - Anal cancer: after failure of chemotherapy/radiation therapy or in the palliative setting
  - Inflammatory bowel disease (i.e., Crohn's with severe perianal disease)

PATIENT HISTORY AND PHYSICAL FINDINGS

- Most patients with rectal tumors generally present after an incidental finding during screening colonoscopy or with occult bleeding and anemia.
- A thorough history and physical examination should include the following:
  - Presence of rectal pain and/or tenesmus
  - Presence of obstructive symptoms
  - Description of anorectal function, with any fecal incontinence or leakage documented preoperatively
  - Documentation of urinary and erectile function/dysfunction
  - A detailed personal and family history of colorectal cancer, polyps, and/or other malignancies
- Physical examination should include the following:
  - Routine abdominal examination, noting any previous incisions
  - Digital rectal examination with assessment of sphincter function
  - Bilateral inguinal nodal examination
  - Rigid proctoscopy is arguably the most critical portion of the physical examination and is the key to proper patient selection of patients for an APR.
- Proctoscopy should be standardized and documented at minimum.
  - The distal and proximal extent of the lesion measured from the anal verge
  - Exact position of the lesion and extent of the rectal circumference involved
  - Presence or absence of fixation to perirectal structures

IMAGING AND OTHER DIAGNOSTIC STUDIES

- A colonoscopy with documentation of all polyps should be performed. Suspicious lesions should be tattooed to facilitate localization during surgery.
- Staging with endorectal ultrasound or rectal magnetic resonance imaging (MRI) should be performed to determine the need for neoadjuvant therapy and to plan operative strategy. A computed tomography (CT) of the chest, abdomen, and pelvis evaluates for potential metastases.
- A preoperative carcinoembryonic antigen level should be obtained.

SURGICAL MANAGEMENT

Preoperative Preparation

- Patients undergo stoma marking by an enterostomal therapist.
- Clinical trials have shown no need for mechanical bowel preparation.
- We use two fleet enemas to evacuate the rectal vault prior to surgery.
- Intravenous cefoxitin is administered within 1 hour of skin incision.
- Use hair clippers if needed and chlorhexidine gluconate skin preparation.
- Preoperative time-out and briefing is performed.
- Ultrasound-guided, bilateral transversus abdominis plane (TAP) block reduces the need for postoperative narcotics.

Equipment and Instrumentation

- 5-mm camera with high-resolution monitors
- 5-mm and 12-mm clear ports with balloon tips. They hold ports in the abdomen and minimize their intraabdominal profile during surgery.
- Laparoscopic endoscopic scissors and a blunt tip 5-mm energy device
- 60-mm linear reticulating laparoscopic staplers with vascular and tan loads
- We use the GelPort hand-assist device due to its versatility and ease of use. This device allows for the introduction/removal of the hand without losing pneumoperitoneum and

allows for insertion of multiple ports through the hand-assist device. It also allows for the introduction of laparotomy pads into the field, which are very useful to retract bowel/omentum in obese patients.

Patient Positioning and Surgical Team Setup

- Place the patient on a modified lithotomy position, with the arms tucked and padded (to avoid nerve/tendon injuries). The patient is taped over a towel across the chest without compromising chest expansion (**FIG 1**).
- Place the legs on Allen stirrup with the heels firmly planted on the stirrups to avoid pressure on the calves and the lateral peroneal nerves.
- Keep the thighs parallel to the ground to avoid conflict between the thighs and the surgeon's arms/instruments.
- The coccyx should be readily palpable off the edge of the table. This will be critical for the perineal step of the operation.
- The surgeon starts at the patient's right lower side with the assistant to his or her left side.
- Align the surgeon, the ports, the targets, and the monitors in straight lines. Place monitors in front of the surgeon and at eye level to prevent lower neck stress injuries.
- Avoid unnecessary restrictions to potential team movement around the table. All energy device cables exit by the patient's upper left side. All laparoscopic (gas, light cord, and camera) elements exit by the patient's upper right side.

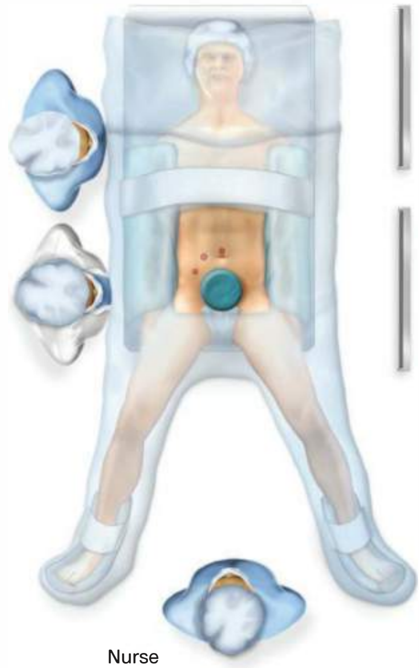

FIG 1 ● Team, patient, and monitor setup. The patient is on a modified lithotomy position. The team, ports, targets, and monitors are aligned.

PORT PLACEMENT AND OPERATIVE FIELD SETUP

- Insert the GelPort through a 5- to 6-cm Pfannenstiel incision. This incision will be also used for specimen extraction. It provides a better cosmetic result and lowers the incidence of wound infections and hernias. It also allows for more working space between the hand and the instruments. (**FIGS 1** and **2**).
- Ports: Insert a 5-mm working port in the right upper quadrant, a 12-mm working port in the right lower quadrant, and a 5-mm camera port above the umbilicus. These three ports are triangulated, with the camera port at the apex of the triangle. This setup avoids conflict between the instruments and the camera and prevents disorientation (avoids "working on a mirror").
- A 5-mm accessory working port may be inserted at the planned colostomy site in the left lower quadrant (LLQ). This port allows the surgeon to operate from the left side of the table (useful for the right-sided pelvic dissection, especially in males). It can also be valuable for the mobilization of the splenic flexure.

FIG 2 ● Ports and instrumentation setup. The GelPort is placed through a Pfannenstiel incision. All ports are triangulated. Notice the energy devices placed in a pouch in front of the surgeon to minimize instrument transfer.

OPERATIVE STEPS

- Our HALS APR operation is highly standardized and consists of eight steps:
  - Transection of the inferior mesenteric vein (IMV)
  - Transection of the inferior mesenteric artery (IMA)
  - Medial to lateral dissection of the descending mesocolon
  - Sigmoid colon mobilization off the pelvic inlet
  - Descending colon mobilization
  - Pelvic dissection

- Transection of the levator ani muscles
- Creation of colostomy and closure of abdominal wounds

Step 1. Transection of the Inferior Mesenteric Vein

- This is the critical "point of entry" in this operation. We favor it over starting dissection at the IMA level due to the IMV's constancy in location, the ease of its visualization by the ligament of Treitz, and the absence of structures that can be harmed around it (no iliac vessels or left ureter nearby). This will be the only time during the operation when a virgin tissue plane is entered. Every step will set up the following ones, opening the tissue planes sequentially.
- The patient is placed on a steep Trendelenburg position with the left side up. Using the right hand, move the small bowel into the right upper quadrant and the transverse colon and omentum into the upper abdomen. If necessary, place a laparotomy pad to hold the bowel out of the field of view, especially in obese patients. This pad can also be used to dry up the field and to clean the scope tip intracorporeally. Make sure that the circulating nurse notes the laparotomy pad in the abdomen on the white board.
- Identify the critical anatomy: IMV, ligament of Treitz, and left colic artery (**FIG 3**).
- If there are attachments between the duodenum/root of mesentery and mesocolon, transect them with laparoscopic scissors. This will allow for adequate exposure of midline structures.
- Pick up the IMV with the right hand. Dissect under the IMV and in front of Gerota's fascia with endoscopic scissors, starting at the level of the ligament of Treitz and proceeding with the dissection caudally toward the IMA. The assistant provides upward countertraction with a grasper.
- Transect the IMV cephalad of left colic artery (which moves away from the IMV and toward the splenic flexure of the colon) with the 5-mm energy device, thus preserving intact the left-sided marginal arterial arcade and maintaining the blood supply to the descending colon segment (**FIG 4**).

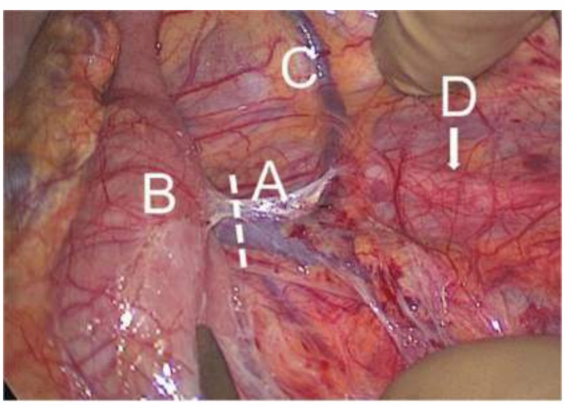

FIG 3 ● Step 1: Key anatomy. IMV *(A)*. Ligament of Treitz *(B)*. Left colic artery *(C)* as it separates from the IMV and goes toward the splenic flexure of the colon. The left ureter *(D)* is located far from the IMV projected transection *(dotted lines)*.

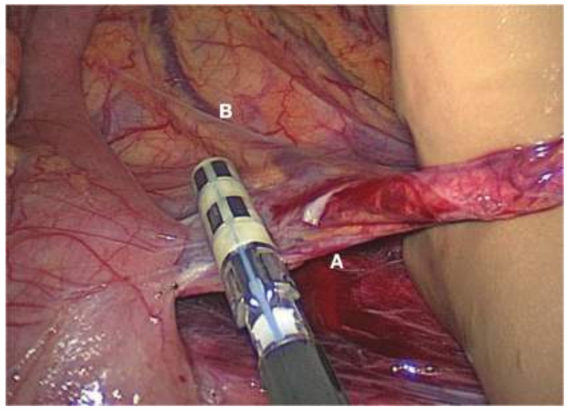

FIG 4 ● Step 1: Transection of the IMV *(A)* cephalad of the left colic artery *(B)*.

Step 2. Transection of the Inferior Mesenteric Artery

- Identify the critical anatomy: the "letter T" formed between the IMA and its left colic and superior hemorrhoidal artery (SHA) terminal branches (**FIG 5**).
- Holding the SHA up with the right hand, dissect the plane along the palpable groove between the SHA and the left iliac artery using laparoscopic scissors and a 5-mm energy device. Preserve the sympathetic nerve trunk intact in the retroperitoneum. Identify the left ureter in front of the left iliac artery and psoas muscle and medial to the gonadal vessels before transecting anything.

FIG 5 ● Step 2: Critical anatomy. Identify the letter T formed between the IMA *(A)* and its left colic artery *(B)* and SHA *(C)* terminal branches. The IMA takeoff is just cephalad from the aortic bifurcation. The thumb and index finger are lifting the SHA off the groove located anterior to the right common iliac artery.

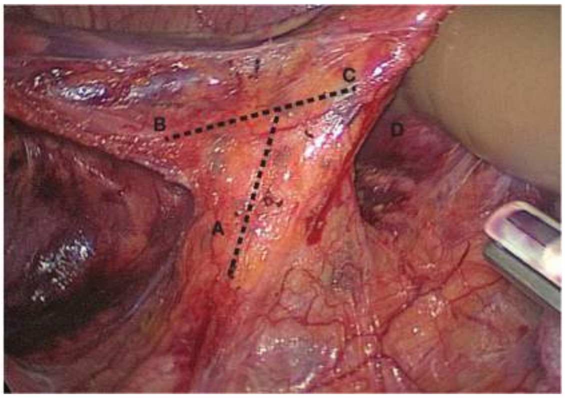

FIG 6 ● The letter T dissected: IMA *(A)*, left colic artery *(B)*, SHA *(C)*. Notice the left ureter *(D)* in the retroperitoneum.

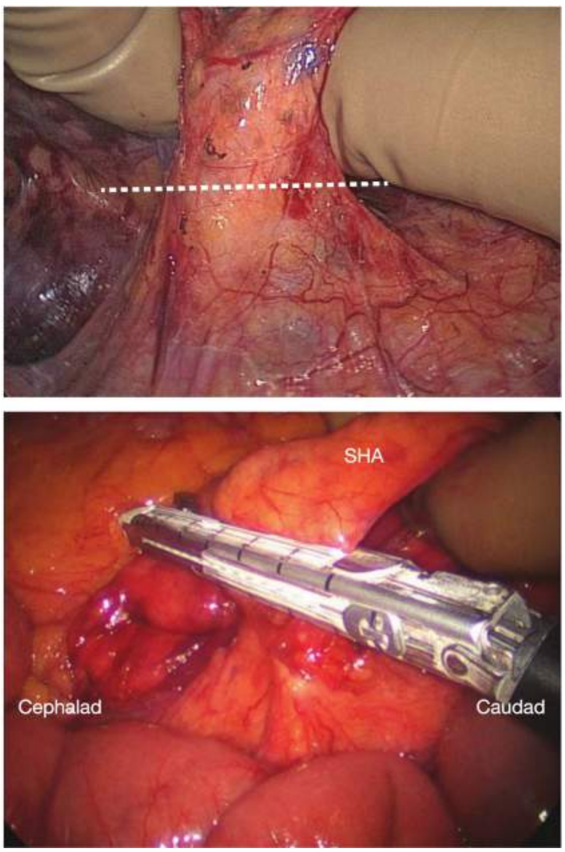
- You can visualize the letter "T" formed between the IMA, the left colic artery, and the SHA (**FIG 6**). Dissect with your thumb and index finger around and behind the IMA and transect the IMA at its origin with a vascular load stapler or energy device (**FIG 7A** and **B**). This ensures excellent lymph node harvest and great exposure for step 3.

A



B

FIG 7 ● The IMA is now completely encircled; a high IMA transection will be perform along the dotted line (Panel **A**). The IMA is transected with a linear vascular stapler (Panel **B**) at it's origin off the aorta.

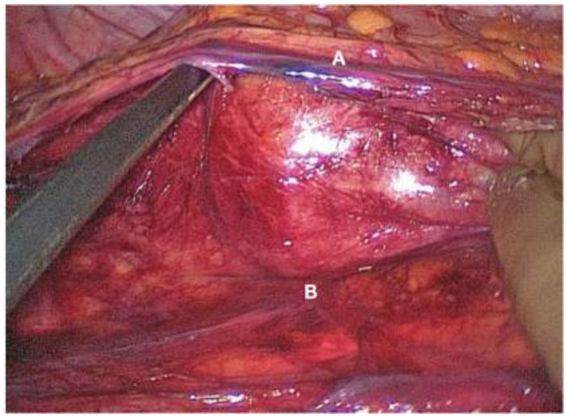


FIG 8 ● Step 3: Medial to lateral dissection of the descending mesocolon. The surgeon's hand is holding the descending mesocolon and colon anteriorly *(A)*, separating them from Gerota's fascia and other retroperitoneal structures *(B)*.

Step 3. Medial to Lateral Dissection of the Descending Mesocolon

- The surgeon's right hand and the assistant's grasper hold the descending mesocolon up, creating a working space between the mesocolon and the retroperitoneum (**FIG 8**). The plane between the mesocolon and Gerota's fascia, readily identified by the transition between the two fat planes, is dissected with the 5-mm energy device.
- Dissect caudally toward the pelvic inlet; this will greatly facilitate performance of steps 4 and 6. Dissect laterally until you reach the lateral abdominal wall; this will greatly facilitate performance of step 5.

Step 4. Sigmoid Colon Mobilization off the Pelvic Inlet

- The surgeon pulls the sigmoid colon medially, exposing the lateral sigmoid colon attachments (**FIG 9A**). Transect the attachments between the sigmoid and the pelvic inlet with laparoscopic scissors in your left hand, staying medially, close to the sigmoid and mesosigmoid, to avoid injuring the ureter/gonadal vessels.
- Dissect caudally until reaching the entrance to the left pelvic inlet.
- The left ureter and gonadal vessels, dissected in step 3, should be visible (**FIG 9B**).

Step 5. Descending Colon Mobilization

- The surgeon stands between the patient's legs. Retract the left colon medially with your hand to expose the white line of Toldt. The assistant holds the omentum/bowel out of way.
- Transect the white line of Toldt up to the splenic flexure using endoscopic scissors or energy device (**FIG 10**).

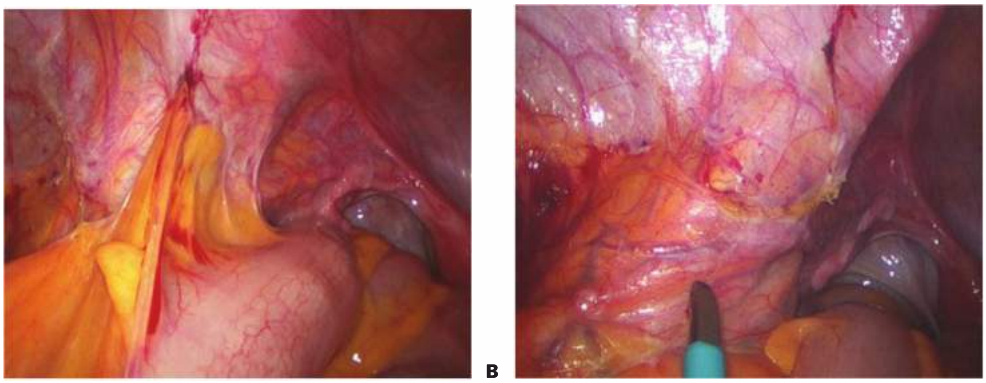

FIG 9 ● Step 4. Panel **A**: Medial traction on the sigmoid exposes its lateral attachments to the pelvic inlet. Panel **B**: After the sigmoid mobilization is completed, the left ureter is visualized as it crosses over the left iliac artery.

You should readily enter the retroperitoneal dissection plane dissected during step 2.

Step 6. Pelvic Dissection

- Start by following the dissection plane under the SHA, initiated during step 2, over the promontory and into the presacral space. Dissect the presacral space using a 5-mm energy device staying between the presacral fascia and the investing fascia of the mesorectum (**FIG 11A**). It is critical to preserve the mesorectum intact to avoid oncologic contamination of the pelvis.
- Transect the lateral rectal ligaments between the rectum and the lateral pelvic wall (**FIG 11B**). There is a space in front and behind the lateral rectal ligaments that can be easily dissected with the 5-mm energy device. Stay medial to the endopelvic fascia to avoid injuring the hypogastric vein and its branches as well as the parasympathetic ganglia.
- From the right side of the table and using his or her right hand, the surgeon retracts the rectum to the right side, exposing the left lateral rectal ligament. The ligament is then transected with a 5-mm energy device.

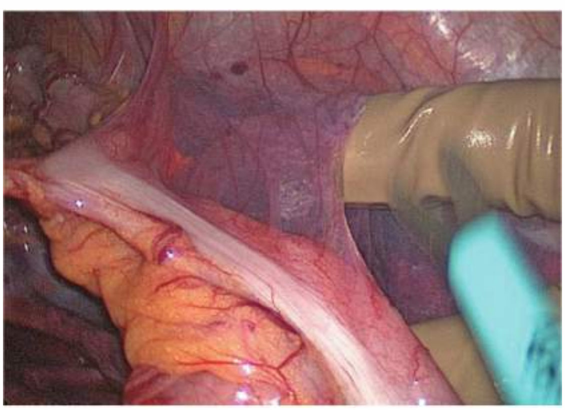

FIG 10 ● Step 5: Transection of the lateral descending colon attachments (white line of Toldt). Notice that the hand has entered the retroperitoneal dissection plane dissected during step 3.

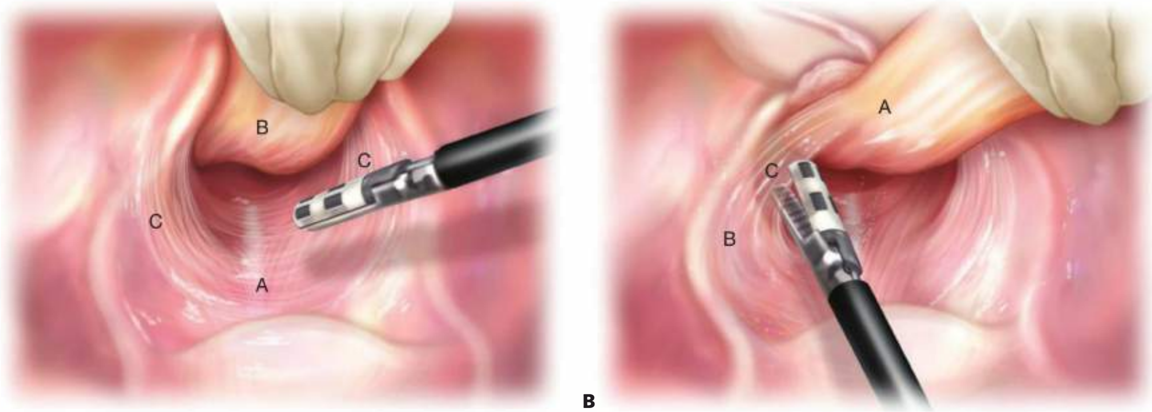
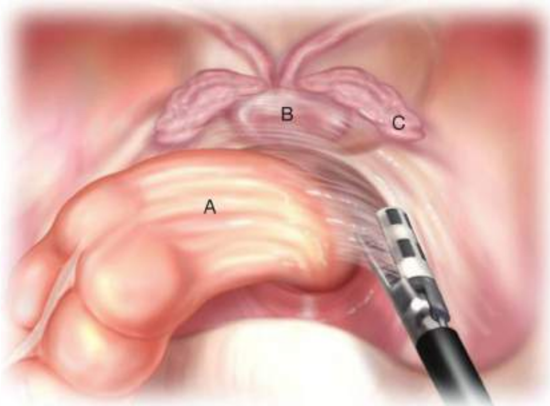
- From the left side of the table and using his or her left hand, the surgeon retracts the rectum to the left side, exposing the right lateral rectal ligament. The ligament is then transected with a 5-mm energy device.
- For the anterior pelvic dissection, the assistant pulls the rectum up into the abdomen with a grasper. The surgeon holds the bladder (in males) or the uterus (in females) anteriorly using his or her right hand and dissects between Denonvilliers fascia and the prostate/seminal vesicles (in males) (**FIG 11C**) or vagina (in females) with the 5-mm energy device. Continue with the circumferential dissection around the rectum until you can actually see pelvic floor (levator ani muscle) (**FIG 12A**).
- At this point, you are ready for the intracorporeal proximal transection of the specimen. Transect the mesocolon between the sigmoid and left colic vessels with the 5-mm energy device. Start at the stapled IMA stump on the specimen side, and move up toward the colon wall, transecting the left colic artery (at its origin, off the IMA stump) and the marginal artery (close to the colon wall).
- Transect the colon intracorporeally using a 60-mm tan load linear stapler.

Step 7. Transection of the Levator Ani Muscle

- There are two alternative techniques to accomplish this step:
  - Laparoscopic anterior circumferential dissection
    - This has become our preferred approach because it obviates the need for a perineal dissection, thus greatly reducing perineal wound complications. Without the use of the hand for exposure, this technique is extremely difficult to accomplish.
    - Very large tumors may impede proper visualization of the levator ani muscle, therefore necessitating a more conventional open transperineal approach.
    - We first transect the posterior aspect of the levator ani with the 5-mm energy device, staying anterior to the coccyx followed by



A B

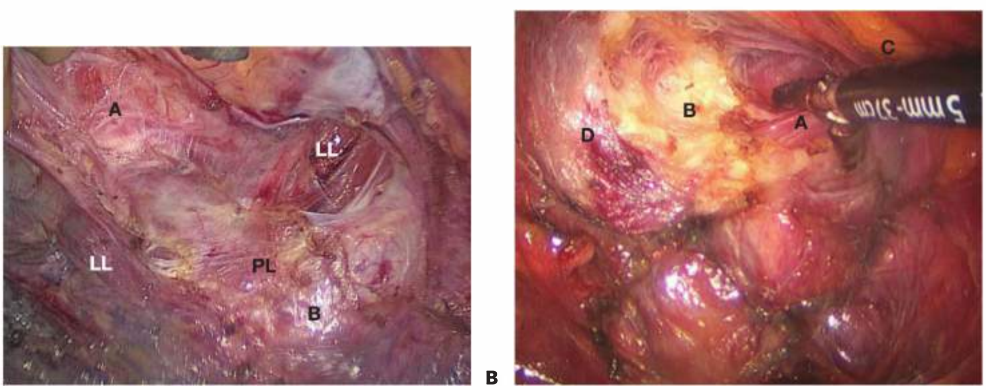


C

FIG 11 ● Step 6: Pelvic dissection. Panel **A**: The posterior dissection is carried in between the presacral fascia posteriorly *(A)*, the investing fascia of the mesorectum anteriorly *(B)*, and the endopelvic fascia laterally *(C)*. Panel **B**: Transection of the lateral rectal ligaments. Dissection of the space between the rectum *(A)* and the lateral pelvic wall *(B)* anterior to the rectal ligament exposes the left lateral rectal ligament *(C)*, which can then be easily transected with the energy device. Panel **C**: The anterior dissection is carried (in men) between the rectum posteriorly *(A)* and the prostate *(B)* and seminal vesicles *(C)* anteriorly.

transection of the levator ani laterally until we reach the fat of the ischiorectal fossa (FIG 12B).

- Finally, we perform the anterior transection of the levator ani muscles, staying posterior to the urethra (in males) or the distal vagina (in females).
- The rectum is now fully mobilized. By pulling up on the rectum, the anal canal comes up into the pelvis (FIG 13A,B). It is remarkable how far up into the pelvis the anal canal can be mobilized with this technique.
- While pulling up on the rectum with the left hand, the surgeon transects the specimen distal



A B

FIG 12 ● Panel **A**: After completing the rectal mobilization, the levators are now fully exposed. Rectum *(A)*. Coccyx *(B)*. Posterior levators *(PL)*. Lateral levators *(LL)*. Panel **B**: Circumferential anterior transection of the levators. Transected lateral levators *(A)*. Exposed ischiorectal fossa fat *(B)*. Rectum *(C)*. Lateral pelvic wall *(D)*.

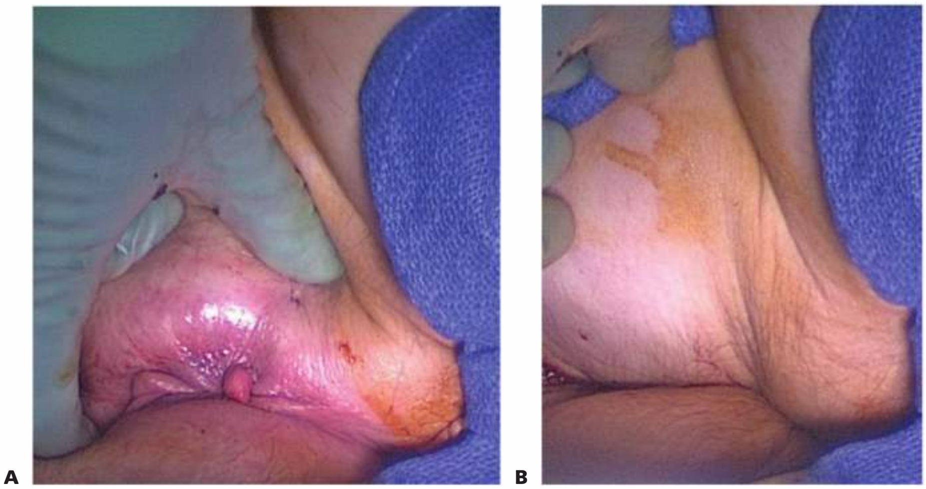


FIG 13 ● After the levators have been circumferentially transected, the surgeon (with his hand through the Gelport) retracts the rectum upwards into the abdominal cavity. This results in the anal canal (Panel **A**) being pulled up into the pelvis and out of view from the perineal side (Panel **B**). The anal canal is now ready for intracorporeal transection distal to the anal sphincter.

to the anal sphincter, using a 45-mm linear tan load stapler introduced through the right lower quadrant (RLQ) port. We reticulate the stapler maximally and we fire the stapler on an anterior to posterior direction.

- The fully disconnected specimen is now extracted through the Pfannenstiel incision with the Alexis wound protector in place. It is paramount that the specimen has an intact mesorectum with no tapering down to the anal canal (**FIG 14**).

FIG 14 ● APR specimen. Note the shiny surface of the intact mesorectum with no tapering.

- Open transperineal approach
  - It is paramount to have completed the anterior pelvic dissection laparoscopically all the way down to the levator ani during step 6.
  - Key anatomic landmark: Identify the coccyx posteriorly.
  - Use headlight for illumination. Dissect circumferentially around the anus with electrocautery across the superficial perineal tissues until you reach the levator ani muscle. Use Gelpi retractors to enhance exposure (**FIG 15A**).
  - Palpate the coccyx posteriorly. Transect the levator ani between the coccyx and the anus with electrocautery and enter the pelvis posteriorly (**FIG 15B**).
  - The assistant pulls the rectum up to facilitate dissection of levator ani muscles.
  - Introduce your left index finger through the posterior opening (careful to avoid avulsing presacral veins) and curve it on top of the left levator ani muscle, pulling it down into view. Transect the left levator ani with electrocautery, staying close to its pelvic wall insertion. Repeat this maneuver on the right side.
  - The assistant now everts the specimen out through the posterior opening on the pelvic floor. The surgeon pulls the specimen out and exposes the anterior attachments of the anal canal to the urethra (in males) or to the vagina (in females), allowing for a safer transection of these anterior attachments and minimizing potential injury to the vagina/urethra. The specimen is now completely removed.
  - After extensive irrigation of the pelvis, close the perineal wound in layers.
  - Place a 19-Fr round Blake in the pelvis through the right lower quadrant port site.

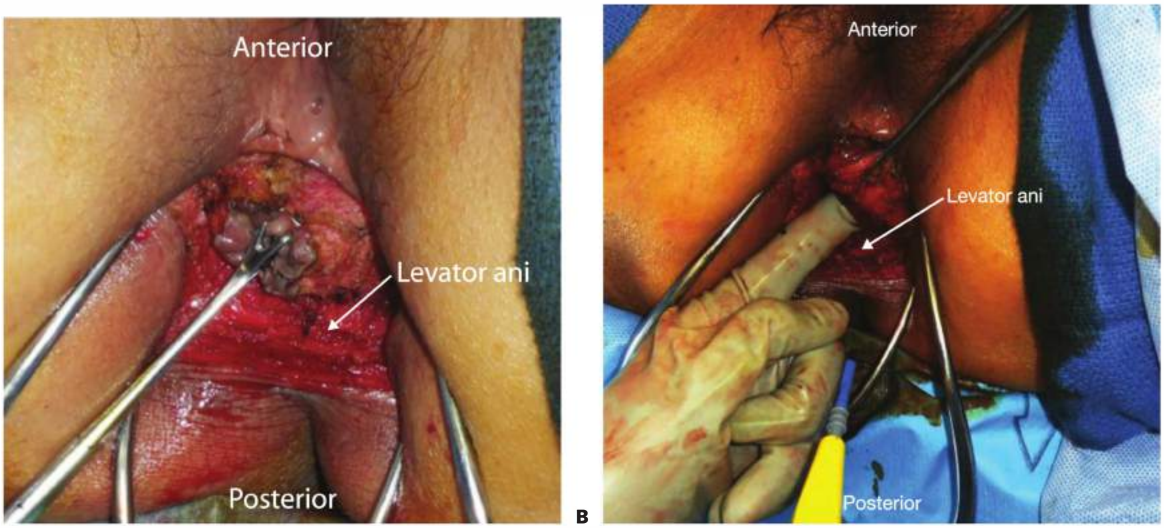

FIG 15 ● Panel **A**: Perineal dissection: Lateral incision around the anal canal. The incision is carried through the skin and subcutaneous tissues until reaching the levator ani muscles. Gelpi retractors are used for exposure. Panel **B**: Perineal dissection: Posterior palpation of coccyx during perineal dissection. The transection of the levators starts posteriorly anterior to the coccyx. The index finger of the surgeon is placed into the pelvis and hooked on to top of the levator muscle, pulling it into the field. This allows for a safe transection of the levator muscle with electrocautery.

Step 8. Creation of Colostomy and Closure of Abdominal Wounds

- Avoid twisting; the descending colon is brought out through the LLQ port site (extended to accommodate two fingers) through the rectus sheet.
- After changing gloves, all ports are removed. Abdominal wounds are closed with absorbable sutures and sealed off with Dermabond.
- Mature the colostomy at skin level with interrupted 3-0 Vicryl sutures. Digitalize the colostomy to ensure that it is patent beneath the fascia.

PEARLS AND PITFALLS

Setup	■ Proper patient, team, port, and instrumentation setup is critical.
Operative technique	■ Point of entry: IMV at the ligament of Treitz. ■ Medial to lateral dissection step sets up all other steps. ■ Vascular dissection to visualize the letter T and high IMA ligation in malignancy; identify left ureter prior to IMA transection. ■ Pelvic dissection progression: first posterior, then lateral, then anterior. ■ We prefer the anterior circumferential transection of the levators to prevent perineal wound complications.
Pitfall: dissecting anterior to the SHA	■ Solution: Identify "groove" between left common iliac artery and SHA and dissect in between the two vessels.
Pitfall: floppy sigmoid difficult to handle	■ Use the back of the hand as a "shelf" to hold the sigmoid up while picking up the SHA with thumb and index finger.

POSTOPERATIVE CARE

- Postoperative care is driven by clinical pathways that includes the following:
  - Pain control: Intravenous acetaminophen for 24 hours (start in the operating room) followed by intravenous ketorolac for 72 hours (if creatinine is normal). The TAP nerve block greatly reduces the need for narcotics.
  - Deep vein thrombosis (DVT) prophylaxis with enoxaparin starting within 24 hours of surgery
  - No additional antibiotics, judicious use of intravenous fluids
  - No nasogastric tube. Remove Foley catheter on post-operative day 1. Remove pelvic drain on postoperative days 2 or 3.
  - Early ambulation, diet ad lib, aggressive pulmonary toilet

- Use soft pillow/jelly doughnut while seating.
- Targeted discharge: postoperative days 3 or 4

OUTCOMES

- HALS leads to improvements in short-term outcomes, including less pain, faster recovery, shorter hospital stay, and lower incidence of cardiac/pulmonary complications when compared to open surgery.
- When compared to conventional laparoscopy, HALS results in higher usage rates of minimally invasive surgery, shorter learning curves, lower conversion rates, shorter operative times, and shorter hospital stays.
- For cancer resection, minimally invasive surgery oncologic outcomes are at least comparable to those of open surgery. Total mesorectal excision with an intact mesorectum is critical to minimize locoregional treatment failures.

COMPLICATIONS

- Wound infections and hernias are markedly reduced with the use of a Pfannenstiel extraction site.
- Perineal wound infection/dehiscence: This complication is virtually eliminated with the use of an anterior circumferential transection technique for the levators. Pelvic abscess are also markedly reduced.
- Urinary/sexual dysfunction: important to preserve hypogastric nerves and parasympathetic ganglia intact
- Ureteral injury: critical to identify the left ureter prior to IMA transection
- DVT: low risk with use of DVT prophylaxis
- Cardiac and pulmonary complications: significantly reduced compared to the open surgery approach

Chapter 35

Abdominoperineal Resection: Robotic-Assisted Laparoscopic Surgery Technique

Rodrigo Pedraza Eric M. Haas

DEFINITION

- Robotic-assisted laparoscopic abdominoperineal resection (APR) is a minimally invasive technique in which the rectum and anus are removed with the creation of a permanent end colostomy. The procedure is accomplished with the assistance of the da Vinci® Surgical System (Intuitive Surgical Inc, Sunnyvale, CA) in a minimally invasive fashion.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history and physical examination should include the following:
  - Presence of rectal pain and/or tenesmus
  - Presence of obstructive symptoms
  - Description of anorectal function, with any fecal incontinence or leakage documented preoperatively
  - Documentation of urinary and erectile function/dysfunction
  - A detailed personal and family history of colorectal cancer, polyps, and/or other malignancies
- Physical examination should include the following:
  - Routine abdominal examination, noting any previous incisions
  - Digital rectal examination with assessment of sphincter function, distal and proximal extent of the lesion measured from the anal verge, exact position of the lesion and extent of the rectal circumference involved, and the presence or absence of fixation to perirectal structures
  - Bilateral inguinal nodal examination
- Robotic-assisted laparoscopic APR is a safe and feasible approach. The most common indication is low rectal cancer in which the sphincter complex cannot be salvaged. Less commonly, APR is performed in those with persistent or recurrent anal cancer following radiation therapy. Other indications include severe inflammatory bowel disease (IBD) involving the rectum and recalcitrant to medical management.
- Low rectal cancer is typically diagnosed during screening colonoscopy or after presenting symptoms such as rectal bleeding, bowel obstruction, or pelvic pain.
- Patients presenting with residual or recurrent anal cancer and those with IBD with recalcitrant perianal disease have typically undergone thorough workup and extensive therapy for the disease prior to be considered candidates for APR.
- Absolute contraindications for robotic-assisted APR are those for any other major abdominal procedure, such as severe cardiovascular or hemodynamic compromise.
- Relative contraindications for robotic-assisted APR include those associated with the patient condition and surgeon experience.
  - Robotic-assisted laparoscopic procedures typically require steep patient positioning and result in prolonged operative times, especially early in the surgeon learning curve; thus, patient inability to tolerate a lengthy procedure may contraindicate the use of robotic-assisted APR.
  - History of prior abdominal surgery is not a contraindication but may additionally prolong the operative time for lysis of adhesions and proper exposure of tissue planes. We advocate performing laparoscopic lysis of adhesions prior robotic docking so as to expedite the procedure.
  - Prior to offering challenging pelvic procedures such as robotic-assisted APR, we suggest the surgeon achieve competency with robotic surgery by performing several less demanding procedures such as rectopexy and/or left/sigmoid colectomy.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Appropriate imaging, endoscopic, and histopathologic evaluation is mandatory in all cases regardless of diagnosis.
- A full colonoscopy must be performed in all patients with rectal cancer. This allows for assessment of tumor location and pathology. It also serves to rule out and possibly remove any synchronous colonic lesions. Malignant synchronous lesions have been reported in 2% to 8% of cases and benign synchronous polyps in 13% to 62% of cases.
- If a colonoscopy has already been done by another provider, consider performing either a rigid proctoscopy or a flexible sigmoidoscopy for accurate documentation of the size, location, and distance of the tumor from the anal sphincter complex.
- Patients with low rectal cancer requiring APR necessitate a full staging workup. Local tumor assessment and regional node involvement are optimally assessed with endoscopic ultrasound or rectal protocol magnetic resonance imaging (MRI). Distant metastases are evaluated with computed tomographic (CT) scan of the chest abdomen and pelvis.
- Following proper staging, the need of neoadjuvant chemoradiation is determined. Patients with T3–T4 and/or N+ distal rectal cancer are offered neoadjuvant chemoradiation. Surgery is typically considered after 6 to 8 weeks following the last pelvic radiation session to allow for a full therapeutic radiation effect and to avoid operating in early inflammatory radiation tissue changes or late fibrosis; however, delayed intervention has been recently suggested.
- For persistent or recurrent anal cancer, APR is the rescue therapy of choice. These patients typically present after thorough imaging staging and following conventional courses

FIG 1 ● Patient positioning. The patient is placed in a modified lithotomy position with moderate Trendelenburg and with both arms tucked. All pressure points are padded to prevent neurovascular injuries. The patient is secured with a wrap technique using a 3-in tape at the level of the chest in such a fashion to prevent movement but avoiding restriction of chest wall expansion.

of chemoradiation with documented residual or recurrence disease.

- Most patients with recalcitrant perianal disease in the background of IBD present for the consideration of an APR after extensive imaging and endoscopic evaluation. It is imperative to endoscopically assess the disease to determine whether the APR should be accompanied with additional large or small bowel resection. Furthermore, the presence of additional fistulous tracts such as rectovaginal or rectovesicular must be investigated during the preoperative planning.
- A carcinoembryonic antigen (CEA) level is obtained preoperatively in cancer patients.

SURGICAL MANAGEMENT

Preoperative Planning

- Bowel preparation is typically achieved with preoperative enema. Full bowel preparation is performed selectively.
- In the operating room and under anesthesia, rigid proctosigmoidoscopy should be performed to affirm the surgical plan.
- The perineum is adequately prepped for the perineal portion of the procedure.
- Prophylactic antibiotics are administered according to the Surgical Care Improvement Project (SCIP) measures.

Positioning

- The patient is placed in a modified lithotomy position with moderate Trendelenburg and with both arms tucked. All pressure points are padded in order to prevent neurovascular injuries. The patient is secured with a wrapped technique using a 3-in tape at the level of the chest in such a fashion so as to prevent movement but avoiding restriction of chest wall expansion (**FIG 1**). It is imperative to secure the patient firmly, as steep Trendelenburg position will be used later in the procedure before robotic docking.
- Optimal modified lithotomy position is crucial to ensure adequate perineal access while allowing appropriate robotic side docking (see the following text) to avoid external robotic arm conflict (**FIG 2**).

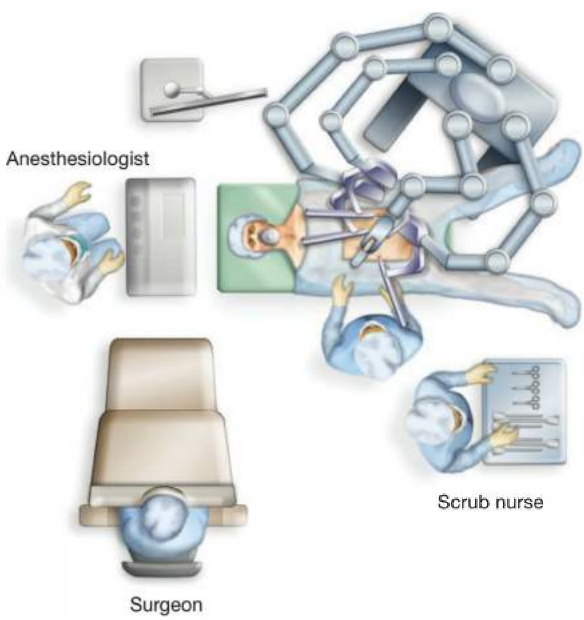

FIG 2 ● Team and robot setup. The robot is docked on the left side of the patient lower extremities in an acute angle. This configuration allows access to the perineum without undocking the robotic cart.

INCISION, PORT PLACEMENT, AND INSTRUMENTS

- A total of five ports are used for robotic-assisted APR: two 12-mm ports for the robotic camera and assistant (the latter is for use with laparoscopic instruments) and three 8-mm ports for robotic instrumentation.
- The robotic camera port is placed in the periumbilical region and the assistant port in the right upper quadrant. The 8-mm instrument ports are placed in the right and left lower quadrants and in the left upper quadrant (**FIG 3**).
- The ports are placed approximately 8 cm apart to prevent conflict between the robotic arms and the camera.

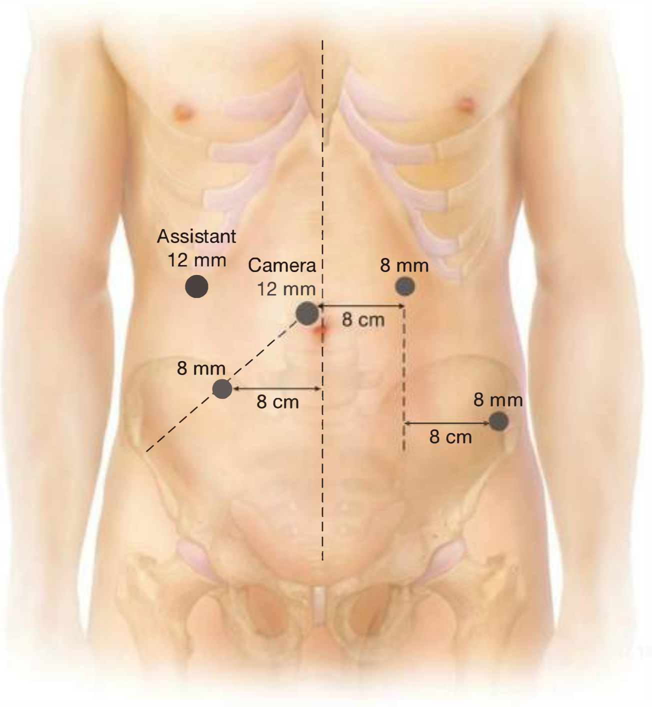

FIG 3 ● Port placement. The camera arm is placed in the 12-mm port in the periumbilical region. The robotic arms 1, 2, and 3 are placed in the right lower, left upper, and left lower quadrants, respectively. A 12-mm port is placed in the right upper quadrant for the assistant to use with laparoscopic instruments. All ports are placed approximately 8 cm apart to avoid conflict between the robotic arms and the camera.

EXPLORATION AND ROBOTIC DOCKING

- The abdominal cavity is assessed and, in oncologic cases, the presence of distant metastases is evaluated.
- Lysis of adhesions is performed laparoscopically, if needed.
- The patient is positioned in a steep Trendelenburg position with the left side elevated 15 degrees. The small bowel and omentum are retracted out of the pelvis.
- The robot is docked on the left side of the patient's lower extremities in an acute angle (**FIG 2**). The camera arm is placed in the 12-mm port in the periumbilical region, whereas the robotic arms 1, 2, and 3 are placed in the right lower, left upper, and left lower quadrants, respectively (**FIG 3**).

ESTABLISHMENT OF THE PRESACRAL PLANE

- A medial to lateral approach is used with an incision of the peritoneum at the level of the sacral promontory. The avascular presacral plane is entered, which is confirmed by the identification of the areolar tissue (**FIG 4**). This plane is developed identifying the superior rectal artery and the left ureter (**FIG 5**). The vascular pedicle is isolated, identifying the inferior mesenteric artery, superior rectal artery, and the left colic artery (**FIG 5**).

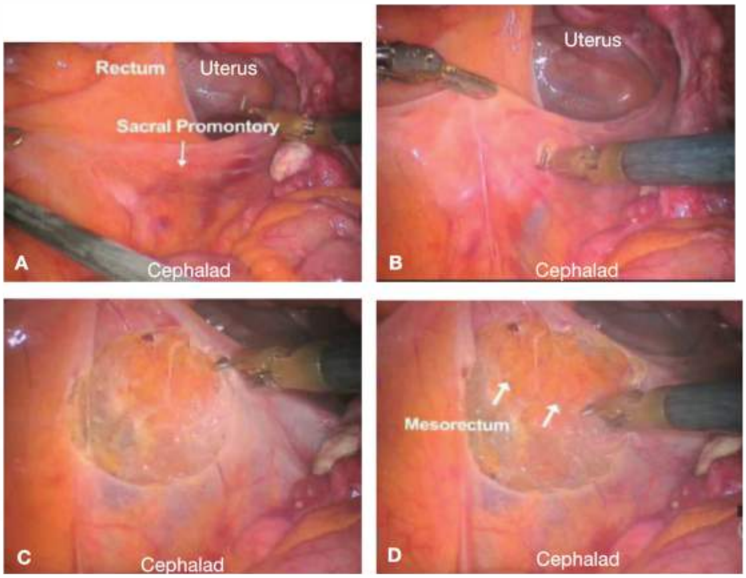

FIG 4 ● Entering the presacral plane. A medial-to-lateral approach is used with an incision of the peritoneum at the level of the sacral promontory *(arrow)* **(A)**. The avascular presacral plane is entered **(B)**, which is confirmed by the identification of the areolar tissue **(C,D)**.

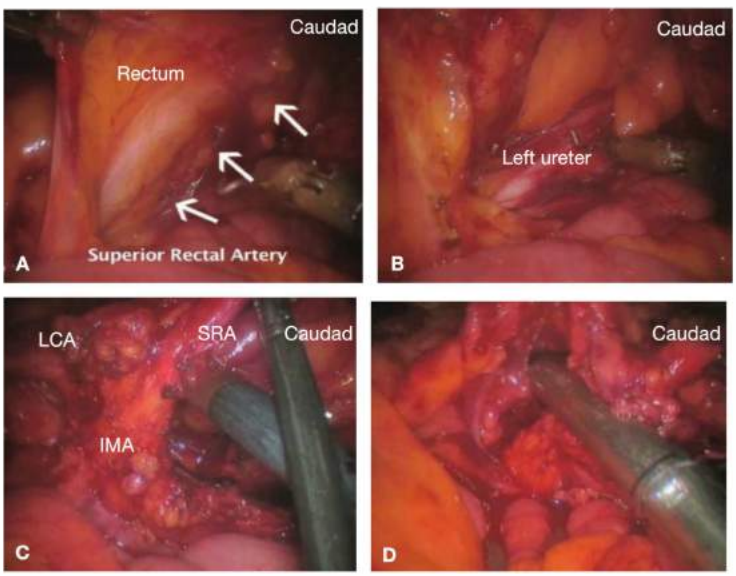

FIG 5 ● Medial to lateral dissection. The anatomic landmarks, superior rectal artery (SRA) **(A)** and left ureter **(B)**, are identified prior to vascular pedicle isolation. The inferior mesenteric artery (IMA), left colic artery (LCA), and SRA are dissected and isolated **(C)**. The IMA is divided **(D)**.

VASCULAR DIVISION

- At this point, the inferior mesenteric artery is ligated at its origin from the aorta using a laparoscopic stapler, electrosurgical device, or clips (FIG 5).

MESORECTAL DISSECTION

- Attention is drawn to the pelvis for the mesorectal excision. The pelvic dissection proceeds posteriorly first, then laterally, and then anteriorly.
- First, the avascular presacral plane is entered for the posterior dissection. Arm 3 is used for retraction, whereas arms 1 and 2 develop a plane of dissection within the avascular presacral space between the presacral fascia, posteriorly, and the mesorectal fascia, anteriorly. Arm 2 of the robot (left hand of the surgeon) should avoid grasping the mesorectum, for the strong robotic arm may tear the mesorectum, which would cause bleeding.
- The fascia propria of the rectum is identified and preserved with sharp dissection using the robotic scissors or monopolar device. Dissection continues in the posterior mesorectal plane through the retrorectal (Waldeyer's) fascia to the level of the anorectal junction (**FIG 6**).
- The lateral mesorectal dissection follows (**FIG 7**). The hypogastric nerve can be seen posterolateral to the plane of the dissection. It is important to preserve these nerves intact to avoid autonomic dysfunction postoperatively (**FIG 7**). Attention is first drawn to the right lateral pelvic attachments, which are divided starting at the level of the anterior peritoneal reflection and extending distally until reaching the levator ani muscle (**FIG 8**). The left lateral rectal ligament is then transected in a similar fashion (**FIG 9**).
- Lastly, the anterior mesorectal dissection is performed (**FIG 10**).
- For the anterior pelvic dissection, exposure is achieved by the assistant retracting the rectum posteriorly and in a cephalad direction, as arm 3 anteriorly retracts the vagina (in females) or the prostate/seminal vesicles (in males).
- In males, the Douglas pouch (rectovesical pouch) is entered by incising the peritoneal reflection between the anterior wall of the rectum and the prostate/seminal vesicles, taking care to avoid injury to the seminal vesicle and prostate (**FIG 11**).
- In the female patient, the anterior cul-de-sac is usually deeper and the rectovaginal plane is readily established once entered.
- Following the anterior dissection, the lateral stalks of the rectum are further divided as necessary, achieving hemostasis with an electrosurgical device. Care is taken at this level to avoid excessive lateral dissection, which may result in injury to the pelvic nerve plexuses (this would lead to autonomic dysfunction postoperatively). It should be noted that, typically, brisk bleeding may occur if the wrong plane is entered (posteriorly, by injuring the

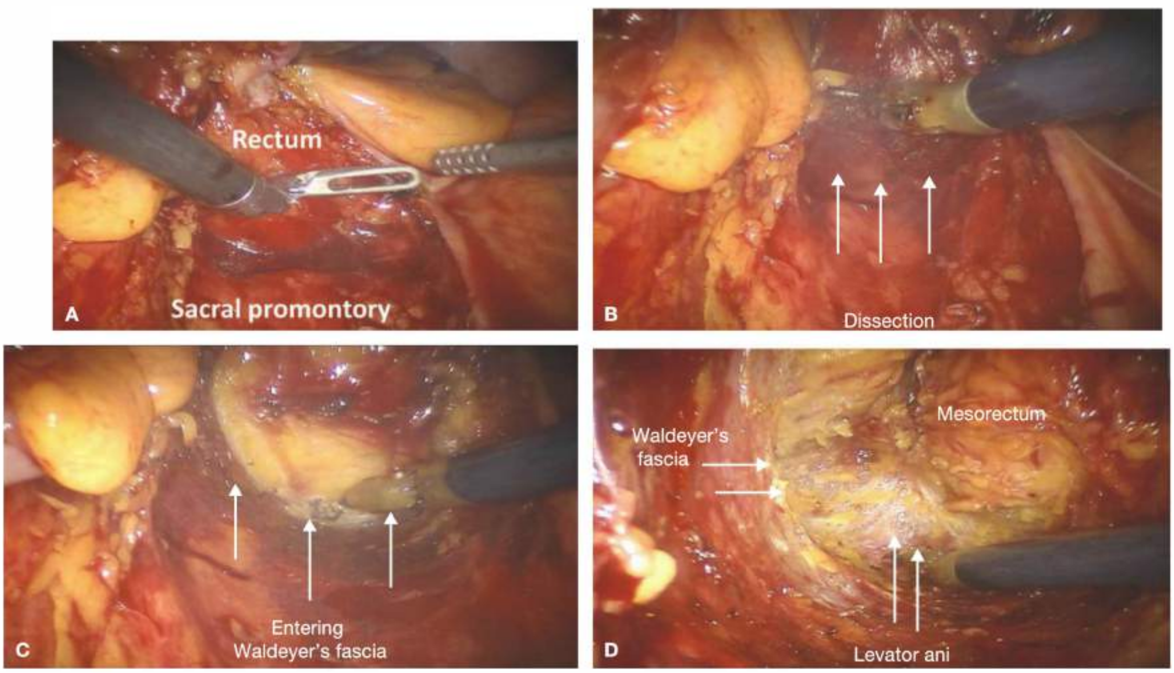

FIG 6 ● Presacral plane dissection. **A.** Development of the avascular presacral plane. The robotic arm 3 (not shown) serves as retractor proximally, whereas robotic arm 2 countertracts the mesorectum anteriorly for dissection with robotic arm 1 (not shown). **B.** The dissection is carried out distally with the robotic arm 1 using monopolar energy or scissors. **C.** The plane is further developed and Waldeyer's fascia is entered. **D.** The plane is completed distally to the level of the levator ani muscles.

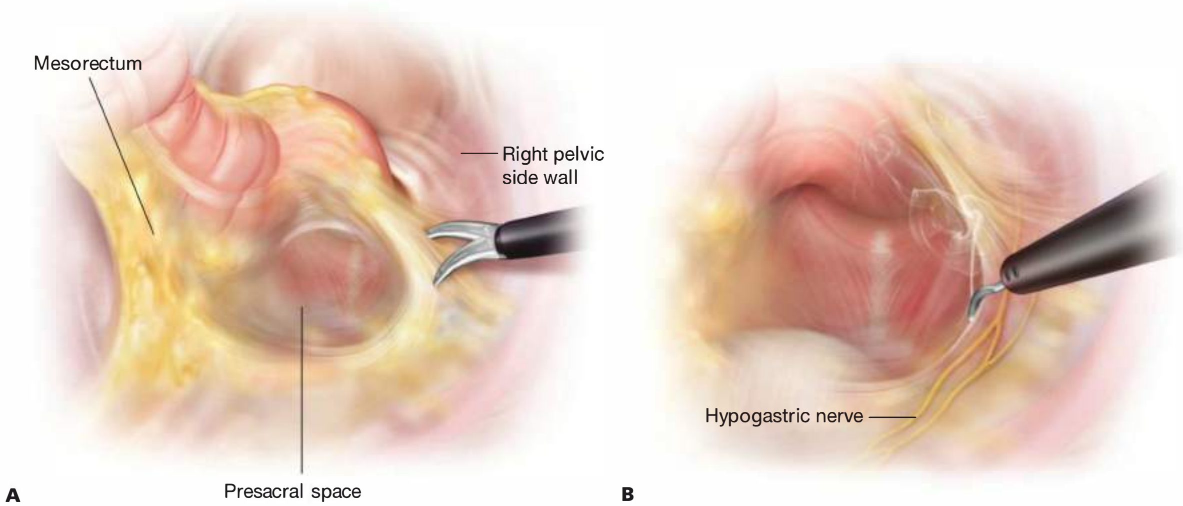

FIG 7 ● Lateral dissection of the mesorectum off the right pelvic sidewall. **A**. Transection of the right lateral rectal ligament. **B.** The hypogastric nerve can be seen posterolateral to the plane of the dissection. It is important to preserve these nerves intact to avoid autonomic dysfunction postoperatively.

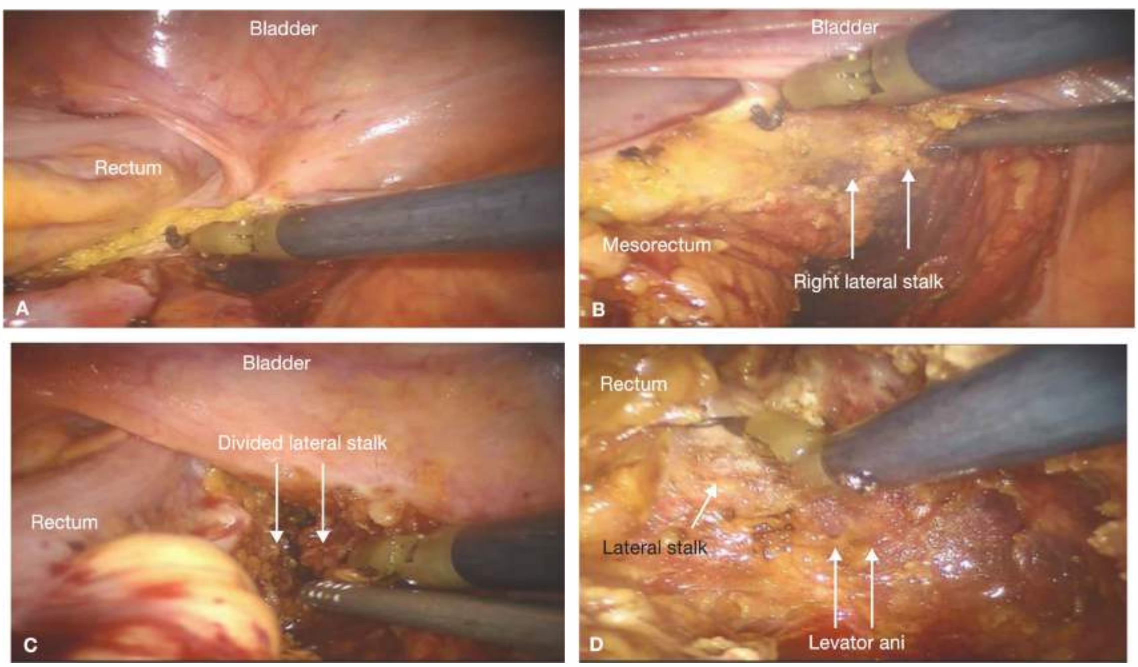

FIG 8 ● Right lateral mesorectal dissection. The right lateral mesorectal dissection is initiated at the level of the cul-de-sac **(A)** and carried out distally taking down the right lateral stalk **(B,C)** and continued distally until reaching the levator ani muscle **(D)**.

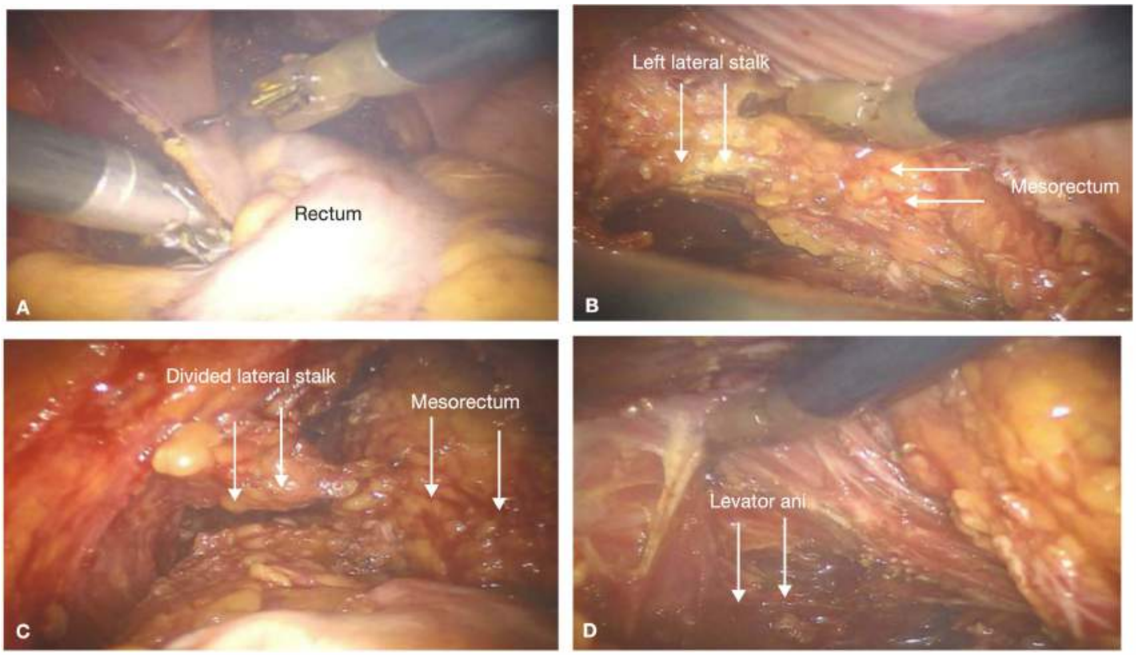

FIG 9 ● Left lateral mesorectal dissection. The left lateral dissection is initiated **(A)** and carried out distally taking down the left lateral stalk **(B,C)** and continued up to the levator ani **(D)** in a similar fashion.

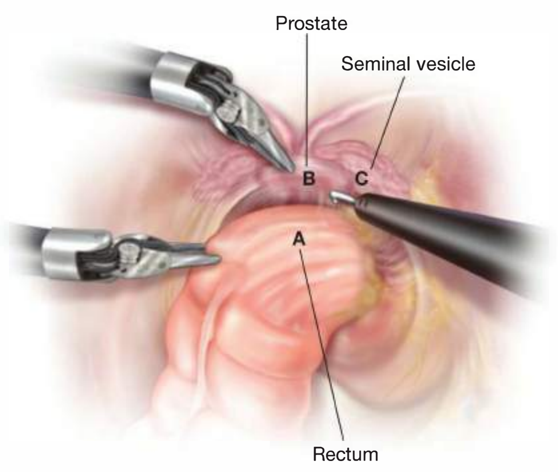

FIG 10 ● Anterior pelvic dissection. Exposure is achieved by the assistant retracting the rectum *(A)* posteriorly and in a cephalad direction as arm 3 anteriorly retracts the prostate/seminal vesicles *(B,C)*, respectively. The anterior plane of dissection is carried along Denonvilliers' fascia, between the rectum posteriorly *(A)* and the prostate *(B)* and seminal vesicles *(C)* anteriorly.

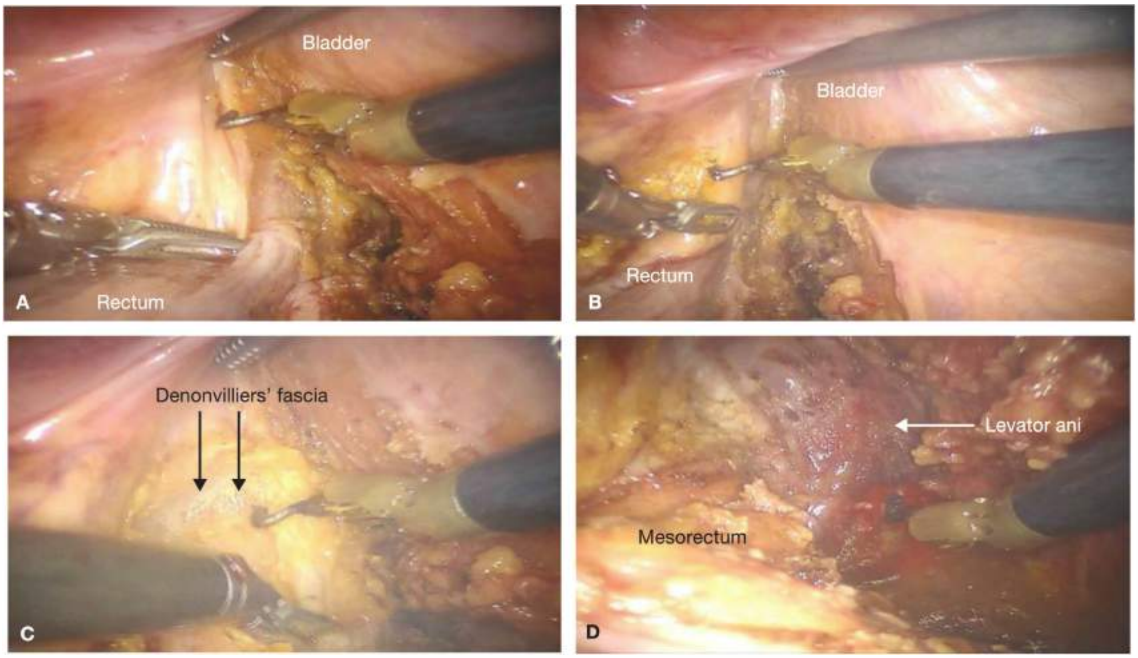

FIG 11 ● Anterior mesorectal dissection. The peritoneum is incised at the peritoneal reflection **(A,B)** and the dissection is carried out distally entering Denonvilliers' fascia **(C)** and continued inferiorly until complete anterior rectal mobilization is achieved and the levator ani muscle is encountered anteriorly **(D)**.

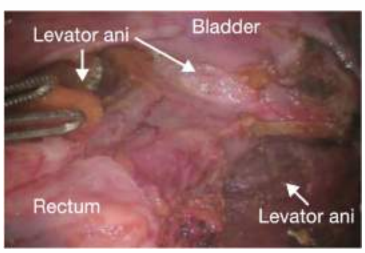
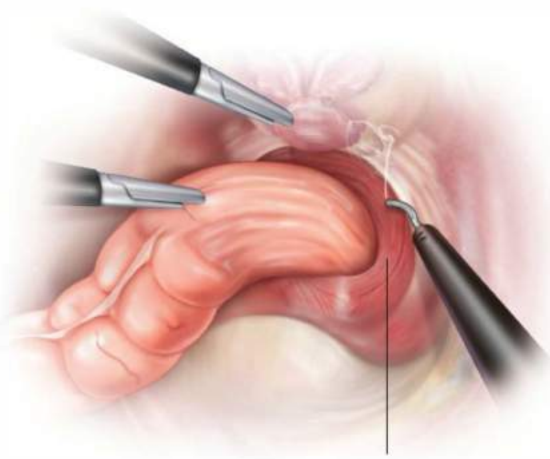
presacral venous plexus, and laterally, by injuring the hypogastric veins or its tributaries).

- Once the planes have been divided, circumferential exposure of the levator complex is achieved. Thus, the robotic portion the APR is carried out into the subcutaneous perineal tissue.
- In malignant cases, a cylindrical excision is then performed through the levator complex to ensure complete resection with proper radial margins. With the assistant retracting the rectum posteriorly and in a cephalad direction with a laparoscopic grasper and with the robotic arm 3 retracting the prostate/seminal vessels anteriorly, the levator ani muscle is exposed circumferentially around the distal rectum (**FIG 12A**). The levator ani is then circumferentially transected using monopolar electrocautery (**FIG 12B**).



A



B

FIG 12 ● Circumferential anterior transection of the levator ani. **A.** With the assistant retracting the rectum posteriorly and in a cephalad direction with a laparoscopic grasper and with the robotic arm 3 retracting the prostate/seminal vessels anteriorly, the levator ani muscle is exposed circumferentially around the distal rectum. **B.** The levator ani is then circumferentially transected using monopolar electrocautery.

PERINEAL PROCEDURE

- For malignant cases, a wide excision of the perineum circumferentially surrounding the anus is performed (**FIG 13A**).
- At this level, the incision is deepened to subcutaneous tissue and the planes achieved during the robotic portion of the procedure are reached (**FIG 13B**).
- The rectum and anus are extracted through the perineal wound.
- Appropriately performed cylindrical excision will result in a rectal specimen with an intact mesorectum and without an hourglass configuration in the final specimen (**FIG 14**).
- In cases involving benign disease, one should preserve levator ani to assist perineal closure and prevent perineal hernias. Such a resection would result in an hourglass configuration.
- Myofascial rotational flaps should be considered for closing the large defect and/or in a radiated pelvic floor.
- For benign cases, a narrow excision should be performed in order to be able to close the levator ani and preserve as much pelvic floor function as possible. In these circumstances, consideration to an intersphincteric excision, in which the external sphincter complex and the levator ani are left intact, is given. These muscle and fascial layers can then be used for primary closure and myofascial flaps can be avoided.

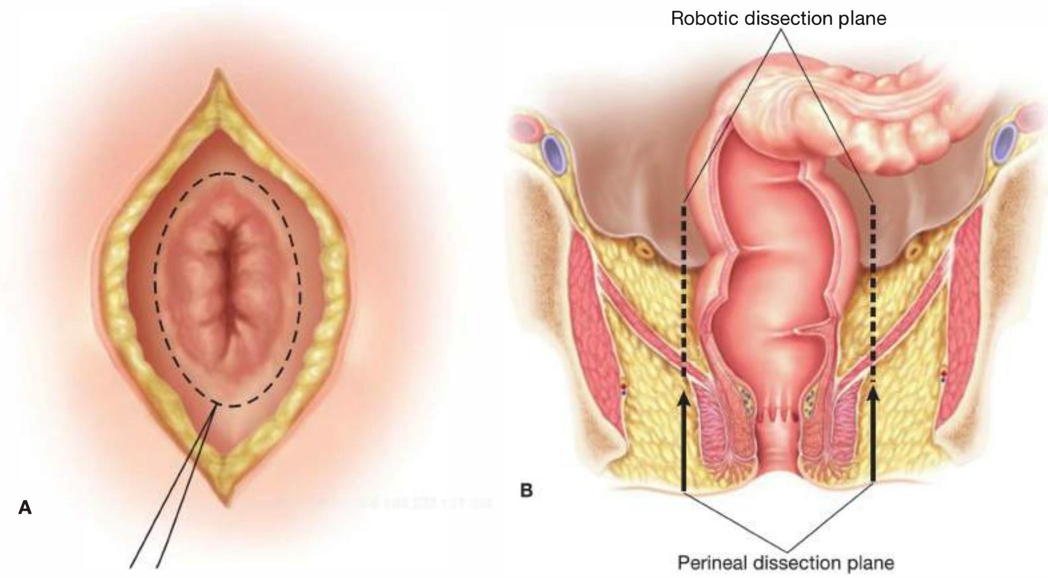


FIG 13 ● The perineal portion of the procedure is performed in a conventional fashion, with an elliptical perianal incision **(A)**. The perineal plane reaches the robotic dissection plane in the subcutaneous level **(B)**.

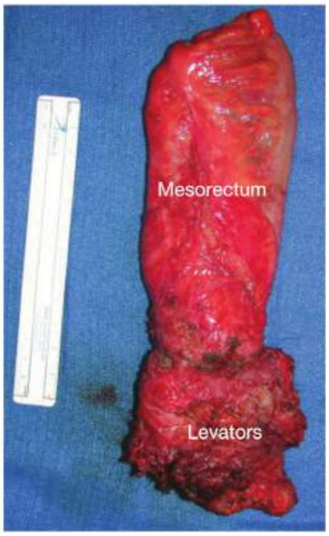

FIG 14 ● APR specimen. Note the shiny surface of the intact mesorectum with no distal tapering, avoiding an hourglass appearance on the specimen.

COLOSTOMY AND CLOSURE

- A circumferential incision in a predetermined size located on the left lower abdominal quadrant is performed through the rectus sheet for the creation of the colostomy.
- The subcutaneous tissue, fascia, and peritoneum are incised with a circumference of at least two fingerbreadths.
- The bowel proximal to the division is brought superficially to the abdominal wall and an end colostomy is performed in a conventional fashion. The colostomy is matured after wound closure.
- Before closure, the perineal incision is irrigated with normal saline and povidone-iodine.
- The perineal wound closure is initiated deep with imbrication of the levator ani (when preserved) with absorbable suture, typically 2-0 polyglactin 910 (Vicryl®). The superficial perineal subcutaneous tissues are reapproximated with 3-0 Vicryl sutures. The skin is closed with interrupted 2-0 nylon sutures.
- Port sites are closed with subcuticular 4-0 polydioxanone (PDS) sutures.

PEARLS AND PITFALLS

Indications	■ Low rectal cancer, anal cancer, recalcitrant IBD with anorectal involvement
Preoperative evaluation	■ Colonoscopy, abdominal CT scan, pelvic MRI, and/or endorectal ultrasound ■ Positron emission tomography (PET) scan selectively
Port placement	■ Two 12-mm ports for camera and assistant in the right upper quadrant and periumbilical region, respectively ■ Three 5-mm ports in the right lower, left upper, and left lower quadrants
Technique—laparoscopic exploration	■ Abdominal exploration and lysis of adhesions are accomplished with conventional multiport laparoscopy.
Robotic docking	■ The robot is docked in the left side of the patient's legs at an acute angle.
Technique—robotic pelvic procedure	■ The posterior mesorectal dissection, along the presacral plane, is done first, followed by the lateral dissection, and then by the anterior dissection. ■ The levator ani muscles are incised circumferentially through an anterior approach; the dissection is continued to the subcutaneous perineal tissue. ■ The pelvic portion is started with a circumferential perianal incision and deepened to reach the robotically established planes. ■ The perineum is closed either primarily or using a myofascial flap. ■ An end sigmoid colostomy is performed in a conventional fashion.
Postoperative management	■ Optimal postoperative outcomes are accomplished with a fast-track perioperative protocol and an ostomy care program.

POSTOPERATIVE CARE

- Patients following minimally invasive colorectal surgery are typically placed in an enhanced recovery pathway.
- Return of oral intake is typically achieved with clear liquids 8 to 12 hours after the procedure and the diet is advanced as tolerated.
- In contrast to purely abdominal procedures, for pelvic surgery the bladder catheter is not removed until postoperative day 2.
- Ambulation is indicated to accelerate recovery.
- Postoperative analgesia is accomplished with a combined modality involving intravenous acetaminophen, opioids, and nonsteroidal antiinflammatory drugs. Alvimopan is used to eliminate the effects of opioids in the gastrointestinal (GI) tract. Additionally, patient-controlled analgesia is limited to 1 to 2 postoperative days.
- Ostomy care is best achieved with a standardized protocol that includes preoperative and postoperative patient education and training. The program involves a multidisciplinary approach with patient and family, surgeon, and ostomy nurse.

OUTCOMES

- Most patients following robotic-assisted colectomy managed with a fast-track perioperative protocol have a length of hospital stay of 4 days.
- Longer hospital stay may be required to address complications.
- Perineal wound complications are common; thus, close postoperative follow-up following APR is required.
- Patients with malignancy should be placed on postoperative surveillance protocols.

COMPLICATIONS

- Vascular injury with intraperitoneal bleeding
- Ureteral injury
- Sexual and/or urinary dysfunction secondary to autonomic nerve injury
- Prolonged postoperative ileus
- Abdominal wound complications (e.g., hematoma, seroma, infection, and dehiscence)
- Persistent perineal sinus
- Intraabdominal abscess

- Perineal sepsis
- Parastomal and perineal hernia formation

Chapter **36**

Restorative Proctocolectomy: Open Technique (Ileal Pouch-Anal Anastomosis)

Hasan T. Kirat   Feza H. Remzi

DEFINITION

- Restorative proctocolectomy with ileal pouch-anal anastomosis (RP/IPAA) is defined as removal of entire colon and rectum and construction of an anastomosis of ileal pouch to the anal canal using stapled or hand-sewn technique.

DIFFERENTIAL DIAGNOSIS

- When the patients with ulcerative colitis become refractory to medical therapy or steroid dependant, RP/IPAA has been the surgical choice.
- RP/IPAA can be performed with good functional results and quality of life, and low pouch failure for indeterminate colitis.
- Patients with Crohn's disease have greater risk of pouch failure following RP/IPAA compared to those with ulcerative colitis.
- In patients with familial adenomatous polyposis, the risk of colorectal cancer is eliminated by performing RP/IPAA.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history and physical examination should be obtained.
- In inflammatory bowel disease, it is important to note previous and/or concurrent use of steroids, immunomodulators, and nonsteroidal antiinflammatory medications. Patients refractory to these medications are typically candidates for this procedure.
- Previous surgeries, particularly in Crohn's patients, need to be taken into consideration.
- Anal and urinary sphincter function needs to be evaluated. Patients with poor anal sphincter function may not be good candidates for RP/IPAA and may need a proctocolectomy with end ileostomy instead.
- A full nutritional assessment should be instituted.
- Significant cardiac and/or pulmonary comorbidities may prevent the patient to have this procedure.
- Family history of colorectal polyps, cancer, and/or inflammatory bowel disease should be elicited.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Preoperative colonoscopy is necessary.
- Diagnosis of ulcerative colitis and exclusion Crohn's disease by colonoscopic biopsy and by an experienced pathologist and/or with the assistance of other laboratory workup, such as Prometheus test, is necessary in order to establish the need for restorative proctocolectomy with ileoanal anastomosis.
- Colonoscopic evidence of terminal ileitis by biopsy may assist in the diagnosis of Crohn's disease.
- Diagnosis of ulcerative colitis with proctitis and involvement of the anal canal by colonoscopy or rigid proctoscopy and biopsy may be necessary in order to establish the need for anal mucosectomy and hand-sewn ileal pouch anastomosis.
- Contrast-enhanced computed axial tomography (CAT) scan may help evaluate cancer patients for locoregional extent of disease and metastases. CAT scan is also helpful in inflammatory bowel disease to evaluate for acute inflammatory processes (phlegmon, abscess, fistula, or obstruction).
- Endorectal ultrasound or rectal protocol magnetic resonance imaging (MRI) may assist with the staging of rectal carcinoma and identification of the anal sphincter muscle involvement. The latter would be a contraindication of a restorative proctocolectomy. It may also delineate the anatomy of the anal sphincter in case of previous obstetric trauma or episiotomies.
- Obtaining a Wexner fecal incontinence score preoperatively may assist with the diagnosis of fecal incontinence. Manometry studies may also be helpful in these patients. Preoperative fecal incontinence may lead to poor functional outcome following an ileoanal pouch anastomosis.
- Preoperative barium enema or small bowel follow-through contrast study may assist with the diagnosis of Crohn's disease.

SURGICAL MANAGEMENT

Preoperative Planning

- The site for a diverting loop ileostomy is marked before surgery.
- A complete bowel preparation is recommended.
- Prophylaxis against deep venous thrombosis and prophylactic perioperative antibiotics should be administered.
- The rectum is washed out with normal saline in the operating room.

Positioning

- The procedure is performed with the patient in a Lloyd-Davies position (**FIG 1**).
- This position is defined as Trendelenburg position with legs apart.
- The thighs are level with the abdomen as this allows efficient placement of a self-retaining retractor without creating excessive pressure between the retractor and the patient's thighs.
- All pressure points are padded to avoid potential neurovascular injuries.
- The perineum is positioned flush with the edge of the operating room table for easy access during the perineal phase of the operation.
- The pelvis is supported with a folded sheet to lift the entire perineum and facilitate exposure during the perineal dissection.
- The arms are placed in a neutral position and supported with suitable armrests or tucked to the side.

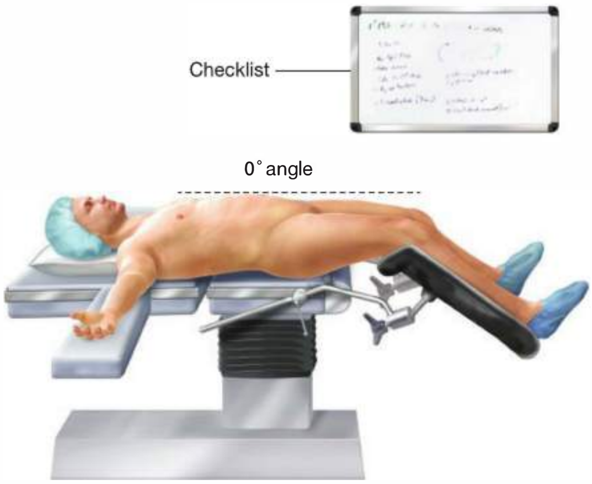

FIG 1 ● Patient positioning. The patient is placed on a Lloyd-Davies position, with the legs on stirrups. The thighs are positioned level with the abdomen, as this allows placement of a self-retaining retractor without creating excessive pressure between the retractor and the patient's thighs. The arms are tucked. All pressure points are padded to prevent neurovascular injuries.

PLACEMENT OF INCISION

- A midline vertical incision is made.
- A suitable laparotomy retractor is inserted.
- After general inspection to see if there are any contraindications to performing RP/IPAA, the small bowel is packed with moist large swab packs into the upper abdominal cavity.

MOBILIZATION OF THE RIGHT COLON: PRESERVATION OF THE ILEOCOLIC VASCULAR PEDICLE

- The surgeon stands to the patient's left side. The patient is placed on a Trendelenburg position with the right side up to facilitate exposure.
- A full Cattell-Braasch maneuver is performed to mobilize the right colon of its retroperitoneal attachments.
- The cecum and ascending colon are freed from the peritoneal reflection by incising along the white line of Toldt (**FIG 2**). The terminal ileum is also freed from the retroperitoneum and mobilized by incising the peritoneum along the root of the mesentery.
- As the colon and terminal ileum are reflected anteriorly and medially, the right gonadal vessels and right ureter should be identified in the retroperitoneum and not mobilized anteriorly so as to avoid injury.

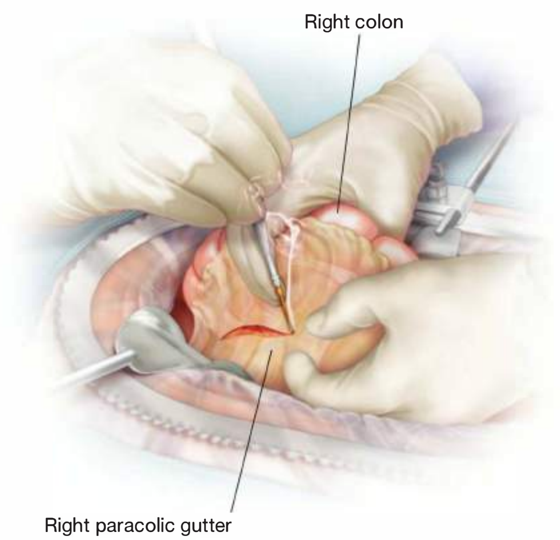

FIG 2 ● Ascending colon mobilization. The surgeon retracts the ascending colon medially. Dissection proceeds along the right paracolic gutter.

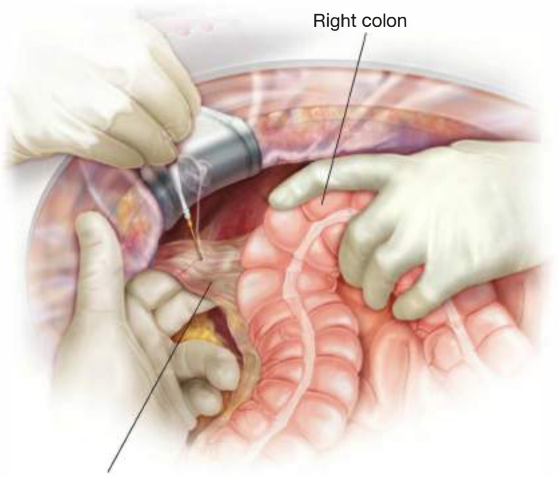

FIG 3 ● Hepatic flexure mobilization. Gentle traction on the hepatic flexure of the colon exposes the hepatocolic ligament, which is then transected with electrocautery.

- The lateral dissection is carried sharply up and around the hepatic flexure in the avascular, embryologic plane between the mesocolon and the duodenum. The second and third portions of the duodenum are identified near the hepatic flexure and injury to this structure must be avoided.
- The hepatocolic ligament is transected (**FIG 3**).
- Using an energy device, we hemostatically divide the ascending colon mesentery between the mesenteric vascular arcade and the colon wall (**FIG 4**) while protecting at all times the ileocolic vascular pedicle up to the mesenteric level of the ileocecal valve. This will allow excellent prograde blood supply to the pouch later on. Avoiding an ileocolic mesenteric bleeding or hematoma is crucial for preservation of the vascular supply to the ileal J-pouch.

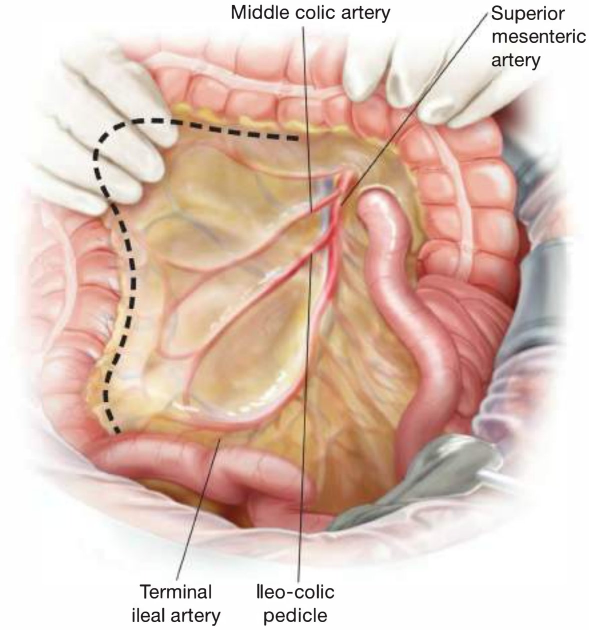

FIG 4 ● Right colon vascular transection. Using an energy device, we hemostatically divide the ascending colon mesentery between the mesenteric vascular arcade and the colon wall *(dotted line)* while protecting at all times the ileocolic vascular pedicle up to the mesenteric level of the ileocecal valve. This will allow excellent prograde blood supply to the pouch later on.

- The mesenteric division extends from the midtransverse colon down to the mesenteric border of the terminal ileum at the selected site of proximal intestinal division—just proximal to the ileocecal valve.

TRANSVERSE COLON MOBILIZATION

- The gastrocolic ligament is exposed as the assistant retracts the greater omentum superiorly while the surgeon retracts the transverse colon anteroinferiorly.
- Diathermy is used to separate the greater omentum from the anterior leaf of the transverse mesocolon.
- Mobilization of the spleen needs to be approached from both sides to facilitate ease of mobilization of the splenic flexure (**FIG 5**). The patient is placed on a reverse Trendelenburg position with the left side up to allow the spleen to come down into the surgical field.

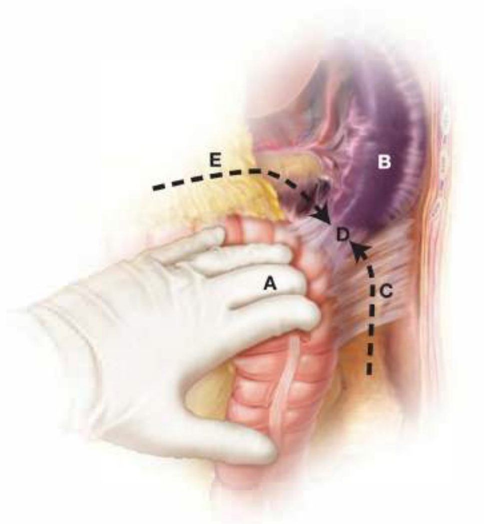

FIG 5 ● Splenic flexure mobilization. The surgeon retracts the splenic flexure of the colon *(A)* downward and medially, exposing the attachments of the splenic flexure to the spleen *(B)*. The phrenocolic *(C)* and splenocolic *(D)* ligaments are transected in an inferior to superior and lateral to medial direction. The gastrocolic ligament *(E)* is then transected in a medial to lateral direction, until both planes of dissection meet and the splenic flexure is fully mobilized.

- Once the gastrocolic ligament has been completely transected, transection of the lateral peritoneal attachments (phrenocolic ligament) allows for lateral mobilization of the splenic flexure.
- At this point and from the right side of the table, the surgeon hooks the splenocolic ligament anteriorly with his or her right index finger, exposing the ligament adequately for the assistant to transect it using electrocautery. The splenocolic ligament is divided as close to the colon as feasible, avoiding undue traction on the spleen.

DESCENDING COLON MOBILIZATION

- The surgeon stays on the right side of the table. The patient is placed on Trendelenburg position with the left side up.
- The descending colon is mobilized by medial traction and dissection along the left paracolic gutter using diathermy.
- The colon is mobilized from the retroperitoneum using a lateral to medial approach.
- Care is taken to identify, and avoid damage to, the left gonadal vessels and left ureter (**FIG 6**). In the lower abdomen, the left ureter is located medial to the gonadal vessels, close to the midline.

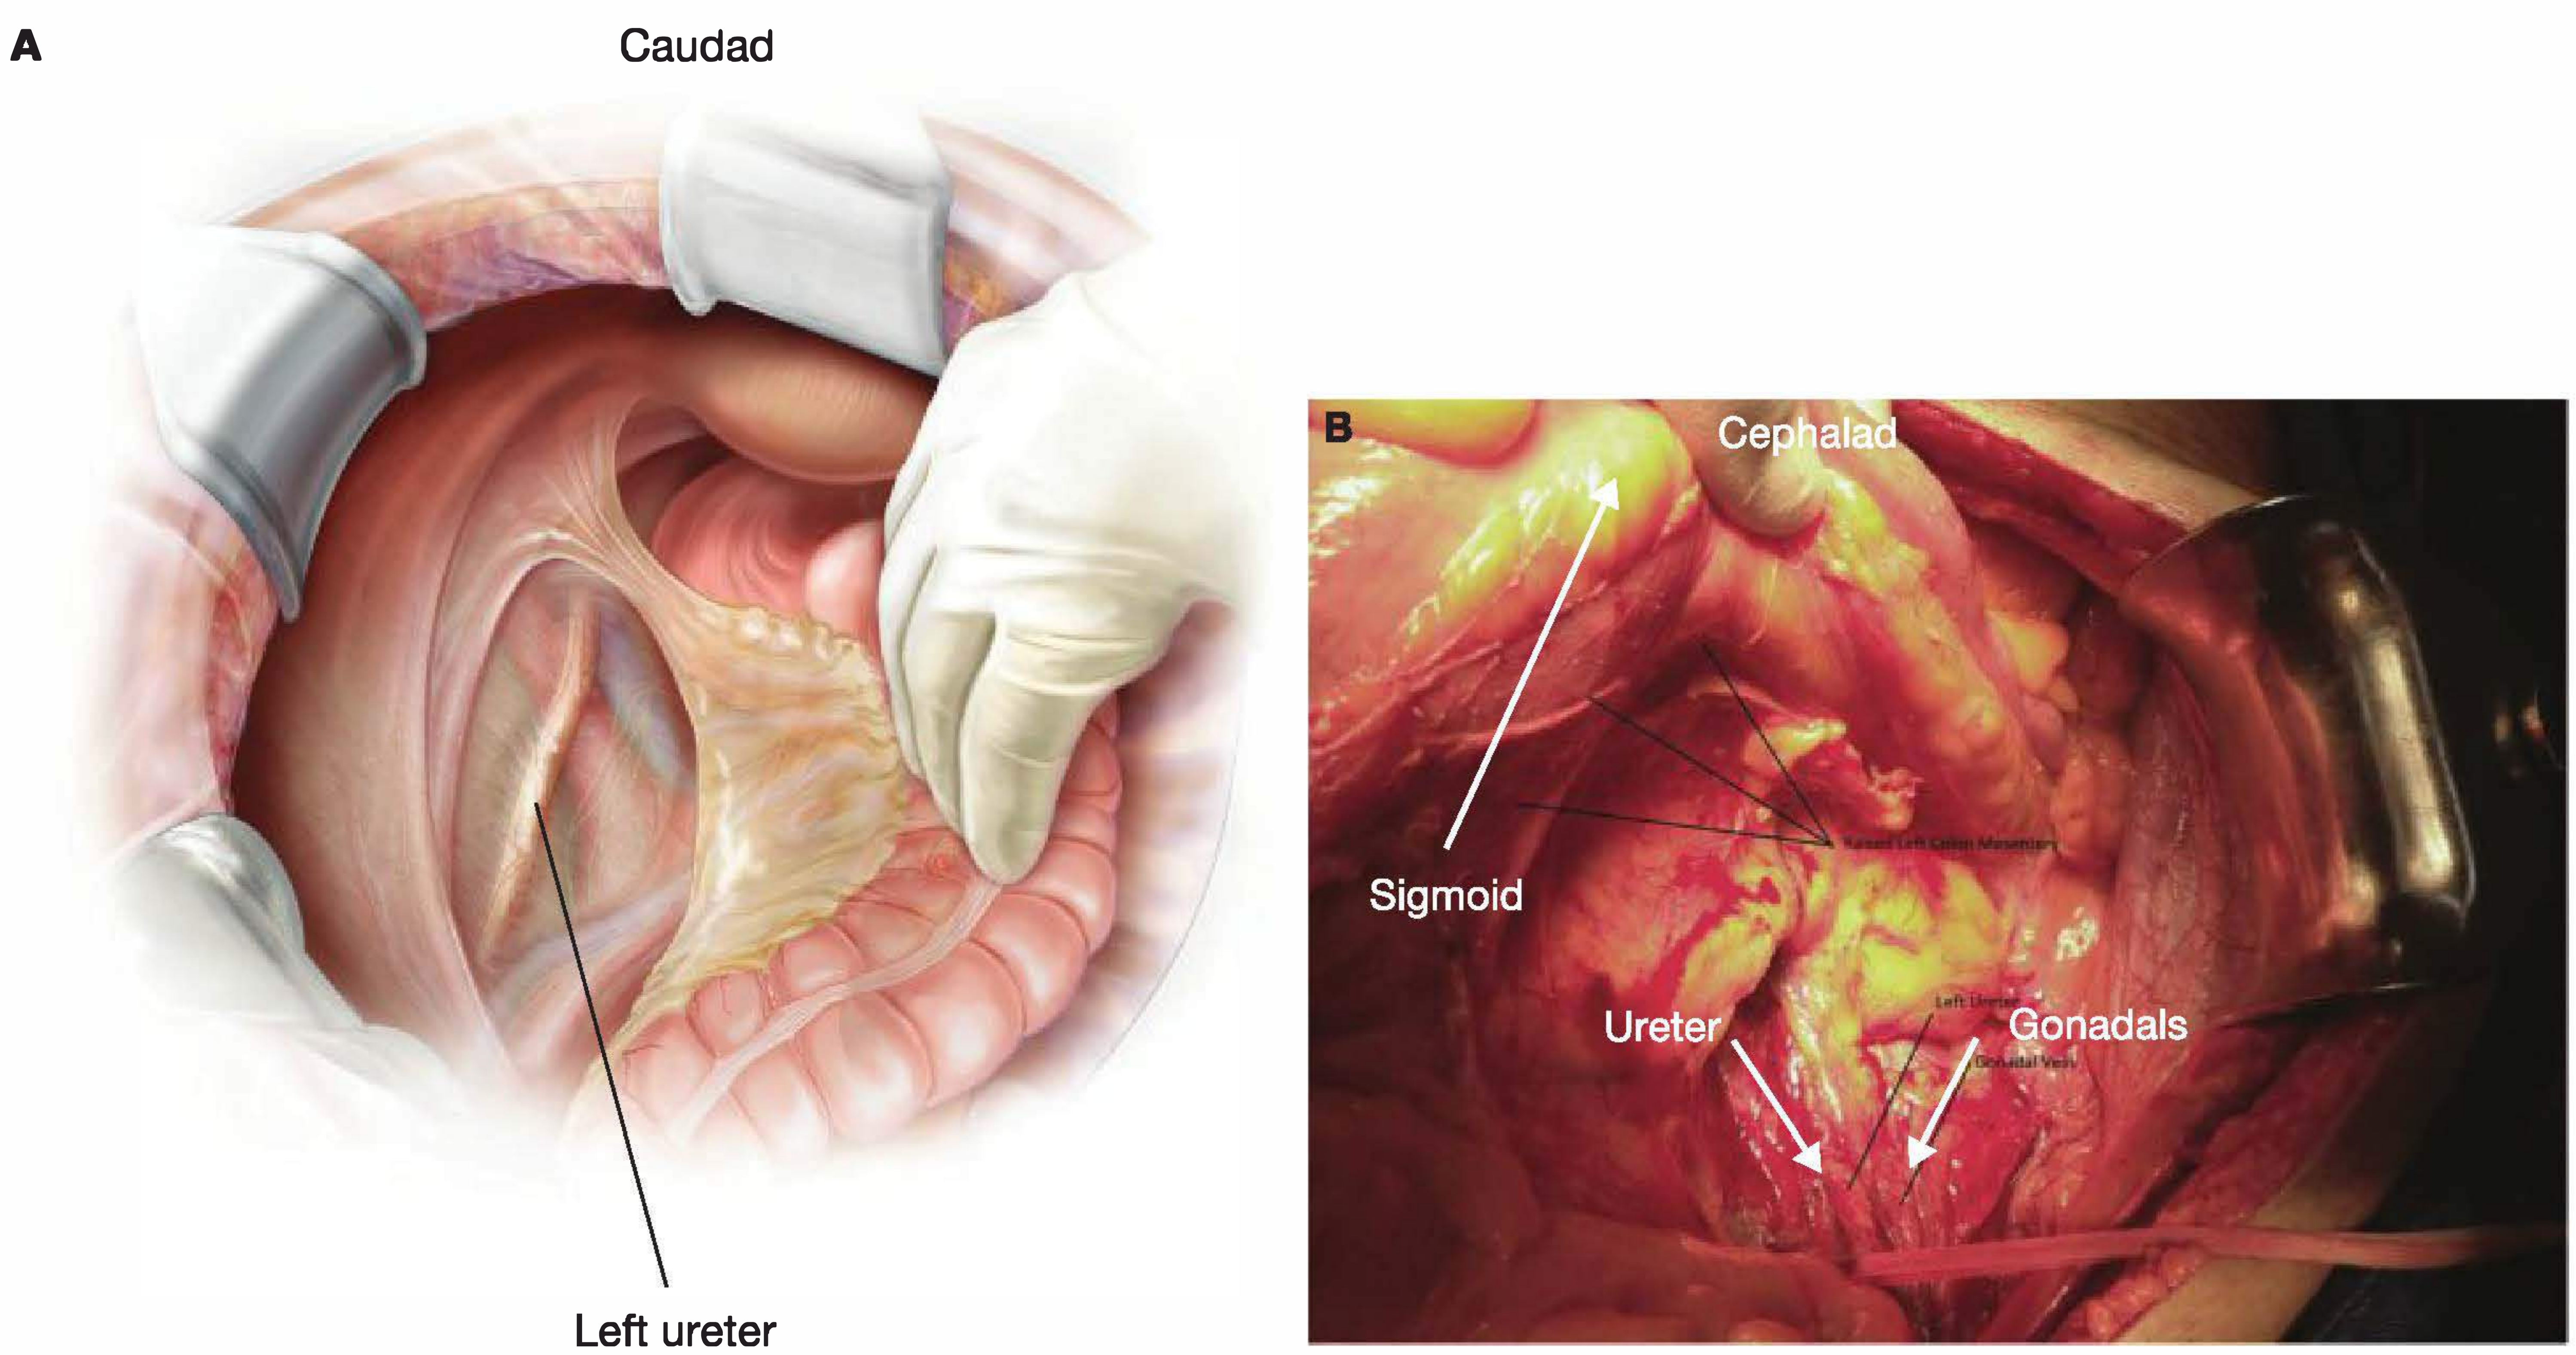

FIG 6 ● Exposure of the left ureter. The illustration **(A)** shows the view of the operative field from cephalad to caudad direction. The operative picture **(B)** shows a caudad to cephalad view of the field. In the lower abdomen, as the descending and sigmoid mesocolon are separated from the retroperitoneum by the lateral to medial dissection, the left ureter is located medial to the gonadal vessels, close to the midline.

INFERIOR MESENTERIC ARTERY TRANSECTION

- With the assistant holding the proximal and distal sigmoid colon up, the root of the mesosigmoid colon is clearly visualized by the surgeon from the right side of the table. At the root of the mesentery, the arch of the superior hemorrhoidal vessels (SHV) can be seen and palpated.
- Placing the index finger behind the SHV arch allows the surgeon to incise with electrocautery the right surface of the peritoneum just under the dorsal surface of the SHV.
- This plane of dissection along the dorsal aspect of the SHV is carried distally over the promontory (leading into the presacral space) and proximally, up to the origin of the inferior mesenteric artery (IMA). The IMA is dissected circumferentially at its origin from the aorta.
- The IMA is then ligated between Sarot clamps, incised, and doubly ligated with braided 2-0 suture (**FIG 7**).

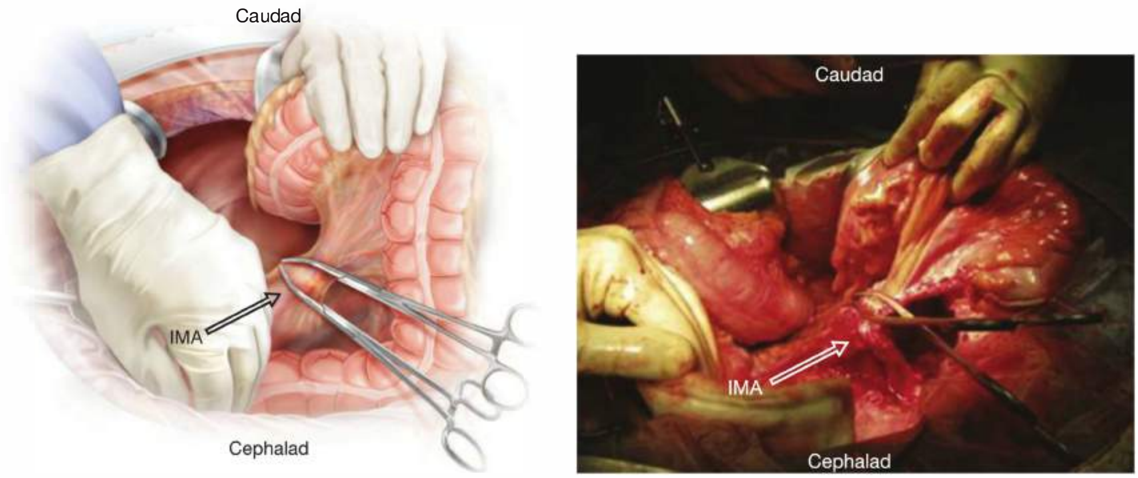

FIG 7 ● IMA division. The IMA is transected between clamps and will subsequently be ligated with heavy silk sutures.

PROCTECTOMY

- The posterior pelvic dissection is performed first. Using a lighted St. Mark's retractor for exposure, the presacral fascia is entered between the investing layer of fascia propria of the mesorectum and presacral fascia (**FIG 8**).
- The hypogastric nerves are identified at the pelvic rim and they are preserved (**FIG 9**).
- The pelvic dissection is continued in the midline between Waldeyer's fascia and the investing layer of the rectum to the level of the levator muscle. It is crucial not to violate the presacral fascia posteriorly where nervi erigentes and the lateral and presacral veins might be damaged.
- After the posterior dissection, a bilateral incision is made on the pelvic peritoneum and joined on the anterior rectal wall 1 cm above the peritoneal reflection. Dissection is then performed closer to the rectum to reduce the risk of nerve injury. The lateral ligaments are divided (**FIG 10**).

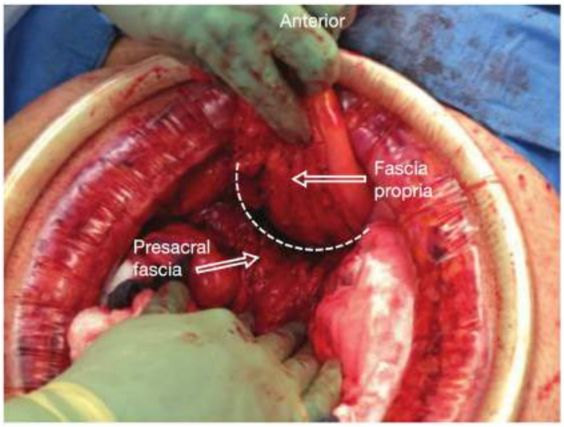

FIG 8 ● Posterior pelvic dissection. The posterior plane of dissection *(dotted line)* proceeds in a semicircular fashion along the presacral space, located between the fascia propria of the rectum, anteriorly, and the presacral fascia, posteriorly. This allows continued exposure of the posterior plane of dissection down to the pelvic floor and prevents vascular and nerve injuries along the lateral pelvic walls.

FIG 9 ● Preservation of the hypogastric nerves. Using a lighted St. Mark's retractor, the rectum is retracted anteriorly, exposing the presacral space posteriorly. The hypogastric nerves are exposed and should be swept posteriorly and away from the mesorectum. This begins the superior and posterior portion of the total mesorectal excision.

- The anterior dissection is done to the lower border of the prostate gland or lower one-third of the vagina (**FIG 10**). The Denonvilliers' fascia is preserved in patients without a carcinoma. The rectum is completely mobilized.
- A transanal digital evaluation with the tip of a finger is performed (**FIG 11**) to mark the level of distal rectal transection. The rectal transection is performed by a linear stapler for double-stapled IPAA or purse-string sutures for a single-stapled IPAA.

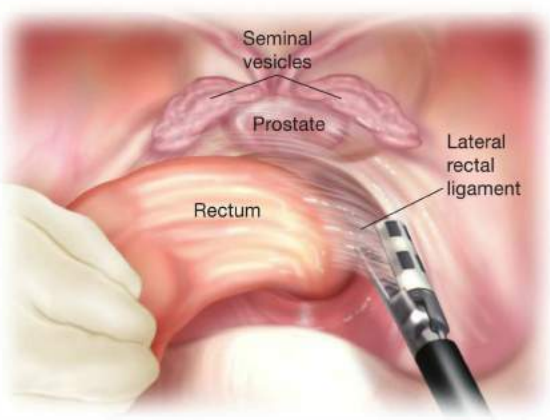

FIG 10 ● Transection of the lateral rectal ligaments and anterior pelvic dissection. Posterolateral retraction of the rectum allows for good exposure of the lateral rectal ligament (the right one is shown here), which can then be transected with an energy device. The anterior dissection will then proceed between Denonvilliers' fascia, posteriorly, and the prostate and seminal vesicles (*B* and *C*, respectively), anteriorly.

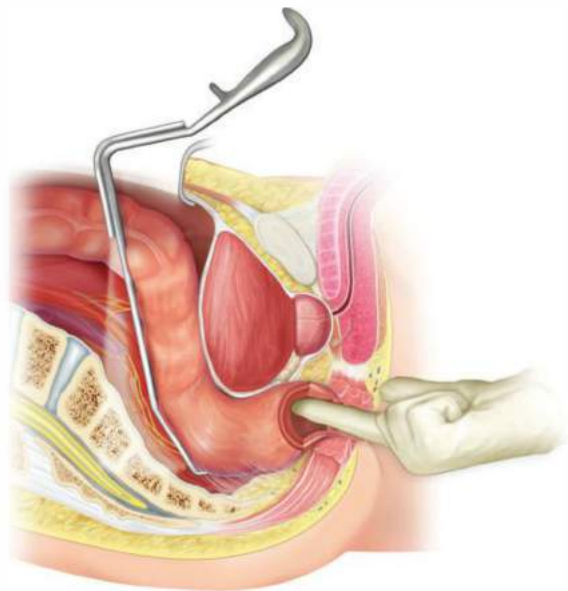

FIG 11 ● A transanal digital evaluation with the tip of a finger is performed to mark the level of distal rectal transection.

CREATION OF THE POUCH

- The pouch designs include J-, S-, or W-pouch (**FIG 12**). The J-pouch is the preferred technique because it is simpler to create. However, if there is an excessive tension in IPAA, an S-pouch can be created, because it usually reaches up to 4 cm further than the J-pouch.
- The J-pouch is created from the terminal 30 to 40 cm of small bowel, folded into two 15-cm or two 20-cm segments (**FIG 13**). A longitudinal 1, 5 cm apical enterotomy is made. A side-to-side anastomosis of the two limbs of the ileum is done with 100-mm linear staplers, which is passed through apical enterotomy. After making sure that no small bowel mesentery is interposed between the anvil and the cartridge, the instrument is fired. A second stapler fire is required in the same way (**FIG 13A**).
- The end of the divided terminal ileum is closed by a linear stapler (**FIG 13B**) and usually reinforced by oversewing with 3-0 polyglycolic acid sutures.
- The pouch is filled with saline to confirm integrity of the anastomosis (**FIG 13C**). The staple lines are checked for hemostasis.
- The apical enterotomy is closed using a 0 polypropylene purse-string suture.
- An S-pouch is created using three limbs of 12 to 15 cm of terminal small bowel with a 2-cm exit conduit. The limbs are approximated by continuous seromuscular 3-0 polyglycolic acid sutures. An S-shaped enterotomy is made. Continuous or running all-coat sutures are applied to the two posterior anastomotic lines from within the pouch. Closure of the anterior wall is done with continuous seromuscular sutures. Lastly, interrupted 3-0 polyglycolic acid reinforcement sutures are applied.

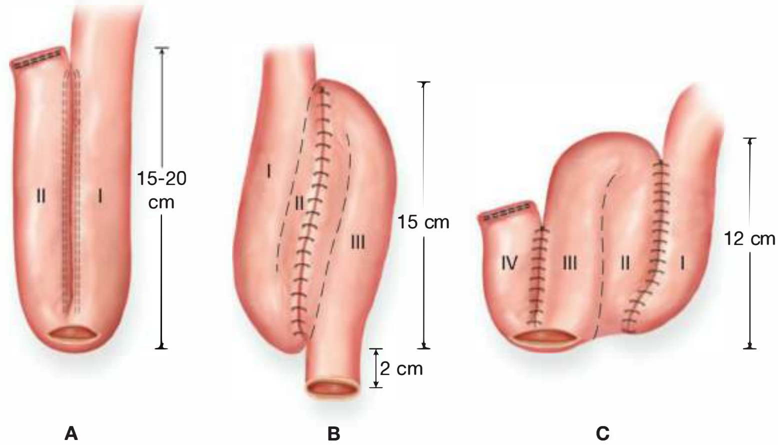

FIG 12 ● Ileal pouch configurations. The potential pouch designs include a J-, S-, or W-pouch.

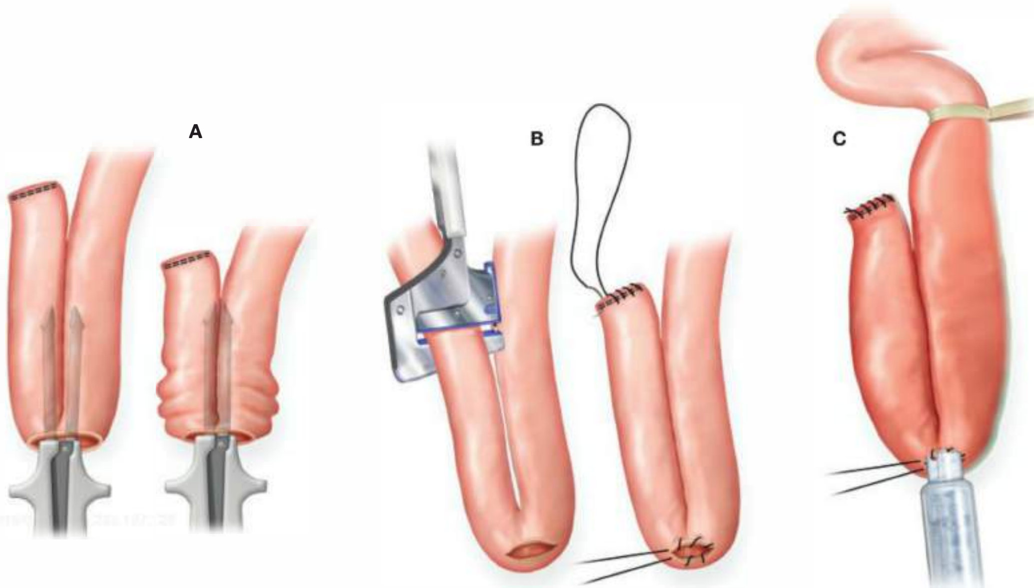

FIG 13 ● Creation of a J-pouch. The J-pouch is created from the terminal 30 to 40 cm of small bowel, folded into two 15-cm or two 20-cm segments by creating a side-to-side anastomosis with two sequential 100-mm linear stapler loads introduced through an apical pouch incision **(A)**. The end of the divided terminal ileum is closed by a linear stapler and reinforced by oversewing with 3-0 polyglycolic acid sutures **(B)**. The pouch is the filled with saline to confirm integrity of the anastomosis **(C)**.

THE POUCH DOES NOT REACH!

- The small bowel should be fully mobilized along the root of the mesentery up to the third portion of the duodenum so that the pouch reaches to the levator floor without tension.
- There may be difficulty with reach of the ileal pouch to the anal canal in obese patients or in patients who have had a previous small bowel resection.
- The reach can be estimated by grasping the ileal pouch at the apex and bringing it down to the pelvic floor.
- If the pouch does not reach, ligation and excision of the ileocolic artery and vein at their origin off the superior mesenteric artery (SMA) provides excellent pouch reach and allows for an anastomosis with no tension (**FIG 14A**).
- If further mobilization is necessary, the peritoneal tissue to the right of the superior mesenteric vessels is excised with the use of translumination. Additionally, transverse 1- to 2-cm peritoneal incisions over the superior mesenteric vessels border anteriorly and posteriorly can be done if needed (**FIG 14B**).
- In a narrow pelvis, a bimanual maneuver can overcome the difficulty in reaching a bulky ileal pouch to the anal canal. A long Babcock clamp is passed transanally to grasp the apex of the pouch and the surgeon's hand is passed behind the pouch to coax and ease the pouch and its exit conduit to the level of the levator floor (**FIG 15**).

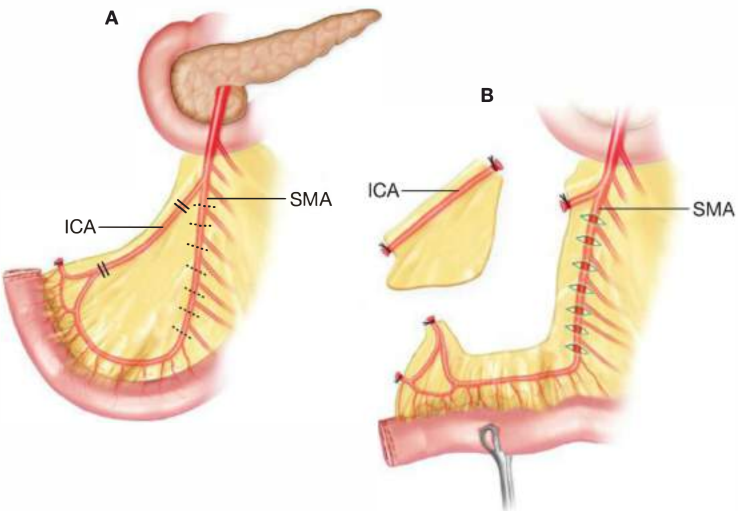

FIG 14 ● **(A)** Pouch elongation. If the pouch does not reach, ligation and excision of the ileocolic artery and vein at their origin off the SMA provides excellent pouch reach and allows for an anastomosis with no tension **(B)**. If further pouch mobilization is necessary, the peritoneal tissue to the right of the superior mesenteric vessels is excised with the use of translumination. Additionally, transverse 1- to 2-cm peritoneal stepladder incisions over the superior mesenteric vessels border anteriorly and posteriorly can be done if needed.

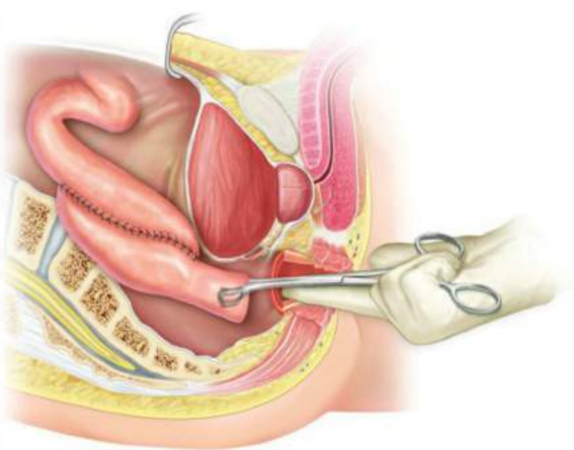

FIG 15 ● Bimanual pouch delivery maneuver. A long Babcock clamp is passed transanally to grasp the apex of the pouch and the surgeon's hand is passed behind the pouch to coax and ease the pouch to the level of the levator floor.

CREATION OF ILEAL POUCH-ANAL ANASTOMOSIS

Stapled Anastomosis

- IPAA can be created by either stapling or hand-sewn techniques. A stapled IPAA is constructed using either a double- or single-stapling techniques.
- In the double-stapling technique (**FIG 16**), the distal anorectal stump is closed with a linear stapler. After the stapler is fired, the specimen is divided above the linear staple line. The linear staple line on the anorectum should rest at a level just below the superior border of the levator floor. Hence, the level of the planned IPAA should be determined and marked beforehand.
- A circular stapler with the anvil detached is inserted into the anus and the pointed shaft/trocar is advanced just posterior to the linear staple line on the anorectum. This can be facilitated by putting the index finger into the anorectal area from the abdominal side and guiding the trocar just posterior to the linear staple line on the anorectum. The shaft of the circular staple line is then mated with the anvil shaft emerging from the ileal pouch. To prevent the twisting of mesentery, the small bowel is correctly oriented. The ends are approximated and anastomosis is completed. Both doughnuts are inspected for integrity. Care must be taken to avoid including the posterior vaginal wall and the anal sphincters within the anastomosis.
- Transanal insufflation with normal saline is performed to confirm that the anastomosis is intact.
- For a single-stapling anastomosis, a distal purse string is applied to the anorectal stump by hand with a 0 polypropylene suture. The surgical circular stapler is inserted transanally, the shaft is advanced completely, and the purse string is tightened. IPAA is then completed.

Hand-Sewn Anastomosis

- A hand-sewn IPAA is performed following mucosectomy of the anorectum (**FIG 17A**). The mucosa is stripped from the underlying sphincters starting at the dentate line to the level of the anorectal transsection. The anal verge is everted using sutures placed in four quadrants. An injection of 10- to 15-mL adrenalin solution (1:100,000) is used to raise the anorectal mucosa. A tube excision of anorectal mucosa is performed using cautery. Meticulous techniques are important to minimize risk of leaving islands of large bowel mucosa that are not amenable to surveillance.
- Excessive stretching of the anal canal may damage the anal sphincters; therefore, it should be avoided.
- 2-0 polyglycolic acid sutures are placed radially at the dentate line, incorporating a small portion of internal anal sphincter. Stitches should not be taken too deeply anteriorly in female patients in order to prevent development of anastomotic-vaginal fistula.
- After the apex of the J-pouch or end of the exit conduit of the S-pouch is delivered to the anal verge using a Babcock clamp (**FIG 17B**), the previously placed sutures at the dentate line are serially placed through the full thickness of the ileum (**FIG 17C,D**).
- The retractor is then removed and the sutures tied.

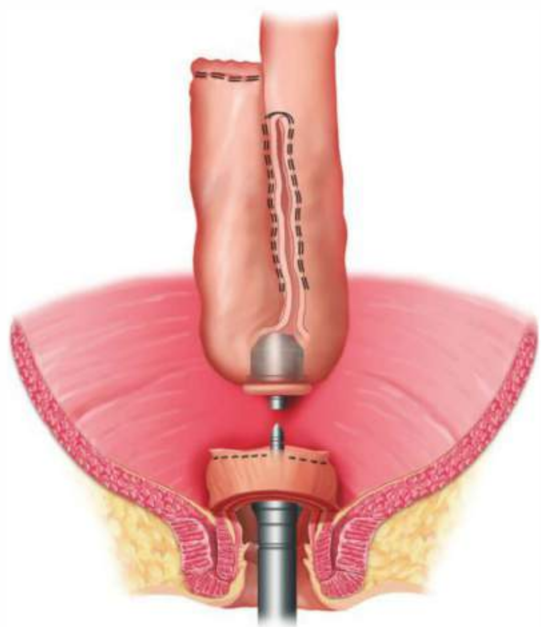

FIG 16 ● J-pouch ileoanal anastomosis: double-stapled technique. An end-to-end stapled anastomosis is performed between the pouch and the anal canal.

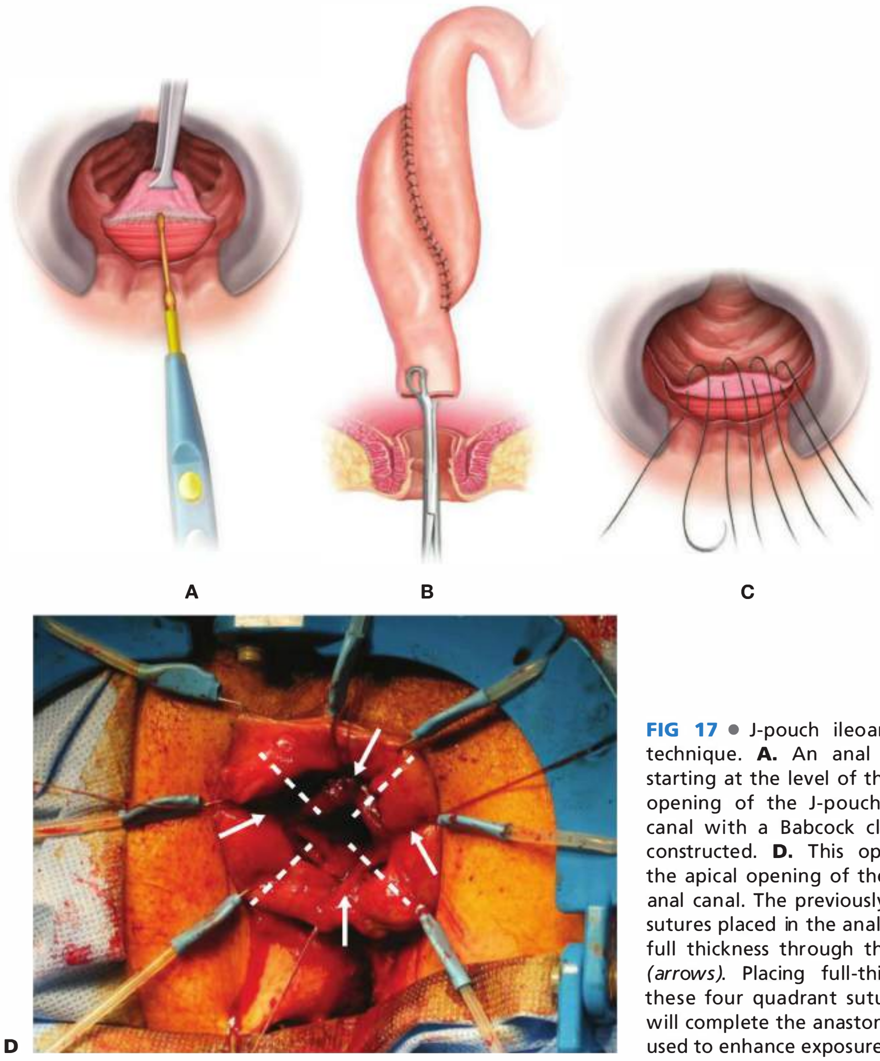

FIG 17 ● J-pouch ileoanal anastomosis: hand-sewn technique. **A.** An anal mucosectomy is performed starting at the level of the dentate line. **B.** The apical opening of the J-pouch is delivered into the anal canal with a Babcock clamp. **C.** The anastomosis is constructed. **D.** This operative picture shows how the apical opening of the J-pouch is anchored to the anal canal. The previously placed four-quadrant distal sutures placed in the anal canal have now been placed full thickness through the open end of the J-pouch *(arrows)*. Placing full-thickness sutures in between these four quadrant sutures (along the *dotted lines*) will complete the anastomosis. A Lone Star retractor is used to enhance exposure.

CREATION OF DIVERTING STOMA AND CLOSURE

- A temporary diverting loop ileostomy is created in the right lower quadrant, 20 to 25 cm proximal to the pouch. In obese patients, if the ileal loop does not reach to the abdominal wall without tension, a divided end ileostomy may be preferred.
- A closed suction drain is placed into presacral space.
- The incision is closed with running no. 1 polydioxanone (PDS) sutures. The skin incision is closed with staples.

PEARLS AND PITFALLS

Patient positioning	■ Place the patient in a Lloyd-Davies position.
Incision	■ Midline incision
In severe fulminant colitis or toxic megacolon	■ RP/IPAA should be performed in multistage: first, subtotal colectomy and end ileostomy, then completion proctectomy, IPAA, and loop ileostomy in 6 months.
Creation of pouch	■ J-pouch should be the preferred technique because of its simplicity. ■ S-pouch can be used if there is excessive tension.

The pouch does not reach	■ Mobilize the small bowel to the third portion of the duodenum. ■ Transect and excise the ileocolic vessels at their origin from the SMA. ■ Stepladder incisions on the mesentery overlying the SMA
IPAA	■ The small bowel should be mobilized sufficiently so that it will reach to the levator floor without tension. ■ Stapled IPAA should be the preferred technique because it is associated with better outcomes.
Diverting stoma	■ Reduces postoperative sepsis ■ In obese patients, if the ileal loop does not reach to the abdominal wall without tension, a divided end ileostomy may be preferred.

POSTOPERATIVE CARE

- Mean time to resuming a liquid diet is 3.8 days after surgery.
- The pelvic drain is left for 3 to 4 days or until the drainage is less than 50 mL a day.
- The mean length of hospital stay after RP/IPAA is 7.8 days.
- The diverting loop ileostomy is reversed in 6 weeks to 3 months, depending on the patient's performance and nutritional status, and only after a contrast study shows that the pouch and the anastomosis are intact.

OUTCOMES

- RP/IPAA is a good option for patients with ulcerative colitis, indeterminate colitis, familial adenomatous polyposis, and selected patients with Crohn's disease.
- J is the preferred design of the ileal pouch.
- Stapled IPAA seems to be associated with significantly less complications and better functional outcomes and quality of life compared to a hand-sewn IPAA.
- Diverting ileostomy during RP/IPAA improves outcomes, especially sepsis.
- However, ileostomy may still be omitted in selected low-risk patients.
- Rate of pouch failure after RP/IPAA can be as low as 5% when it is performed at specialized centers.
- Patients who undergo RP/IPAA report good functional outcomes and quality of life after a long-term follow-up.

COMPLICATIONS

- Early complications: pelvic sepsis, anastomotic leak, hemorrhage, wound infection, small bowel obstruction, pouch fistula, stricture
- Late complications: small bowel obstruction, pelvic sepsis, pouch fistula, anastomotic leak, stricture, pouchitis, chronic pouchitis, pouch failure

Chapter 37

Restorative Proctocolectomy: Single-Incision Laparoscopic Technique (Including Pouch Ileoanal Anastomosis)

Theodoros Voloyiannis

DEFINITION

- Single-incision laparoscopic restorative proctocolectomy, including pouch ileoanal anastomosis with temporary diverting loop ileostomy, is another application of the single-incision laparoscopic technique where a single multichannel laparoscopic port is used via a 2.5- to 3.5-cm total incision length.
- The procedure can be performed for benign or neoplastic diseases that require elective restorative proctocolectomy with a hand-sewn or stapled coloanal anastomosis including ileoanal pouch anastomosis such as ulcerative pancolitis, polyposis syndromes such as familial adenomatous polyposis or synchronous noninvasive rectal carcinoma and colonic carcinomas and polyps after appropriate oncologic staging workup.
- A variation of this procedure may be applied for mid- or low rectal cancer with adequate oncologic distal rectal wall margin, preferably of at least 2 cm, for creation of an anastomosis. In these cases, a low anterior resection with stapled coloproctostomy or hand-sewn coloanal anastomosis and temporary loop ileostomy may be performed.
- A completion proctectomy, an ileoanal pouch anastomosis with temporary loop ileostomy after a total abdominal colectomy for ulcerative colitis, is another application of this technique.
- A new approach, the transabdominal-transanal single-port technique or transanal single-port total mesorectal excision (ta-TME) for completion of the total mesorectal excision with placement of a transanal single port, is discussed in this chapter.
- The goal is to keep the procedure simple, safe, and cost effective, with comparable outcomes to hand-assisted or multiport laparoscopic technique.
- Although single-incision laparoscopic surgery differs technically from conventional laparoscopic surgery, it follows the same steps and oncologic principles. However, it requires advanced laparoscopic skills.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A detailed history and physical examination is essential preoperatively to determine if the patient is suitable for a laparoscopic approach. Rectal neoplasia after preoperative neoadjuvant chemoradiation or T4 rectal tumor extension to the sacrum, bladder trigone, prostate, posterior vaginal wall, or side pelvic wall with ureteral or major vessel involvement should be addressed preoperatively with appropriate staging workup. In these cases, laparotomy may be the best option, or if the procedure can be accomplished laparoscopically, a hybrid approach with a single-port laparoscopic technique at the suprapubic area with subsequent conversion to a Pfannenstiel incision may be considered.
- Potential intraoperative consultation to other subspecialties, such as gynecology for addressing an incidental neoplastic adnexal pathology, urology for ureteral or bladder tumor involvement or other surgical service, may be necessary. It is the primary surgeon's responsibility to communicate with the consulting service regarding the feasibility of a single-incision laparoscopic approach in order to avoid a lengthy single-incision procedure that may lead to conversion to hand-assisted laparoscopy or to a laparotomy.
- A restorative proctocolectomy allows for extraction of the specimen via the single port or transanally, in case of a planned coloanal or ileoanal pouch hand-sewn anastomosis. A full-thickness rectal division is performed at the level of the dentate line. In case of underlying colonic or rectal neoplasia, the size of the tumor determines if it can be extracted without tension via the single-port wound protector. In general, tumors up to 7 cm can be extracted via a 5-cm maximum length single incision. The procedure can still be performed with elongation of the incision for extraction of larger tumors. In that case, the benefit of the single port is eliminated, with the exception of the avoidance of use of multiple laparoscopic ports. If the single port is placed via the new ileostomy site, then partial approximation of the fascia may be required prior to maturation of the ileostomy.
- A large palpable tumor preoperatively with fixation to the abdominal wall or other organs may be a contraindication to single-incision laparoscopy, although excision en bloc with soft tissue abdominal wall is still possible via a single incision in some cases.
- It is important to define the underlying pathology—benign versus malignant disease and the location of the lesion—preoperatively. Neoplasia may require formal lymphadenectomy with preferable high ligation of the involved vascular supply. This may not be necessary in benign conditions such as ulcerative colitis or polyposis syndromes without dysplasia or neoplasia.
- In case of a planned ileoanal pouch anastomosis, particular attention is paid to the preservation of the ileocolic vascular pedicle in order to maintain the vascular supply of the pouch. The ileal pouch can be fashioned extracorporeally, following extraction of the colon and rectum via the single incision wound protector.
- Previous abdominal surgeries with extensive abdominal or pelvic adhesions may increase the operative time.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Preoperative colonoscopy is necessary to justify the planned restorative proctocolectomy.
- Diagnosis of ulcerative colitis and exclusion of Crohn's disease by colonoscopic biopsy and by an experienced pathologist

and/or with the assistance of other laboratory workup, such as Prometheus test, are necessary in order to establish the need for restorative proctocolectomy with ileoanal anastomosis.
- Colonoscopic evidence of terminal ileitis by biopsy may assist in the diagnosis of Crohn's disease and avoidance of an ileoanal pouch formation.
- Diagnosis of ulcerative colitis with proctitis and involvement of the anal canal by colonoscopy or rigid proctoscopy and biopsy is necessary in order to establish the need for anal mucosectomy and hand-sewn ileal pouch anastomosis.
- Contrast-enhanced computed axial tomography (CAT) scan of the abdomen/pelvis assists the surgeon to decide on the feasibility of a single-incision laparoscopic approach. It also helps in identifying the exact location of large colonic or rectal neoplastic lesions, the potential involvement of adjacent organs or structures, and the potential presence of mesenteric adenopathy and/or metastases as well as inflammatory processes (phlegmon, abscess, fistula, or obstruction).
- Endorectal ultrasound or rectal protocol magnetic resonance imaging (MRI) may assist with the staging of rectal carcinoma and identification of the anal sphincter muscle involvement. The latter would be a contraindication of a restorative proctocolectomy and may also delineate the anatomy of the anal sphincter in case of previous obstetric trauma or episiotomies.
- Fecal incontinence—Wexner score preoperatively may assist with the diagnosis of fecal incontinence. Preoperative fecal incontinence may lead to poor functional outcome following an ileoanal pouch anastomosis.
- Preoperative barium enema or small bowel follow-through contrast study may assist with the diagnosis of Crohn's disease.
- A carcinoembryonic antigen (CEA) level is obtained in malignancies as a tumor marker.

SURGICAL MANAGEMENT

- Full bowel preparation is administered the day prior to surgery to reduce the weight and volume of the colon. This facilitates the laparoscopic handling of the colon and the extraction of the specimen via a small 3.5-cm single incision.
- Obtain preoperative medical or pulmonary cardiac clearance as necessary.
- Correct anemia, electrolyte imbalances, and malnutrition preoperatively as needed.
- Wean off preoperative steroids to preferably less than 20 mg prednisone per day, if possible.
- Give consideration to weight loss prior to surgery, especially in cases of chronic preoperative steroid usage. A short and thick ileal mesentery may preclude an ileoanal pouch anastomosis.
- Intravenous (IV) antibiotics are administered prior to skin incision.

Instrumentation

- A laparoscopic operating room (OR) table with steep tilting is used. Test maximum tilting prior to draping to assess patients' secure positioning on the table (**FIG 1**).
- Two laparoscopic high-definition screens, one on each side of the OR table, are used.
- We use a bariatric length, 10-mm 30-degree camera. If needed, we use a right-angle adaptor for fiberoptic attachment to the camera to avoid conflict of the fiberoptic cord with other laparoscopic instruments. Using camera heaters and a smoke evacuator channel can avoid the need for repeated camera cleansing, leading to a decrease in operative length.
- We use two bariatric length laparoscopic bowel graspers, laparoscopic scissors, and bariatric length laparoscopic 5- to 10-mm suction irrigation.
- We prefer to use a bariatric length laparoscopic energy device such as the 43-cm LigaSure 5-mm device. Energy devices that produce excessive moisture or fog may impair visibility.
- Laparoscopic Endoloop polydioxanone (PDS) for the ileocolic vascular pedicle
- Staplers
  - Linear GIA 100-mm, triple blue staple lines for the ileal pouch formation
  - A 28- to 29-mm circular stapler for a stapled ileoanal pouch anastomosis
  - A 60-mm Endo GIA for distal division of the rectum as indicated
- A second set of instruments is necessary for an extracorporeal anastomosis.

FIG 1 • Patient setup. The patient is secured to the table, with the arms tucked, a strap across the chest, and the legs on Yellofin stirrups. All pressure points are padded to avoid nerve and vascular injuries. The table tilt is tested prior to starting the case to ensure that the patient does not slide.

Patient Positioning

- The patient is placed on modified lithotomy position on Allen stirrups with arms tucked (**FIG 1**). The patient is secured to the table, with foam pad placed under the patient's torso and with Velcro or broad tape placed across the chest. Rolled surgical towel is placed under the sacrum to elevate the pelvis and assist with the coloanal or ileoanal anastomosis.
- A Foley catheter is inserted and taped over the right thigh in order to avoid urethral trauma with the OR table tilting.
- A bear hugger or other thermal device is applied to the chest and legs.
- A protecting foam pad is placed over the head to protect from injury with laparoscopic instrument positioning.
- We recommend using laparoscopic draping with side plastic bags or pockets to allow for bariatric instrument placement. All laparoscopic cords and energy device cords are brought out via the patient's upper chest.

DIAGNOSTIC LAPAROSCOPY—SINGLE MULTICHANNEL PORT TECHNIQUE

- A 2.5-cm circular incision is performed at the right lower quadrant (RLQ) premarked temporary ileostomy site. Alternatively, a 3.5-cm periumbilical vertical midline incision is performed. A wound protector is inserted, followed by attachment of the single-incision laparoscopic surgery (SILS) port (**FIG 2A,B**).
- Assemble all channels of the SILS port on the back table to avoid losing parts outside the sterile field. Insert the laparoscopic multichannel single port with a wound protector. Insufflate pneumoperitoneum carbon dioxide (CO_2) to 15 mmHg of pressure.
- Perform a diagnostic laparoscopy. The surgical assistant/camera holder and the surgeon stand by the patient's right side when addressing the left colon, sigmoid, or rectum and by the patient's left side when addressing the right colon. For the transverse colon mobilization, either side may be suitable or the surgeon may be positioned between the patient's legs. Tilt the OR table to a steep Trendelenburg position and airplane it to the left or right for maximum exposure.
- Minimize excursion/cluster effect around hands and camera between the surgical assistant and operating surgeon with adherence to the principle that the surgeon should position his or her assisting (nondominant hand) instrument's distal tip (used for grasping, retracting, or suctioning) as close as possible to his or her operating (dominant hand) instrument's (i.e., energy device) tip. This distance should be about 3 to 4 cm between the two instruments' tips. For example, hold the ileocolic vascular pedicle just above the site of the division site rather than holing the cecum itself, which is far more distant from the pedicle. This technique allows achieving a wide angle between the two instruments outside the abdomen as they exit and cross via the single port, thus minimizing instrument conflict effect between the surgeon's hands.
- The assistant/camera holder will avoid conflict with the surgeon's instruments outside the abdomen by holding the camera as far as possible from the surgeon's hands and by using the camera's 30-degree angulation for side view as well as the zoom-in option (**FIG 2B**).
- Minimize the need for frequent laparoscopic instrument exchange, such as exchanging of graspers with monopolar laparoscopic scissors. Instead, consider using multiuse energy devices that provide dissection and sealing-cutting capabilities, thus allowing constant progress in the operating field and significant time saving.
- The surgeon and the assistant can either switch sides during the various steps of the procedure or just rotate the single port clockwise or counterclockwise while the instruments stay in the abdomen under direct visualization with the camera, thus achieving different camera angles, better exposure, and better visualization.
- The OR table can also be tilted accordingly during the various steps of the procedure to increase the exposure and prevent instrument conflict.

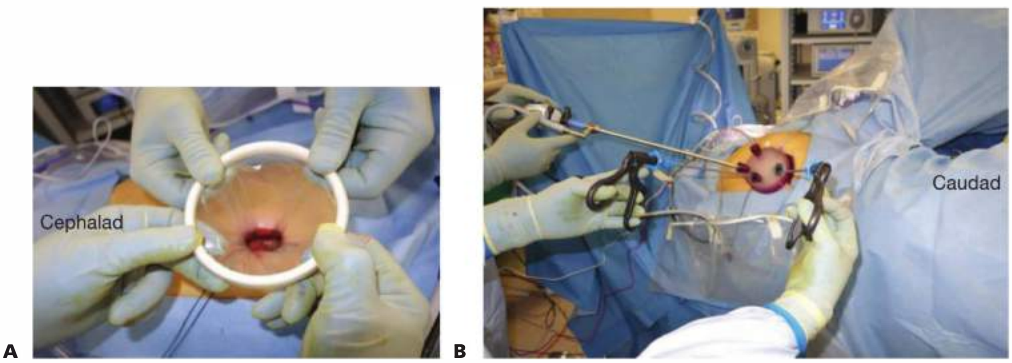

FIG 2 ● SILS port placement and configuration. **A.** A wound protector is inserted in the RLQ at the diverting loop ileostomy site. **B.** A multiport channel with four working ports, insufflation port, and a smoke evacuator port is used. The port is assembled on a side table prior to insertion in the patient. The assistant/camera holder will avoid conflict with the surgeon's instruments outside the abdomen by holding the camera as far as possible from the surgeon's hands.

MOBILIZATION OF THE RIGHT COLON: PRESERVATION OF THE ILEOCOLIC VASCULAR PEDICLE

- The patient is positioned in a steep Trendelenburg position with the OR table tilted maximally toward the patient's left side. The surgeon is standing on patient's lower left side using a grasper in the nondominant hand and the energy device on the dominant hand. The camera holder stands cephalad to the surgeon.
- If the omentum is adherent medially to the hepatic flexure or the ascending colon itself, we start the procedure with the dissection of the omentum off the colon. We may perform omentectomy by including the omentum with the transverse colectomy.

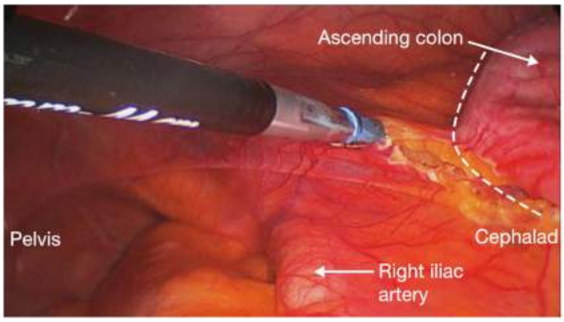

FIG 3 ● Mobilization of the ileum and ascending colon. The mobilization starts by transecting the ileocecal retroperitoneal attachments *(dotted line)*. The dissection will then proceed on a caudad to cephalad direction, eventually exposing the origin of the superior mesenteric artery and the third portion of the duodenum.

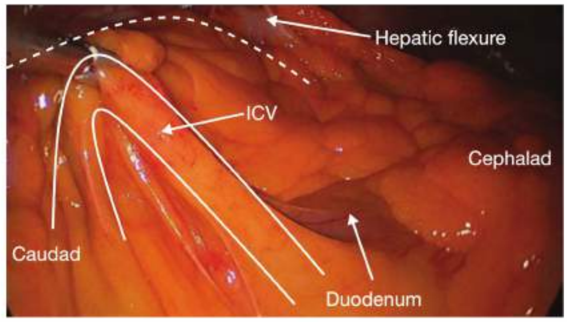

FIG 4 ● Preservation of the ileocolic vessels (ICV). During the dissection of the right colon, it is critical to divide the mesentery close to the colonic wall *(dotted line)*, preserving the ICV (here seen crossing over the third portion of the duodenum) intact. This will ensure excellent blood supply to the pouch.

- Dissect the terminal ileal retroperitoneal attachments and mobilize it toward the midline (**FIG 3**), exposing the origin of the superior mesenteric artery and the third and fourth portions of the duodenum. Morbidly obese patients require a generous terminal ileal medial mobilization to allow for a tension-free ileoanal pouch anastomosis.
- Proceeding from a caudad to cephalad direction, dissect the ascending colon mesentery off its retroperitoneal attachments without entering Gerota's fascia and preserving the right gonadal vessels and the right ureter intact. Dissect the ascending colon mesentery off the second and third portions of the duodenum in an atraumatic fashion.
- Using an energy device, we hemostatically divide the ascending colon mesenteric vascular arcade while protecting the ileocolic vascular pedicle up to the mesenteric level of the ileocecal valve (**FIG 4**). This is critical to ensure a good blood supply to the pouch. Avoiding an ileocolic mesenteric bleeding or hematoma is crucial for preservation of the vascular supply to the ileal J-pouch.
- Divide with the energy device the ascending colon mesentery flush to the ileocolic vascular pedicle (staying close to the colonic wall), up to the mesenteric border of the terminal ileum at the selected site of proximal intestinal division, just proximal to the ileocecal valve.
- Proceed with laparoscopic division of the incidental right colonic artery/vein if present.
- Mobilize the ascending colon medially by transecting the white line of Toldt.

MOBILIZATION OF THE TRANSVERSE COLON

- The surgeon stands in between the patient's leg. Place the patient on Trendelenburg and keep the OR table tilted to the left for the proximal transverse colon mobilization or to the right for the distal transverse colon and the splenic flexure mobilization. Alternatively, we may place the patient on reverse Trendelenburg for exposure and the assistant may use a laparoscopic grasper to assist with the retraction—"tenting"—of the transverse colon.
- Enter the lesser sac via the antimesenteric border of the proximal transverse colon and perform a hepatic flexure mobilization by dividing the hepatocolic ligament with the energy device (**FIG 5**).
- Divide the gastrocolic ligament adjacent to the mesenteric border of the transverse colon while preventing inadvertent injury of the gastroepiploic arcade.

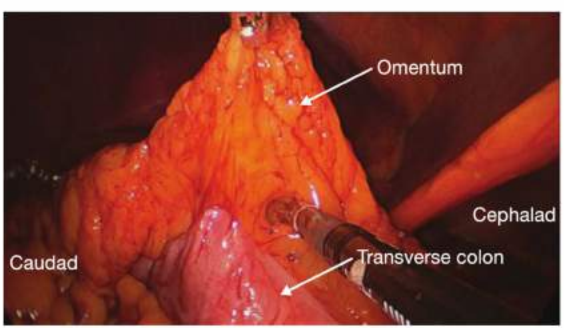

FIG 5 ● Entrance to the lesser sac. Enter the lesser sac via the antimesenteric border of the proximal transverse colon and perform a formal hepatic flexure mobilization using the energy device.

- The omentum may be included with the transverse colon into the specimen.
- Dissect the root of the hepatic flexure and proximal transverse colon mesentery and identify the origin of the middle colic artery and vein. Using an energy device, divide the middle colic vascular pedicle at the root of the mesocolon while holding the stump with a grasper to avoid retraction or residual bleeding (FIG 6).
- Place hemostatic clips or Endoloop PDS at the divided stump to secure the hemostasis. There is no need to use an Endo GIA stapler, unless severe atherosclerosis or vessels larger than 7 mm in size are present, which preclude usage of an energy device.
- Complete the dissection of the root of the distal transverse mesocolon off the retroperitoneum, pancreas, and fourth portion of the duodenum with the energy device.

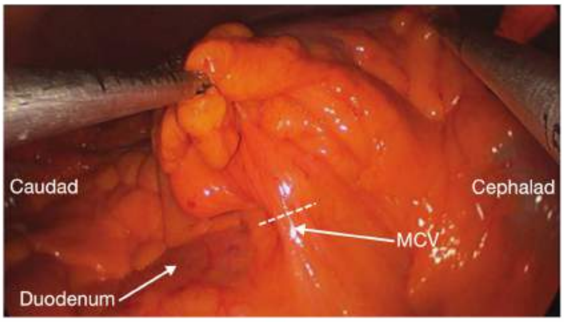

FIG 6 ● Identification and division of the middle colic vascular pedicle. With the transverse colon tented up with two graspers, the middle colic vessels (MCV) can be identified at the intersection of the root of the mesotransverse colon and the third portion of the duodenum. After dissection, the middle colic vessels will be transected *(dotted line)* with an energy device.

SPLENIC FLEXURE MOBILIZATION, LEFT COLECTOMY, AND SIGMOID COLECTOMY

- The surgeon stands on the patient's right side and caudally to the assistant, with the OR table tilted to the right.
- Start the dissection of the root of the sigmoid mesocolon off the retroperitoneal attachments by dissecting dorsal to the superior hemorrhoidal vessels (FIG 7A). Identify and preserve the left ureter (FIG 7B), gonadal vessels, and hypogastric nerves intact.
- Skeletonize the origin of the inferior mesenteric artery (IMA). Perform a high IMA transection (FIG 8A,B) as described earlier for the middle colic vascular pedicle.
- Perform a medial to lateral mobilization of the descending colon mesentery off the retroperitoneal attachments by sweeping the retroperitoneal tissues down (dorsally) with an energy device (FIG 9). This dissection is carried laterally to the lateral abdominal wall, superiorly separating the tail of the pancreas from the splenic flexure of the colon, and inferiorly to the pelvic inlet. This dissection greatly facilitates the lateral mobilization of the descending colon and the splenic flexure mobilization.

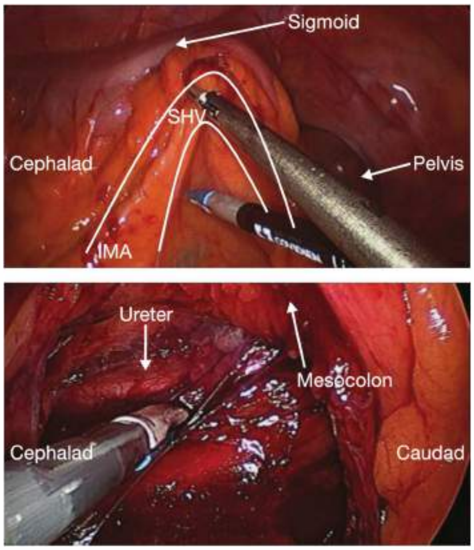

FIG 7 ● Dissection of the IMA and the superior hemorrhoidal vessels (SHV). **A.** The dissection starts at the root of the sigmoid mesentery, dorsal to the SHV. **B.** The retroperitoneal structures, including the left ureter, are swept down (dorsally) with the energy device, separating them for the mesocolon.

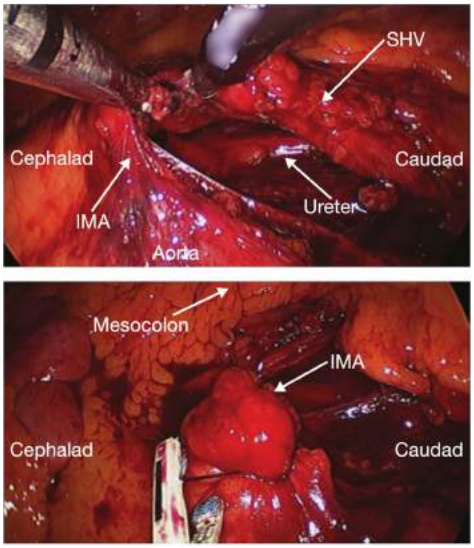

FIG 8 ● IMA transection. **A.** With the left ureter safe in the retroperitoneum, a high IMA transection is performed off the aorta with the energy device. **B.** The IMA stump is secured with an Endoloop.

- Divide the inferior mesenteric vein and the left colic artery by the ligament of Treitz with the energy device.
- Perform a lateral mobilization of the descending and sigmoid colon by transecting the white line of Toldt. The medial to lateral dissection plane is readily entered.
- Mobilize the splenic flexure of the colon by dividing the gastrocolic, splenocolic, and phrenocolic ligaments using an energy device. Care is taken to avoid injury to the pancreatic tail and to the spleen (**FIG 10**).

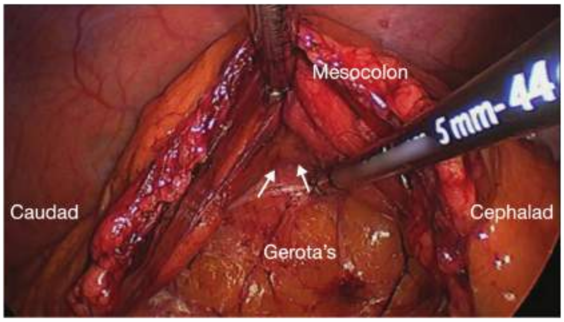

FIG 9 ● Medial to lateral mobilization of the descending colon. The descending mesocolon is separated from Gerota's fascia and other retroperitoneal structures. The dissection proceeds laterally until reaching the lateral abdominal wall. The dissection proceeds at the transition between the two distinctive fat planes *(arrows)*.

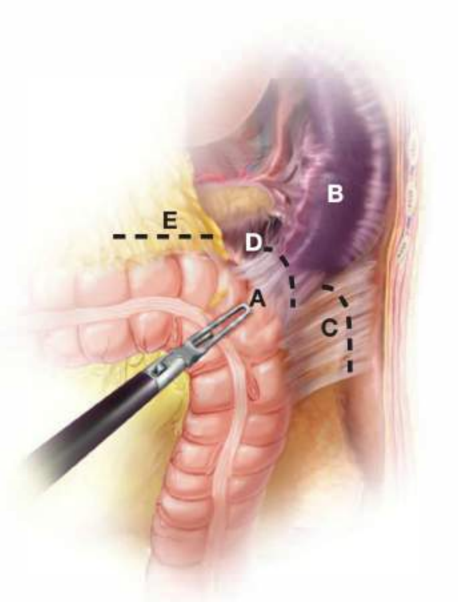

FIG 10 ● Mobilization of the splenic flexure. The splenic flexure *(A)* is separated off the spleen *(B)* by transecting the phrenocolic *(C)*, the splenocolic *(D)*, and the gastrocolic *(E)* ligaments using an energy device.

PROCTECTOMY AND TOTAL MESORECTAL EXCISION

- The surgeon stands on the patient's right side and cephalad to the assistant; the OR table is tilted to the right. The RLQ single port site allows for excellent exposure during the total mesorectal excision.
- Start with the posterior mobilization of the rectum by dissecting the presacral avascular plane. The dissection proceeds caudally in this plane to the level of the levator muscles while preserving the hypogastric nerves (**FIG 11**). Avoid penetrating the presacral fascia in order to avoid potentially serious bleeding from the presacral venous plexus.
- The lateral mobilization of the rectum is then performed by dissecting the lateral rectal attachments and dividing the lateral ligaments with the energy device. Care is taken to avoid penetrating the endopelvic fascia at the lateral pelvic walls, which could result in severe bleeding from injury to the hypogastric vein and its branches (**FIG 12**).
- At this point, mobilize the rectum anteriorly. Include into the specimen the anterior (Denonvilliers') fascia for mid- to low anterior rectal carcinoma while completing the dissection caudally to the levator muscles. Care is taken to avoid injury to the nervi erigentes, bladder, trigone, seminal vesicles, prostatic capsule, and urethra in males or the uterus and posterior vagina in females (**FIG 13**).
- The superior hemorrhoidal pedicle is divided with the energy device at the chosen distal rectal division site if a stapled coloproctostomy is planned.

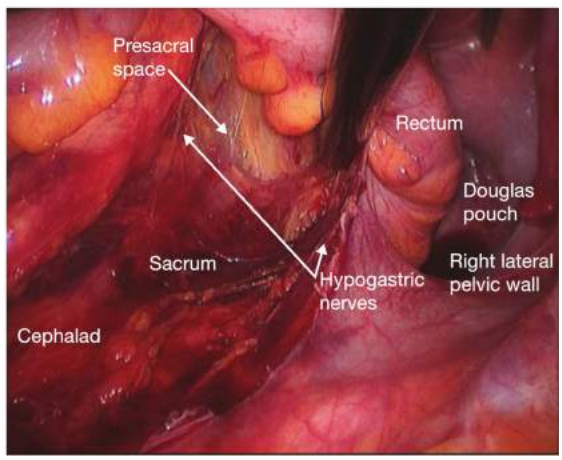

FIG 11 ● Posterior mobilization of the rectum. With the assistant retracting the rectum anteriorly, the presacral space is dissected with the energy device. The dissection proceeds caudally to the level of the levator muscles while preserving the hypogastric nerves. Avoid penetrating the presacral fascia in order to avoid potentially serious bleeding from the presacral venous plexus.

- The perineum may be pushed manually into the pelvis by the assistant surgeon. This maneuver may add another critical 2 cm to the distal rectal resection margin caudally.
- Intraoperative identification of the distal rectal resection site, either with preoperative anterior rectal wall tattoo

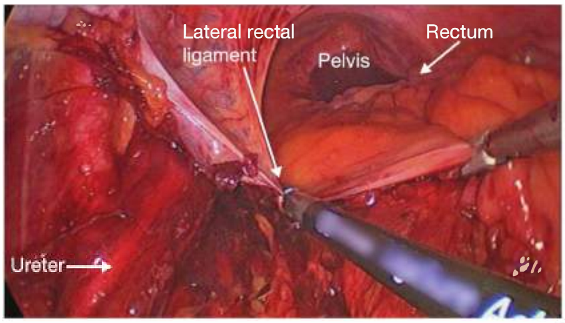

FIG 12 ● Lateral mobilization of the rectum. The lateral rectal ligaments (the left one is shown here) are transected with the energy device. Care is taken to avoid violating the endopelvic fascia along the lateral pelvic walls, which could lead to injury to the ureters and, more distally, the hypogastric vein and its branches. The latter could result in serious bleeding that is difficult to control.

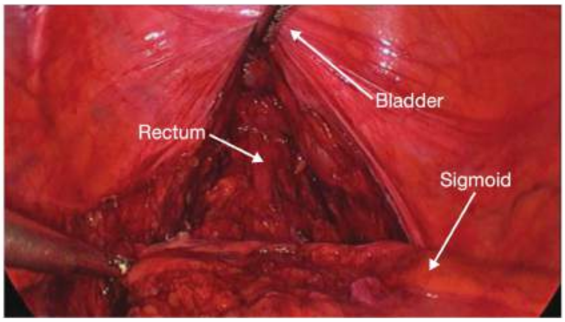

FIG 13 ● Anterior mobilization of the rectum. The dissection proceeds anterior to Denonvilliers' fascia, separating the rectum from the bladder, and more distally, from the seminal vesicles and prostate in men (shown here) or the vagina in females.

placement 2 cm distal to the carcinoma or with intraoperative proctoscopy, is necessary. Preoperative tattooing is particularly helpful in cancer patients that had a complete response to neoadjuvant therapy.

- In case of a distal rectal division at the level of the dentate line with the intention of a stapled coloproctostomy, an Endo GIA laparoscopic stapler is used either via the single port site at the RLQ or by placing a suprapubic 12-mm port and stapling the rectum vertically via that site.
- A vertical stapling of the rectum via a suprapubic port (**FIG 14A,B**), especially in males or patients with narrow pelvis, may prevent from usage of multiple overlapping Endo GIA loads for the rectal division, which lowers anastomotic leak rates. The suprapubic port may be used for placement of the low pelvic Jackson-Pratt drain at the end of the case.
- If a hand-sewn anastomosis is planned, then the dissection is carried to the levator muscle/dentate line with care to obtain an adequate negative radial mesorectal margin.

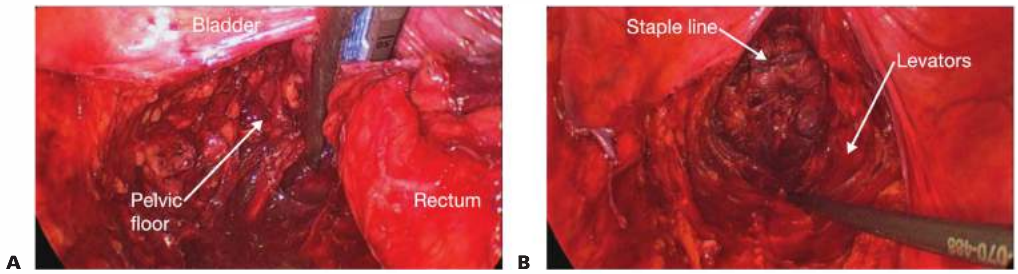

FIG 14 ● Distal rectal transection. **A.** When a stapled coloanal anastomosis is planned, the distal rectum is stapled from an anterior to posterior direction above the dentate line. This technique avoids the need for multiple stapler fires, reducing anastomotic leak rates. **B.** After resection of the rectum, the staple line can be seen in the distal pelvis at the level of the pelvic floor.

TRANSANAL SINGLE-PORT TOTAL MESORECTAL EXCISION: THE NARROW PELVIS

- The surgeon is now seated between the patient's legs, with the patient on Trendelenburg position. A back table with instruments for the perineal portion of the procedure is used.
- The surgeon may use a Mayo tray placed on his or her knees and a headlight.
- In case of a planned hand-sewn coloanal or ileoanal pouch anastomosis, a Lone Star retractor may be placed in the anus for exposure.
- In case of neoplasia, the rectum proximally to the dentate line is obliterated with a mucosal 0-Vicryl or 2-0 PDS purse-string suture (**FIG 15**). A full-thickness division of

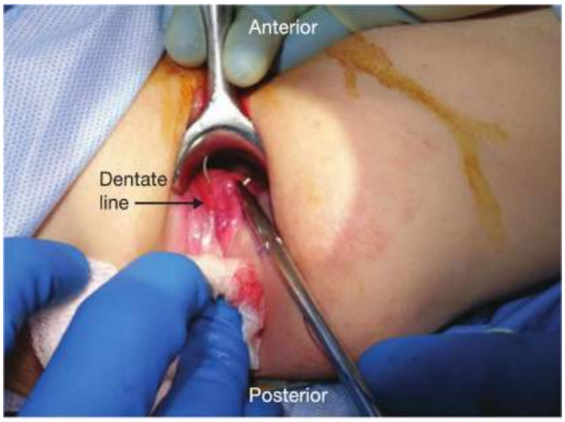

FIG 15 ● Transanal single-port total mesorectal excision. In case of neoplasia, the rectum proximally to the dentate line is obliterated with a mucosal 0-Vicryl or 2-0 PDS purse-string suture.

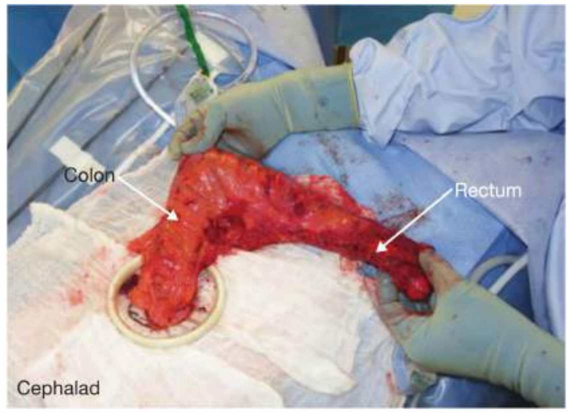

FIG 17 ● Extracorporeal mobilization of the specimen. The colon and rectum may be extracted via the RLQ abdominal single port site with the wound protector in place.

the rectum at the level of the dentate line is performed with electrocautery, with care not to injure the internal sphincter muscle (**FIG 16**).

- If the pelvic total mesorectal excision is adequate caudally, then the rectum is freed up and the colon and rectum may be extracted either via the RLQ abdominal single port site with the wound protector in place (**FIG 17**) or via the anus. The specimen is divided at the level of the terminal ileum/ileocecal valve with a linear stapler.
- If the rectum is still adherent in the inner pelvis secondary to a narrow/deep pelvis precluding further laparoscopic dissection transabdominally, then a Transanal Minimally Invasive Surgery (TAMIS) laparoscopic single port is inserted in the anus after placement of the purse-string rectal lumen obliteration and the division of the rectum at the dentate line is completed (**FIG 18A,B**). This allows for excellent visualization in the distal narrow pelvis.
- Pneumoperitoneum CO_2 to 15 mmHg is insufflated via the transabdominal and pneumopelvis via the transanal single port; you will need two insufflators.
- Using the transanal single port, a 30-degree 5-mm laparoscopic camera, a 5-mm laparoscopic grasper, and the same laparoscopic energy device (**FIG 19**), we proceed with the completion of the total mesorectal division with a circumferential caudal to cephalad direction. The endpoint of the dissection is accomplished by meeting the transabdominal distal dissection site in the inner pelvis (**FIG 20**).

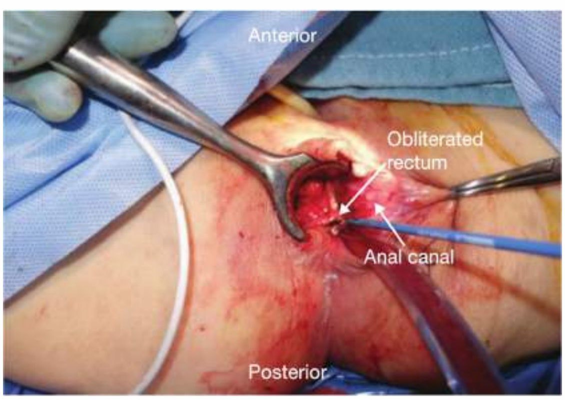

FIG 16 ● Transanal single-port total mesorectal excision. A full-thickness division of the rectum at the level of the dentate line is performed with electrocautery. In this picture, the dissection is proceeding right lateral to the obliterated distal rectum and the distal rectal wall.

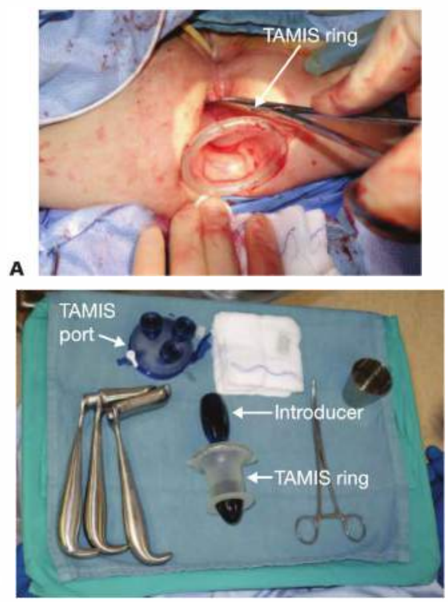

FIG 18 ● Transanal single-port total mesorectal excision: transanal insertion of the TAMIS port. **A.** The TAMIS ring is introduced first, followed by application of the TAMIS port. **B.** The multichannel TAMIS port is assembled on a side table prior to insertion into the anus.

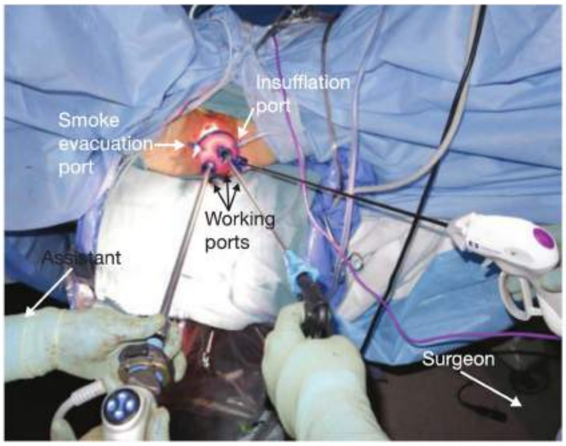

FIG 19 ● Transanal single-port total mesorectal excision. The surgeon operates with an energy device and a grasper while the assistant operates the camera.

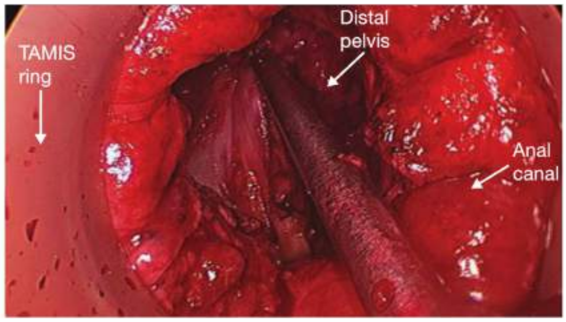

FIG 20 ● Transanal single-port total mesorectal excision. The dissection is carried through the TAMIS port into the distal pelvis until the distal dissection planes from the transabdominal phase of the operation are reached.

- Upon completion of the transanal single port dissection, the specimen is extracted as described earlier. If the specimen is too thick, then elongate the circular incision superiorly using an Army-Navy to "hook" under the fascia protecting the wound protector from perforation. Use a no. 11 scalpel in a sawing move or electrocautery to elongate the incision; extract the specimen, divide it at the terminal ileum, and send it to pathology.
- The transanal single port is removed and an anal canal mucosectomy may be performed as indicated (such as in ulcerative colitis with involvement of the anoderm) by elevating the anoderm with a submucosal injection of Marcaine with epinephrine and performing a sharp excision anal mucosectomy with scalpel or scissors.

ILEOANAL POUCH FORMATION AND J-POUCH ILEOANAL ANASTOMOSIS

- Following division of the terminal ileum at the level of the ileocecal valve with a linear GIA blue load stapler, the ileal pouch is fashioned.
- Place wet lap sponges around the abdominal wound protector and use a second towel for the instruments used for creation of the pouch formation in order to avoid fecal contamination to the laparoscopic surgical drapes.
- Fold the distal 30 cm of terminal ileum in the shape of a J; a pouch length of 15 cm is usually adequate (**FIG 21**). Use a linear GIA stapler 100-mm blue load (double line) or 75-mm blue (triple line) or, if already opened and used, the Endo GIA laparoscopic triple line 60-mm stapler (blue load for Ethicon or tan load for Covidien staplers) to create the pouch.
- Insert the stapler via the antimesenteric border of the terminal ileum at the tip of the J-pouch and fire the loads (usually two loads with the 100-mm linear stapler) in an antimesenteric side-to-side fashion. Inspect the inside of the pouch for bleeding.
- If a stapled anastomosis is planned, place a 28- to 29-mm circular stapler anvil into the tip of the pouch and secure it with a 3-0 Prolene purse string.
- Reintroduce the pouch into the abdomen and place it into the inner pelvis with the pouch mesentery facing posteriorly. Reinsufflate the pneumoperitoneum via the abdominal single port and perform a circular stapled ileal pouch-anal anastomosis (**FIG 22A,B**). Two intact doughnuts should be obtained.
- Test the integrity of the anastomosis by insufflating the pouch under saline immersion. If a major anastomotic leak is noted, 2-0 Vicryl or 2-0 PDS sutures maybe placed transanally using a Hill Ferguson or a Sims Parks retractor. The air leak test may be repeated as discussed earlier to confirm resolution of the leak.
- If a hand-sewn anastomosis is planned, then place a purse string to close the tip of the pouch in order to

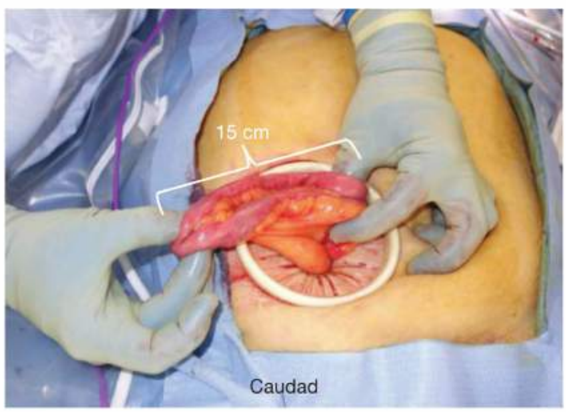

FIG 21 ● Creation of the J-pouch. After delivering the distal 30 cm of terminal ileum through the SILS port site (with the wound protector in place), the ileum is folded in the shape of a "J." The J-pouch will then be created with a 100-mm stapler (usually two loads are needed) inserted via the antimesenteric border of the terminal ileum at the tip of the J-pouch.

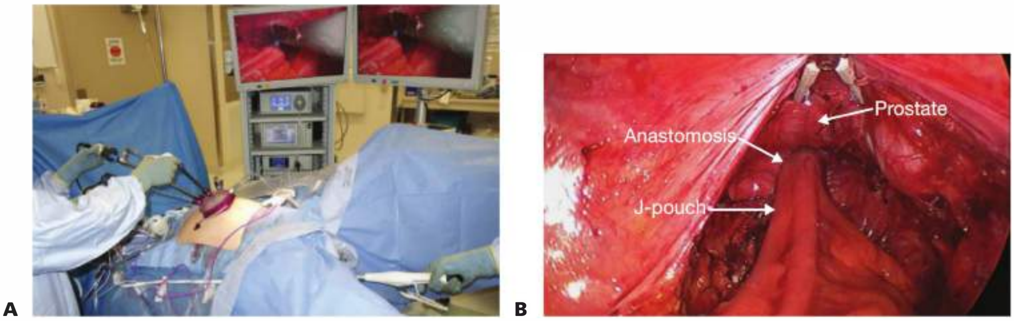

FIG 22 ● Creation of the stapled J-pouch ileoanal anastomosis. **A.** After reintroducing the J-pouch with the anvil in its tip into the abdomen, the pneumoperitoneum is reinsufflated. With an experienced assistant introducing the 28mm end-to-end anastomosis (EEA) stapler transanally and the scrub nurse holding the camera, the surgeon mates the anvil to the stapler's opened torch intracorporeally, as seen in the OR monitors. **B.** After firing the stapler, the anastomosis is now completed. The J-pouch, its mesentery (posteriorly located along the sacrum), and the tension-free anastomosis can be seen here.

prevent soilage in the pelvis. Place the pouch into the inner pelvis with the pouch mesentery facing posteriorly toward the sacrum. The pouch should reach to outside of the anal canal (**FIG 23**). Perform a hand-sewn ileo-anal pouch anastomosis using the Lone Star retractor for exposure (a 2-0 Quill double ended may be used alternatively) using 2-0 Vicryl or 2-0 PDS in interrupted full-thickness fashion, incorporating the internal sphincter muscle and the anoderm at the level of the dentate line (**FIG 24**).

- A Surgicel hemostatic agent may be placed into the anus following completion of the anastomosis.
- A 19-Fr Jackson-Pratt circular drain, placed posteriorly to the pouch with the tip superiorly to the anastomosis, is brought via the suprapubic port site and is placed on bulb suction.

FIG 23 ● Hand-sewn J-pouch ileoanal anastomosis. The pouch should reach to outside the anal canal.

FIG 24 ● Hand-sewn J-pouch ileoanal anastomosis. The completed anastomosis is seen here.

ILEOANAL POUCH ANASTOMOSIS: THE POUCH WILL NOT REACH!

- Perform mesenteric J-pouch serosal dissections.
- Perform mesenteric pouch "windows" by dividing the afferent or efferent mesenteric vessels. Consider the risk for pouch ischemia-necrosis.
- Perform mesenteric ileal serosal dissections laparoscopically up to the origin of the superior mesenteric artery.

DIVERTING LOOP ILEOSTOMY

- Remove the abdominal wound protector and bring a loop of terminal ileum proximal to the afferent limb of the pouch.
- It is advised to place an antiadhesive sheet posterior to the ileostomy fascia edges.
- Mature the loop ileostomy with the proximal limb in a Brooke's fashion and the distal limb as a mucous fistula (**FIG 25**) and place an ileostomy appliance.
- The patient has no wound for approximation!

FIG 25 ● The abdomen after the completed SILS restorative proctocolectomy with J-pouch ileoanal anastomosis and protective temporary diverting loop ileostomy. The temporary ileostomy is constructed at the SILS port site.

PEARLS AND PITFALLS

Preoperative workup	■ Correct identification of the underlying pathology allows for careful selection of the laparoscopic single-incision restorative proctocolectomy technique.
Patient positioning, laparoscopic instruments, surgeon assistant position	■ Securing the patient's position, OR table tilting, single port rotation, and usage of instruments and camera with bariatric length are necessary for a laparoscopic single-incision surgery. Surgeon should change his or her position in relation to the assistant several times during the procedure in order to achieve adequate exposure and visualization.
Laparoscopic instrument tissue handling	■ The tips of the assisting and dominant laparoscopic instruments are positioned as close as possible to each other in the surgical field in order to avoid hand conflict outside the abdomen.
Insertion of the SILS port	■ May use the new temporary loop ileostomy site at the RLQ. Alternatively, an umbilical or suprapubic site may be chosen.
Will the pouch reach?	■ Preoperative evaluation is essential. Intraoperative laparoscopic single port evaluation and surgical approach may be challenging.
Difficult dissection in the distal narrow pelvis	■ Consider the ta-TME technique.
Distal rectal division	■ Divide the rectum on an anterior to posterior direction with a linear reticulating stapler inserted via the suprapubic port. Use this port site to bring a Jackson-Pratt pelvic drain out at the end of the case.

POSTOPERATIVE CARE

- A fast-track postoperative laparoscopic pathway is initiated.
- The orogastric tube is discontinued in the OR upon completion of the procedure.
- IV acetaminophen alvimopan and opioid patient-controlled anesthesia (PCA) is used as per surgeon's preference the day of surgery, with the goal of discontinuing the PCA within 36 hours and adding IV or oral nonsteroidal antiinflammatory drugs (NSAIDs), such as ketorolac, and transition to oral analgesics.
- Ice chips/water diet is introduced the day of surgery with the goal to advance to clear liquids within 24 hours and to regular high-fiber diet within 48 hours postoperatively.
- The Foley catheter is kept until the third postoperative day secondary to the risk for urinary retention from the pelvic surgery/hypogastric nerves manipulation.
- Perioperative antibiotics, pharmacologic venous thromboembolism protocol, incentive spirometry, and early ambulation are initiated the day of surgery.
- Wound care need is minimal. If the umbilicus is used for the single port entry, umbilical skin edges are tucked with Vaseline/Adaptic gauze and cotton, which is removed in 48 to 72 hours. If the ileostomy site is used for single port entry, there is no abdominal wound.
- Surgicel is removed from the anus after 24 hours and the anastomosis is inspected for bleeding.
- The patient usually can be safely discharged home within 72 hours when passage of flatus/succus is documented from the ileostomy and a regular diet is tolerated by at least two consecutive meals and there are no other adverse postoperative findings.
- No weight lifting of more than 20 lb is recommended for 4 to 6 weeks postoperatively in order to avoid incisional hernia.

OUTCOMES

- Single-port laparoscopic restorative proctocolectomy is considered to be an equally safe and cost-effective technique with excellent cosmesis, similar morbidity and operative time, possible less postoperative pain and faster return to full activities, possible shorter hospital stay, and comparable oncologic outcomes when performed for neoplastic diseases to conventional hand-assisted or multiport laparoscopic approach.
- It is achieved with equipment that the hospital already has available and requires no additional training for the operative room personnel.
- It is feasible by surgeons who perform advanced laparoscopy.
- It does require one assistant who has advanced laparoscopic skills for camera handling.
- The laparoscopic single-incision restorative proctocolectomy technique may therefore contribute to decreased total hospital cost.

COMPLICATIONS

- The procedure has similar morbidity and mortality and comparable rates for conversion to laparotomy with conventional laparoscopy.
- The single-incision laparoscopic technique for restorative proctocolectomy has the option for conversion to multiport or hand-assisted laparoscopy.
- Mobilizing/elongating the small intestinal mesentery for an ileoanal anastomosis may be challenging laparoscopically.
- The ileal pouch may not reach the perineum. In these cases, an end ileostomy is needed.
- It may require a longer operative time during the learning curve of the surgeon; this can complicate an already challenging procedure.
- Elongating the ileostomy site single port incision for specimen extraction with fascial reapproximation prior to the ostomy maturation may increase the incidence of parastomal hernia rate.
- It is intrinsically a one-operating surgeon technique with less involvement of the assistant surgeon and a potential impact on resident education during the learning curve period.

Chapter 38 Restorative Proctocolectomy: Hand-Assisted Laparoscopic Surgery Ileal Pouch-Anal Anastomosis

Robert R. Cima

DEFINITION

- An ileal pouch-anal anastomosis (IPAA) is a restorative procedure used when the entire colon and rectum needs to be removed and the patient wishes to avoid a permanent ileostomy. The two most common indications for IPAA are chronic ulcerative colitis (CUC) and familial adenomatous polyposis (FAP) syndrome. Although the procedure is basically the same, the frequency and indications for surgery are different, and for the purposes of this chapter, the focus will be on the surgical treatment of CUC.[1]
- IPAA involves removal of the entire colon and rectum followed by construction of an ileal reservoir most commonly in a "J shape" that is anastomosed to the anal canal by either a stapled or hand-sewn technique.
- This maintains the normal route of defecation, although the frequency and consistency of the stool is different than normal bowel function.

DIFFERENTIAL DIAGNOSIS

- Primarily, CUC needs to be distinguished from Crohn's colitis. This is particularly important, because a restorative IPAA is not recommended in Crohn's disease patients.
- Other acute colitis syndromes (i.e., toxic bacterial colitis, cytomegalovirus [CMV] colitis, ischemic colitis) can mimic CUC. Thus, a thorough workup to differentiate between CUC and other disease processes needs to be considered prior to surgery.
- A detailed review of the patient's disease course including past endoscopic findings, prior imaging studies, and any history of perianal disease needs to be evaluated. Any history of small bowel inflammation or perianal abscesses, fistulas, or fissures is highly suggestive of underlying Crohn's disease.

FIG 1 ● CT enterography (coronal view, venous phase). Severely inflammed distal colon in a CUC patient with normal appearing small bowel.

- In patients with an established history of CUC presenting with an acute worsening of their symptoms, it is important to rule out an infectious cause such as *Clostridium difficile* or CMV colitis as the *cause* of their disease exacerbation.

PATIENT HISTORY AND PHYSICAL FINDINGS

- CUC is characterized by recurrent episodes of bloody diarrhea associated with urgency and tenesmus.
- Approximately 15% of patients will present initially with fulminant disease, characterized by high-volume bloody diarrhea, severe abdominal distension and pain, fever, and systemic signs of illness. In severe situations, the patient might have peritonitis as the result of colonic perforation or hemodynamic compromise from volume depletion and systemic inflammation.
- More commonly, the CUC patient with medically refractory disease will not have any characteristic physical findings. However, prolonged disease activity can be associated with poor overall nutritional status and significant weight loss.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Computed tomography (CT) enterography is the most commonly used imaging study in CUC patients (**FIG 1**). The use of intravenous (IV) contrast is essential to highlight intestinal inflammation and helps identify any evidence of small bowel inflammation, which is highly suggestive of Crohn's disease.
- In active CUC, the CT will demonstrate inflammatory changes around the involved colon with thickening of the colonic wall. This inflammation usually starts in the rectum and extends proximally into the colon for a varying distance.
- Endoscopic imaging of the colon is essential (**FIG 2**). It should demonstrate continuous inflammation from the rectum for a variable distance, extending proximally into the colon. Evidence of discontinuous mucosal inflammation is worrisome for an underlying diagnosis of Crohn's disease.

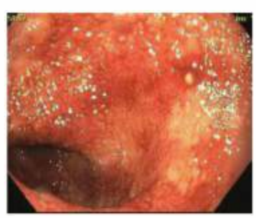

FIG 2 ● Colonoscopy shows diffuse severe inflammation and friable mucosa, with a loss of the vascular appearance of the colon, erythema, hemorrhage, and inflammatory pseudopolyps.

SURGICAL MANAGEMENT

- Frequently, an IPAA for the treatment of CUC is performed in stages, depending on the patient's overall health at the time of surgery or the indications for surgery.
- The primary indications for surgery are toxic or fulminant disease activity, medically refractory disease, and/or evidence of dysplasia/malignancy.
- In an emergency situation, or in an ill patient on multiple immunosuppressive medications, the first operation is a subtotal colectomy with an end ileostomy.
- Once the patient recovers his or her health, a completion proctectomy with IPAA and diverting ileostomy may be performed. At the last operation (the third stage), the ileostomy is reversed.
- In outpatients with mild disease that are coming to surgery, the total proctocolectomy with IPAA and diverting loop ileostomy may be performed at a single operation.
- In some institutions, the diverting loop ileostomy may be routinely omitted, depending on a number of patient- and procedure-specific factors. However, the majority of centers recommend use of a temporary diversion.

PATIENT PREPARATION PRIOR TO SURGERY

- After a detailed discussion regarding the risks, alternatives, benefits, and expected outcomes from the IPAA, the patient should see a certified wound, ostomy, and continence nurse (WOCN) for preoperative education and appropriate site marking for a temporary diverting loop ileostomy. Many patients are provided with a mechanical bowel preparation with oral antibiotics. This is an optional step as there is mixed data as to the necessity of such preparation. An alternative approach would be to perform a tap water enema the morning of surgery to clear the distal colon and rectum. All patients are provided with antimicrobial soap (Hibiclens™) to shower with the night prior to surgery and the morning of surgery.

PATIENT INDUCTION AND POSITIONING

- Prior to the induction of anesthesia, the patient is given 5,000 units of heparin subcutaneously and sequential compression devices are placed on the lower extremities. The patient is positioned supine on the operating table lying on an upper body gel pad to minimize movement during operating room (OR) position changes. Once induction of anesthesia is complete, an orogastric tube is placed. An indwelling urinary catheter is placed using sterile technique.
- Once all necessary IV access is secured, the patient is repositioned in a modified lithotomy position (**FIG 3**). The heels are firmly planted on the stirrups to avoid pressure along the calves and the lateral peroneal nerves. The thighs are placed parallel to the ground to avoid conflict with the surgeon's arms and instruments during the procedure.
- Both arms are wrapped in gel pads and the patient's right arm is placed next to his or her side and secured in position by positioning of an acrylic toboggan. The left arm is placed on an arm board positioned straight outward (**FIG 3**). Alternatively, both arms may be placed at the patient's side, but this will impede access to the arms during the procedure in case the anesthesia team needs to intervene. A chest strap is applied to minimize the risk of the patient shifting on the operating table during frequent position changes during the procedure. A forced warm air warming device is placed on the chest and over the left arm is positioned outward.
- The abdominal wall skin is prepared with a chlorhexidine–alcohol mixture after the perineum has been scrubbed and painted with a Betadine–iodine skin preparation kit. The patient is then draped in a fashion that allows access to the entire abdomen and perineum (**FIG 4A**).
- Video monitors should be placed directly off of the patient's left and right shoulders. If a monitor is available on a boom and it can be positioned over the patient's head which facilitates the dissection in the midportion of the patient's upper abdomen. The scrub nurse should have his or her instruments positioned over the patient's chest and head and he or she should stand on the patient's left side above the outward-positioned left arm (**FIG 4B**). The surgeon will stand between the patient's legs for the hand-assisted laparoscopic mobilization and resection of the abdominal colon. The first assistant/camera operator will initially stand on the patient's right side (**FIG 5**).
- Prior to incision, Surgical Care Improvement Project (SCIP)–compliant antibiotics are administered and documented. A procedural pause is performed, confirming the patient identity, procedure, position, antibiotic administration, allergies, and special equipment needs.

FIG 3 ● Patient positioning. The patient is on a modified lithotomy position with the thighs parallel to the ground to avoid conflict with the surgeon's elbows and instruments. The left arm is placed laterally on an arm board for access by the anesthesia team during the operation. The patient is strapped to the Yellofin stirrups and taped to the table across the chest to avoid sliding during the procedure.

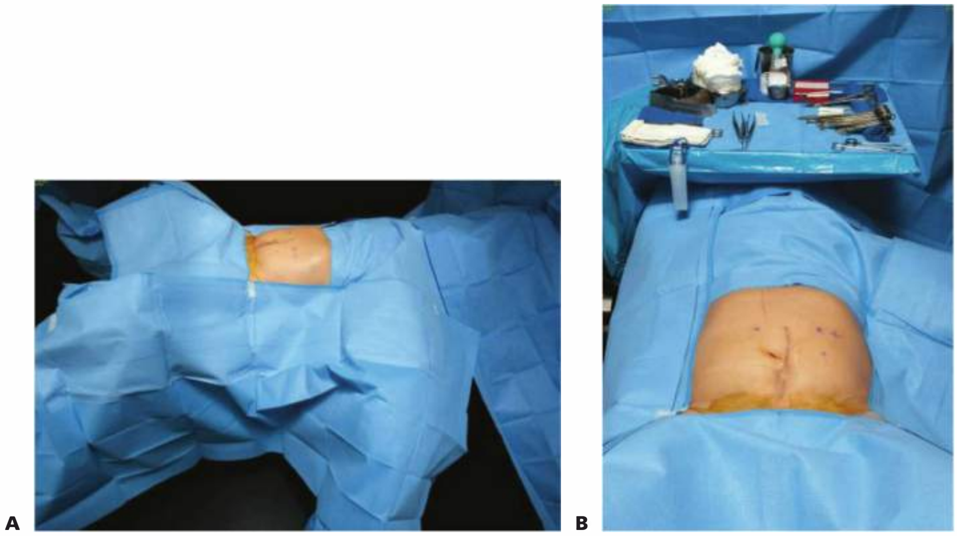

FIG 4 ● **A.** Field setup. The patient is draped in a fashion that allows access to the entire abdomen and perineum. **B.** Field setup. The scrub nurse sets his or her instruments positioned over the patient's chest and head.

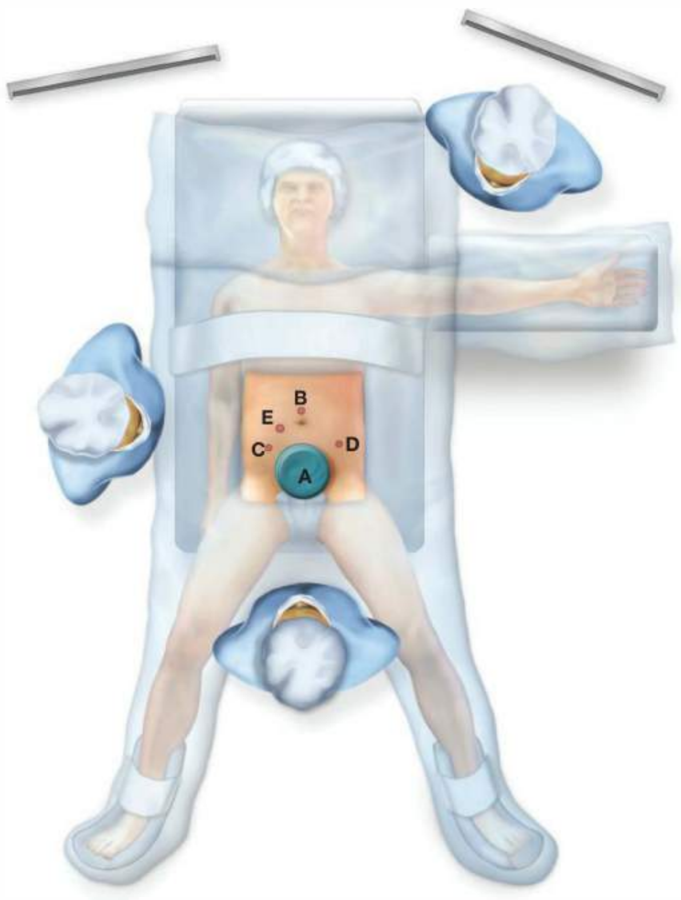

FIG 5 ● Team and monitors setup. The surgeon stands between the patient's legs for the hand-assisted laparoscopic mobilization and resection of the abdominal colon. The first assistant/camera operator stands on the patient's right side. The scrub nurse stands on the patient's left side above the outward-positioned left arm. The monitors are positioned above the right and left shoulders.

INCISION AND TROCAR PLACEMENT

- A midline incision is marked on the patient's abdomen from the pubis to the xiphoid process in case emergent entry into the abdomen is required. In men, our preferred incision for the hand port is a 7-cm lower midline incision starting 1.5 cm above the pubic bone. In women, we prefer a 7-cm Pfannenstiel incision centered on the midline 1.5 cm above the pubis. If a prior midline or Pfannenstiel incision exists, we will use that incision.[2,3]
- The hand-port incision is made and the abdomen is entered under direct vision. With the surgeon's hand in the abdomen through the primary incision, a small 5-mm incision is made in the upper aspect of the umbilicus and a nonbladed 5-mm trocar is guided into the abdomen with the surgeon's hand protecting the abdomen content form inadvertent injury. Next, the hand access device is placed in the lower abdominal incision and pneumoperitoneum is established.
- Under laparoscopic visualization, a 5-mm nonbladed trocar is placed in the left lower abdomen and another in the right lower abdomen. Usually, the best location is 2 to 2.5 cm medial and 1 cm inferior to the superior iliac crest (**FIG 6**).

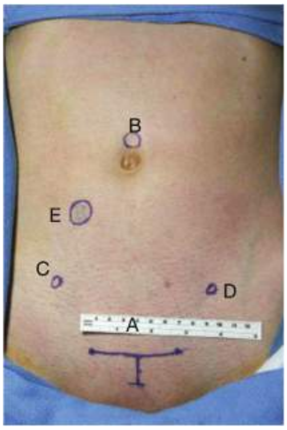

FIG 6 ● Port placement. The hand port will be placed through a 7-cm Pfannenstiel incision *(A)*. Three 5-mm ports are placed for the camera (supraumbilical, *B*) and instruments (right and left lower abdomen, *C,D*). The diverting ileostomy site *(E)* is marked in the right lower quadrant.

MOBILIZATION OF THE LEFT COLON

- The patient is placed in steep Trendelenburg position with left side up. The surgeon stands between the legs and the camera operator is on the patient's right side. A 5-mm camera is placed through the supraumbilical trocar. The surgeon places his or her left arm through the hand-port device and uses the left lower quadrant trocar for his or her dissecting scissors (**FIG 7**). The surgeon uses his or her hand to push the small bowel into the right lower quadrant and to lift the omentum into the upper abdomen. The left colon is then grasped and pulled medially and anteriorly. The camera is used to look over the surgeon's hand into the left abdomen.
- The surgeon starts dissecting from the mid- to lower sigmoid and works upward toward the splenic flexure while maintaining medial retraction of the left colon. The dissecting scissors attached to monopolar cautery are used to incise the peritoneal lining about 1 cm lateral to the edge of the colon (**FIG 8**). A common mistake is to incise too far laterally from the colon in what appears to be a "natural" plane. The surgeon should move in a cephalad direction along the entire left colon in a continuous fashion upward toward the spleen while maintaining medial traction (**FIG 9**).

FIG 7 ● Finalized setup. The surgeon stands between the patient's legs with his or her left hand in the abdomen and his or her right hand controls the dissecting scissors for the mobilization of the left colon. The assistant operates the camera from the right side of the table.

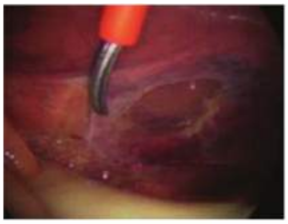

FIG 8 ● Mobilization of the left colon. The lateral peritoneal attachments are incised about 1 cm lateral to the edge of the colon while the surgeon's hand retracts the colon medially.

- The mesentery of the left colon is then dissected off the retroperitoneum (anterior to Gerota's fascia) in a lateral to medial direction. Care is taken to identify the left ureter and gonadal vessels, which should be preserved intact in the retroperitoneum.

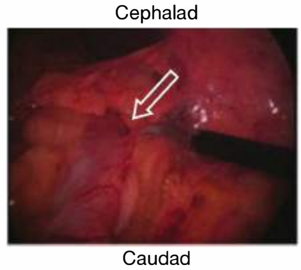

FIG 9 ● Mobilization of the left colon. The lateral dissection is continued in a cephalad direction until reaching the splenic flexure *(arrow)*.

SPLENIC FLEXURE MOBILIZATION AND MESENTERY DIVISION

- Once the left colon mesentery is mobilized medially toward the lateral border of the aorta, the patient is placed in steep reverse Trendelenburg position. The surgeon retracts the upper left colon medially to see the back portion of the splenic flexure as it attaches to Gerota's fascia. Using the dissecting scissors attached to monopolar cautery, the phrenocolic is divided as the surgeon retracts the flexure medially and downward toward the right lower quadrant (**FIG 10**).

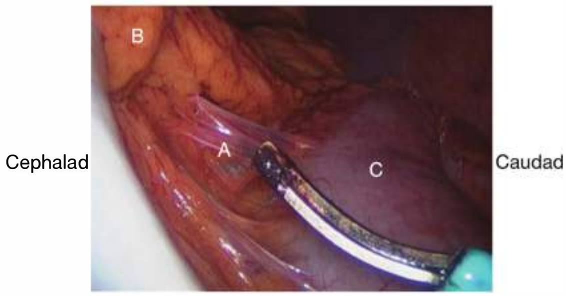

FIG 11 ● Exposure of the gastrocolic ligament. The surgeon exposes the gastrocolic ligament *(A)* by retracting the omentum *(B)* in a cephalad direction with his or her left hand while the assistant retracts the transverse colon *(C)* in a caudad direction.

- To further free up the splenic flexure of the colon, the gastrocolic ligament, exposed by retracting the omentum in a cephalad direction with the left hand (**FIG 11**), is transected at the midline, entering the lesser sac (**FIG 12**). The gastrocolic ligament is then transected from medial to lateral, toward the splenic flexure of the colon, until

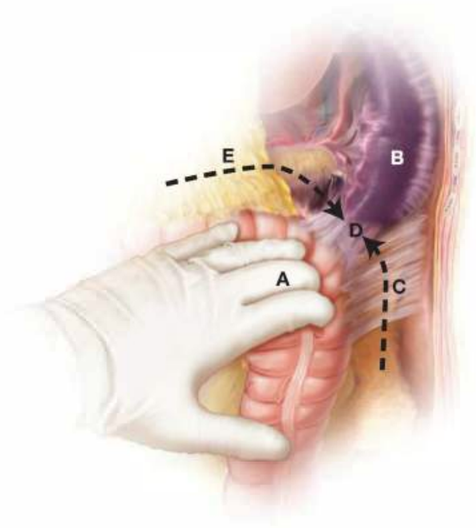

FIG 10 ● Mobilization of the splenic flexure. The surgeon retracts the splenic flexure of the colon *(A)* downward and medially, exposing the attachments of the flexure to the spleen *(B)*. The phrenocolic *(C)* and splenocolic *(D)* ligaments are transected in an inferior to superior and lateral to medial direction. The gastrocolic ligament *(E)* is transected in a medial to lateral direction, until both planes of dissection meet and the splenic flexure is fully mobilized.

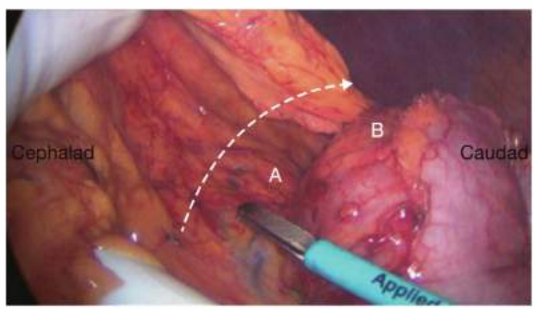

FIG 12 ● Transection of the gastrocolic ligament allows for entrance into the lesser sac, exposing the tail of the pancreas **(A)**. While holding the omentum in a cephalad direction, the gastrocolic ligament is transected in a medial to lateral direction *(arrow)* toward the splenic flexure of the colon **(B)**, until the precious dissection plane is encountered and the splenic flexure of the colon is fully mobilized.

the previous dissection plane around the flexure is encountered (**FIG 12**). At this point, the splenocolic ligament is easily visualized and transected (**FIG 13**).

- Once the splenic flexure is fully mobilized, a 5-mm vessel-sealing device is placed through the left lower quadrant port, replacing the scissors, and the transverse colon mesentery is divided. Once the flexure mesentery is divided, the left colon mesentery and what remains of the gastrocolic ligament are divided (**FIG 14**) while working toward the hepatic flexure. To ensure that the small bowel mesentery is not divided, the surgeon's hand is used to control the colon mesentery while pushing the small bowel mesentery away below the hand.

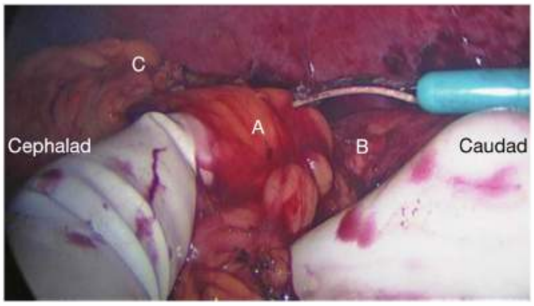

FIG 13 ● Completing the splenic flexure mobilization. After the superior to inferior and the medial to lateral dissection planes meet around the splenic flexure of the colon, the splenocolic ligament *(A)* is easily exposed between the colon *(B)* and the spleen *(C)* and is transected.

FIG 14 ● After the splenic flexure has been mobilized, the transverse colon mesentery is divided, proceeding from the splenic toward the hepatic flexure *(arrow)*, with an energy device.

HEPATIC FLEXURE AND RIGHT COLON MOBILIZATION

- Once the dissection of the transverse colon mesentery has proceeded past the midline of the abdomen, the camera assistant moves to the patient's left side. The patient is kept in reverse Trendelenburg but is placed with the right side up. The surgeon places his or her left hand through the hand access device and uses the dissecting scissors attached to monopolar cautery through the right lower quadrant port. The surgeon's left hand is used to retract the hepatic flexure downward and toward the left lower quadrant (**FIG 15**), exposing the hepatocolic ligament. This ligament is transected with scissors. Once incised, the surgeon's index finger is placed under the lateral peritoneal attachments of the right colon and the dissection is started downward along the lateral edge of the right colon (**FIG 16**). All the while, the surgeon is placing firm and constant traction on the colon toward the left lower quadrant. This action literally peels the right colon and its mesentery off of the retroperitoneum.
- The dissection is carefully continued medially toward the duodenum. The filmy attachments of the colon mesentery are divided off of the anterior wall of the duodenum, the head of the pancreas, and Gerota's fascia (**FIG 17**).
- Once the right colon mesentery is completely mobilized, the 5-mm vessel-sealing device is placed through the right lower quadrant trocar and the hepatic flexure

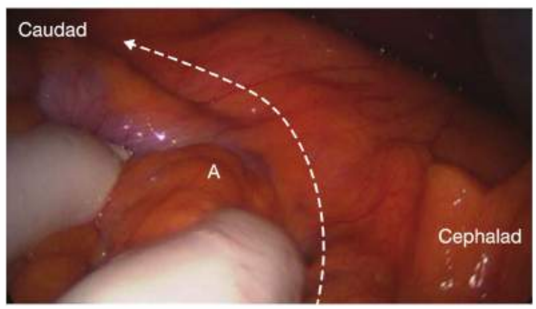

FIG 16 ● While retracting the hepatic flexure of the colon *(A)* with the hand, the hepatocolic ligament and the lateral peritoneal attachments of the right colon are transected in the direction shown *(arrow)*.

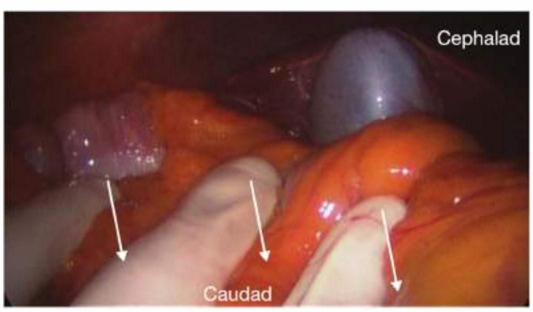

FIG 15 ● The surgeon pulls the hepatic flexure of the colon downward and toward the left lower quadrant of the abdomen *(arrows)*.

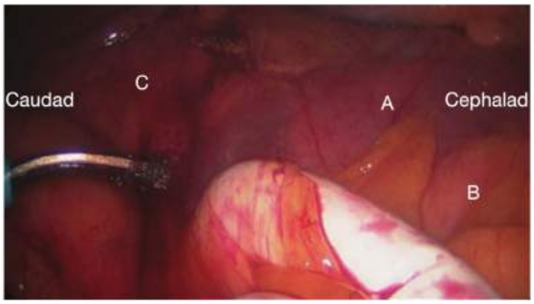

FIG 17 ● Mobilization of the right colon off the retroperitoneum. The right mesocolon is dissected off the duodenum *(A)*, head of the pancreas *(B)*, and Gerota's fascia *(C)*.

mesentery is divided, progressing from right to left. To facilitate this dissection, the surgeon's left hand grabs the transverse mesentery from where the previous mesenteric division was performed. The surgeon places his or her fingers behind the mesentery while the thumb is anterior to the mesentery. The fingertips are near the hepatic flexure mesentery and these are used to facilitate the movement of the vessel-sealing device as it traverses the mesentery from right to left, eventually completing the division of the transverse colon mesentery.

- Once the hepatic flexure and transverse colon mesentery are divided, the entire colon and distal small bowel can be exteriorized through the hand access port site with the wound protector in place (**FIG 18**). The right colon mesentery is divided under direct vision close to the colon wall, thus preventing any injury to the ileocolic vessel and the right-sided marginal arterial arcade. This is critical to ensure good antegrade blood supply to the J-pouch to be constructed later.
- The terminal ileum is divided using a linear stapling device about 1 to 2 cm proximal to the ileal–cecal valve. The distal sigmoid colon is divided with a stapling device. The abdominal colon is sent to pathology to confirm the diagnosis of ulcerative colitis.
- To facilitate pouch placement in the pelvis, the small bowel mesentery needs to be mobilized off of the retroperitoneum. Once the abdominal colon is removed, the small bowel is returned to the abdomen and the pneumoperitoneum is reestablished. The surgeon with his or her left hand in the abdomen places his or her hand under the small bowel mesentery and pushes it up and to the left upper quadrant. Using the dissecting scissor from the right lower quadrant trocar, the mesentery is dissected off of the retroperitoneum and duodenum. If needed, this dissection can be carried out up over the pancreas to the origin of the superior mesenteric vessels.

FIG 18 ● Extracorporeal delivery of the colon and terminal ileum.

OPEN PROCTECTOMY THROUGH THE HAND ACCESS DEVICE

- The patient is leveled from a right to left perspective and then placed in steep Trendelenburg position. The surgeons then moves to the patient's right side, the first assistant is on the left side, and the second assistant goes between the patient's legs. The small bowel is packed off into the upper abdomen. The hand access device is maintained in the incision as a wound protector. The distal sigmoid colon is exteriorized through the hand access device and used as a "handle" to initiate the dissection into the pelvis. The superior rectal vessels are divided and the presacral space is entered posteriorly.
- The dissection is carried out into the posterior deep pelvis facilitated by the use of two long, narrow, specially designed St. Mark's retractors, one lighted and the other not lighted (**FIG 19**). Both retractors are used through the hand access device so that no hands are placed through the device that would obstruct the view into the pelvis.
- The posterior pelvic dissection is carried first, along the presacral space between the presacral fascia, posteriorly, and the investing fascia of the mesorectum, anteriorly (**FIG 20**). The lateral rectal ligaments are transected with an energy device.
- The pelvic dissection is then carried anteriorly in a circumferential fashion around the rectum. The Douglas

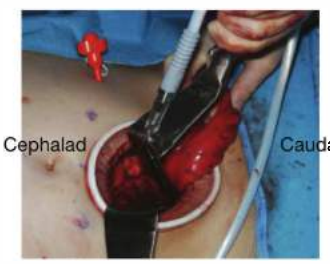

FIG 19 ● Rectal dissection through the hand access device using two narrow, double bent St. Mark's retractor (one lighted).

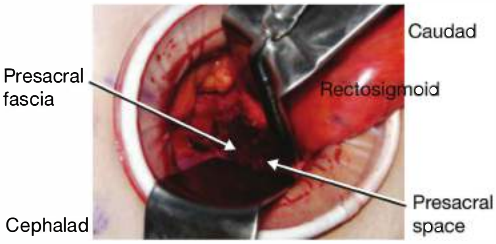

FIG 20 ● The posterior pelvic dissection is carried along the presacral space between the presacral fascia, posteriorly, and the investing fascia of the mesorectum, anteriorly.

pouch is incised open with cautery. The plane of dissection anteriorly is carried in between Denonvilliers fascia (along the anterior wall of the rectum), posteriorly, and the prostate/seminal vesicles (in males, **FIG 21**) or the vagina (in females), anteriorly. The pelvic floor (with the levator muscles) is identified (**FIG 21**).

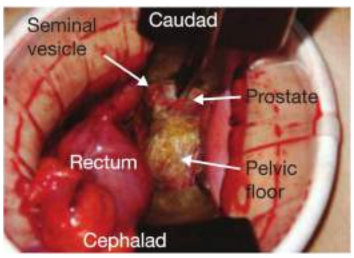

FIG 21 ● The pelvic dissection is then carried anteriorly in a circumferential fashion around the rectum. The pelvic floor (with the levator muscles) is identified. The seminal vesicles and the prostate can be seen anteriorly.

- Once the pelvic floor is reached, a transverse stapling device is placed through the hand access device and around the low rectum at the level of the pelvic floor (**FIG 22**). Before the stapler is fired, a digital rectal examination is performed to ensure that the device will be dividing the rectum at the top of the anal canal. Once the device is fired, the rectum is removed and a check of hemostasis in the pelvis is made.

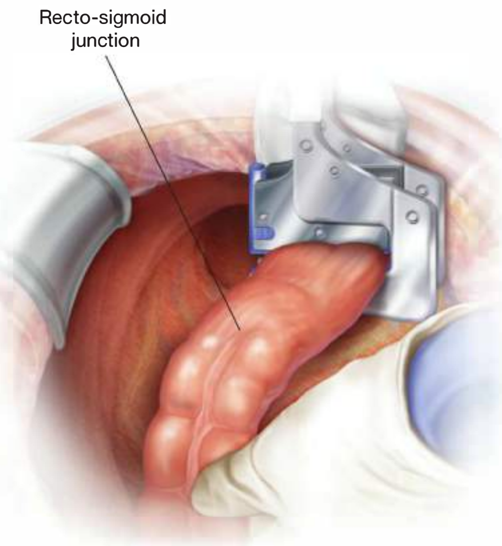

FIG 22 ● Once the pelvic floor is reached, a transverse stapling device is placed through the hand access device and around the low rectum at the level of the pelvic floor.

J-POUCH CONSTRUCTION AND POUCH ANAL ANASTOMOSIS

- Once the rectum is removed, the small bowel is exteriorized through the hand access device. The last 25 to 30 cm of the terminal ileum is folded into a "J" shape and the apex of the fold is opened anteriorly to allow placement of a linear stapler (**FIG 23**). The common wall between the two limbs of the J is divided with the linear stapler. To make an adequate-sized pouch (approximately 15 cm in length), many sequential firings of the linear stapler are usually required. Before the stapler is fired, care must be taken to ensure that the small bowel mesentery of the pouch is not trapped by the stapler in between the limbs of the pouch.
- Through the same opening that the linear stapler was placed, a monofilament suture is placed as a purse string and the anvil of a circular stapling device is secured to the apex of the J-pouch (**FIG 24**). The end of the J staple line and the anterior pouch staple lines are oversewn with 3-0 suture to reinforce the staple lines.

FIG 23 ● Creation of the J-pouch. The small bowel is exteriorized through the hand access device. The last 25 to 30 cm of the terminal ileum is folded into a J shape and the apex of the fold is opened anteriorly to allow placement of a linear stapler. The common wall between the two limbs of the J is divided with the linear stapler.

FIG 24 ● Creation of the J-pouch. Through the same opening that the linear stapler was placed, a monofilament suture is placed as a purse string and the anvil of a circular stapling device is secured to the apex of the J-pouch *(arrow)*. The pouch is approximately 15 cm long.

- An end-to-end stapled anastomosis is performed between the pouch and the anal canal (**FIG 25**). The mesentery of the pouch should be placed posteriorly against the sacrum. In a woman, prior to the firing of the circular stapler, great care must be taken to ensure that the vagina is not trapped into the circular stapling device. A diagnostic rigid proctoscopy is performed through the anus after the pelvis has been filled with saline to check for any evidence of an air leak from the pouch (**FIG 26**).
- Two 19-Fr closed bulb suction drains are placed behind the pouch and brought out the lower abdominal trocar sites. These are secured to the skin with monofilament suture.

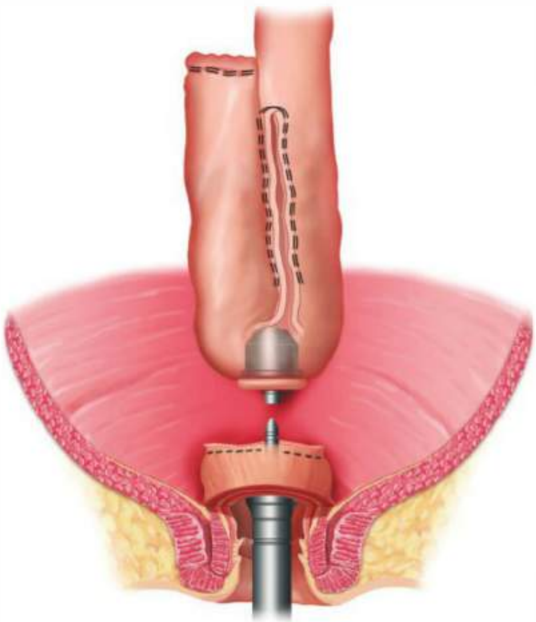

FIG 25 ● An end-to-end stapled anastomosis is performed between the pouch and the anal canal.

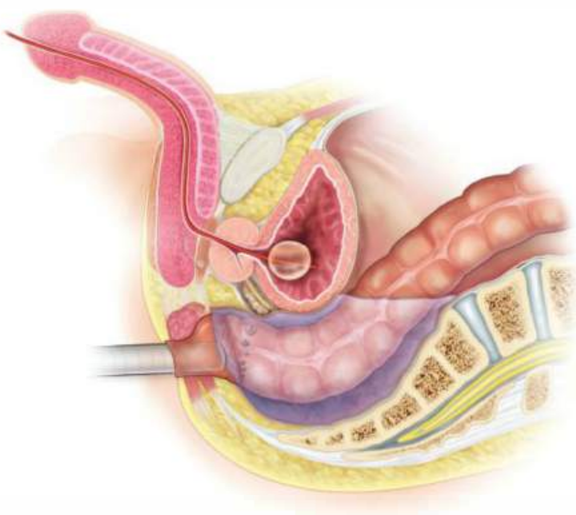

FIG 26 ● A diagnostic rigid proctoscopy is performed through the anus after the pelvis has been filled with saline to check for any evidence of an air leak from the pouch.

TEMPORARY DIVERTING LOOP ILEOSTOMY CONSTRUCTION

- Prior to surgery, the patient should have been counseled by a WOCN and site marked for a temporary ileostomy. At the marked site in the right lower quadrant, a diverting loop ileostomy is constructed. Usually, the loop should be 20 to 30 cm proximal to the J-pouch. To facilitate ileostomy reversal in the future, the bowel can be wrapped in an adhesion barrier material, which should also be placed in the abdomen under the site of the stoma to minimize adhesions.
- The hand access device/wound protector is removed and the incision is closed in the standard fashion. The 5-mm camera trocar site is closed at the skin level with a monofilament suture.
- The loop ileostomy is matured, with the proximal limb matured in a Brooke's fashion. The distal limb is matured as a mucous fistula (**FIG 27**).

FIG 27 ● The end result after a HALS-IPAA.

PEARLS AND PITFALLS

Indication	■ In cases of acute disease or indeterminate colitis, proceeding to a subtotal colectomy as the initial operation is preferred to allow thorough pathologic review of the specimen and withdrawal of the medications to unmask potential Crohn's disease.
Conduct of the abdominal portion	■ It is best to start with the left colon and the splenic mobilization first as this will determine if you can use a hand-assisted laparoscopic surgery (HALS) approach.
Creation of the J-pouch	■ Preservation of the right-sided marginal arterial arcade is critical to ensure good blood supply to the pouch. ■ Separation of the pouch mesentery from the retroperitoneum allows for adequate pouch length to reach the pelvic floor. ■ Place the pouch mesentery along the presacral space posteriorly.
Conduct of the pelvic portion	■ Avoid placing the surgeon's hands into the pelvis as this will completely obstruct the view through the hand access device.

POSTOPERATIVE CARE

- We use an enhanced recovery pathway approach to the postoperative care in our patients. They are started on a regular ileostomy diet upon arrival to the ward.
- IV fluids are kept to a minimum (<40 mL per hour) the night of surgery. All IV fluids are discontinued the morning after surgery.
- The urinary catheter is removed at 8 AM the morning after surgery.
- The two drains are removed the morning of the second day after surgery.

OUTCOMES

- The functional outcomes of IPAA over the last few decades in numerous institutional experiences have been quite comparable. Most patients report six to eight bowel movements in a 24-hour period, with one of those occurring at night.
- Depending on the patient's age and gender, about 20% to 30% will experience minor leakage of stool, particularly at night.
- The majority of patients will experience one or more episodes of pouchitis, with approximately 20% having chronic pouchitis, which requires treatment.
- IPAA patient's quality of life is usually significantly improved relative to his or her presurgery health state.
- Finally, IPAA is a durable operation with over 90% of patients having a well-functioning pouch at 20 years after surgery.

COMPLICATIONS

- The most concerning complication is a pouch leak or pelvic sepsis. Unexplained tachycardia, lower abdominal pain, or low back/pelvic pain are worrisome signs for a pouch leak. Early operative intervention with pelvic irrigation/washout and drain placement is the procedure of choice. Later presentation with fever, pelvic pain, and urinary symptoms warrant abdominal imaging with a CT scan and percutaneous drain placement.[4]
- Prior to ileostomy reversal, usually 2 to 3 months after the pouch surgery, a contrast enema is obtained to evaluate for a possible anastomotic leak or narrowing. If a small anastomotic sinus is observed, closure should be delayed for another 2 to 3 months and a repeat contrast study obtained. Commonly, the sinus will close. However, if it persists, an examination under anesthesia is required in an attempt to open the sinus or to curette the tract to promote healing.

Chapter **39** # Pelvic Exenteration

Cherry E. Koh Michael J. Solomon

DEFINITION

- Pelvic exenteration, also known as extended radical resection, is a form of radical surgery first described for the treatment of locally advanced cervical cancer, which was adopted for locally advanced colorectal cancer shortly thereafter. Currently, locally advanced primary rectal cancers (LARC) and locally recurrent rectal cancers (LRRC) are amongst the more common indications for pelvic exenteration.
- The fundamental surgical principle of pelvic exenteration is complete en bloc removal of all viscera or structures contiguously involved by tumor with a clear resection margin (R0 resection). Therefore, depending on the location of the tumor, different types of exenteration will be required, which may include en bloc cystoprostatectomy, vaginectomy, radical hysterectomy, or even sacrectomy. The same surgical principles may be applied to other locally advanced pelvic cancers including uterine, bladder, and prostate cancers and sarcomas.
- Different classifications have evolved to describe the different types of recurrence and exenteration, although of note, there is no universally accepted terminology.
- Although lengthy anatomical discussion is beyond the scope of this chapter, a brief discussion is necessary to facilitate understanding of the key concepts and principles of surgery.

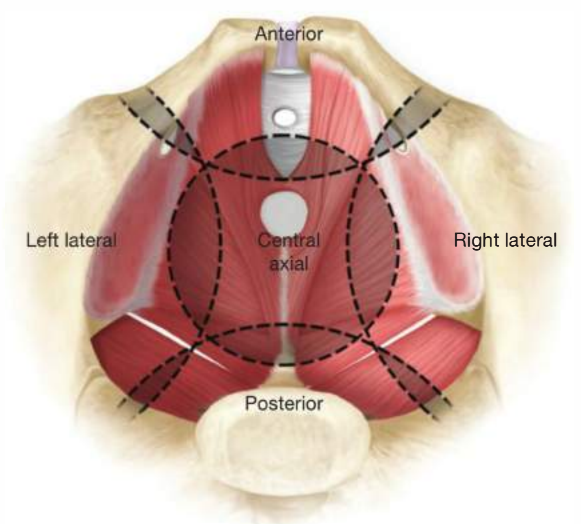

FIG 1 ● The compartments of the pelvis are shown in this diagram. The pelvis can be divided into the anterior, central, posterior, and lateral compartments, which are centered on the urethra, the tip of the coccyx, the third sacral vertebra, and the ischial spines, respectively. A complete pelvic exenteration is one where all viscera are removed and involves surgery in all five compartments of the pelvis with or without bony resection, whereas a partial exenteration is one which involves removal of at least three compartments of the pelvis with or without bony resection.

- Anatomically, the pelvis can be divided into four compartments: the anterior, central, posterior, and lateral compartments (**FIG 1**). Each compartment overlaps at their margins but the axis of each compartment is centered on a different structure. The urethra, the tip of the coccyx, the third sacral vertebra, and the ischial spine form the axis of the anterior, central, posterior, and lateral compartments, respectively.
- For clarity, exenteration is best classified as complete exenteration or partial exenteration. Complete exenteration is defined as complete removal of all compartments of the pelvis with or without en bloc bony resection, whereas a partial exenteration is defined as the removal of at least three compartments of the pelvis, with or without en bloc bony resection. Within partial exenteration, there are many subtypes of exenterations that often involve surgery on parts of different compartments (**FIGS 2A,B**).
- As a general principle, the resection margin for a compartment will involve excision of the soft tissue at its attachment to the bone or en bloc excision of the involved bone (e.g., en bloc sacrectomy, excision of ischial spine or of pubic ramus). Attempting to obtain a soft tissue margin within a compartment will invariably result in a very rate of highly involved margins. **FIGS 2A** and **2B** illustrate the potential dissection planes depending on the location of the tumor.
- In addition to consideration of the compartments of the pelvis, the "height" of the tumor is also important to determine resectability (if there is high sacral involvement), the extent of perineal resection and reconstruction required as well as whether or not intestinal continuity can be restored.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with LARC are usually symptomatic. Patients with LRRC may be symptomatic or asymptomatic (see below), although most patients are symptomatic.
